Abstract—In this comment, we raise serious concerns over the
derivation of the rate of convergence of fractional steepest descent
algorithm in Fractional Adaptive Learning (FAL) approach pre-

dented in “Fractional Extreme Value Adaptive Training Method:
Fractional Steepest Descent Approach” [IEEE Trans. Neural
Netw. Learn. Syst., vol. 26, no. 4, pp. 653–662, April 2015].

We substantiate that the estimate of the rate of convergenceis
grandiloquent. We also draw attention towards a critical flaw in

the design of the algorithm stymieing its applicability for broad

adaptive learning problems. Our claims are based on analytical
reasoning supported by experimental results.

Index Terms—Fractional calculus, fractional differential, frac-
tional energy norm, fractional extreme point, fractional gradient.

I. INTRODUCTION

THE Least Mean Squares (LMS) algorithm is a widely
used tool in adaptive signal processing due to its sta-
ble performance and simple implementation. However,
its convergence is slow. Accordingly, many variants of LMS
have been proposed in recent years in order to achieve an
accelerated convergence without compromising on the steady-
state residual error. In the same spirit, the FAL method based

on a fractional steepest descent approach was proposed in [1].

Unfortunately, the rate of convergence of the FAL algorithm
is derived in terms of an approximation of the general update
rule that furnishes unreliable estimate. We elaborate on this
issue in Section IIA. Further, we draw attention towards a critical flaw in the design of the algorithm stymieing its
applicability on general adaptive learning problems in Section
IIB. The consequences of these flaws on the proposed method
are discussed in Section III. A brief conclusion is provided in

Section IV.

II. MAIN REMARKS

In order to facilitate ensuing discussion, we follow the
notation and equation numbering used in [1], the corrected and
the new numbers are distinguished by a superposed asterisk
and a prime, respectively.

A. Remarks on Convergence Analysis

In [1], the update equation of the proposed FAL algorithm
based on fractional gradient descent is provided in (19) as

\[ s_{k+1} = s_k - \frac{2\mu}{(3 - \nu)} (s_k - s^{\nu})^2 s_k^\nu, \quad \text{if } \nu \neq 1, 2, 3. \]  

(19)

Since, (19) is nonlinear, it is intriguing to derive an explicit
expression for \( s_k \). Towards this end, \( s_k \) is regarded as a discrete sample of a continuous function \( s(t) \) at \( t = k \) in [1], and (19) is converted to an ordinary differential equation (ODE),

\[ D_1 \nu s(t) \equiv \frac{-2\mu}{(3 - \nu)} v(s^{\nu})^{\nu-1} s(t) = s(t) - s^{\nu}, \]  

(20)

using a power series expansion of \( s^{\nu} \) about \( s - s^{\nu} \) (furnishing

\( s^{\nu} \equiv v(s^{\nu})^{\nu-1} s \)). Here, \( D_1 \nu \) is the derivative with respect to \( t \).

The ODE (20) is solved in [1] for \( s(t) \), thereby furnishing

\[ s_k \equiv s^{\nu} + e^{\left[ -\frac{-2\mu k}{(3 - \nu)v(s^{\nu})^{\nu-1}} \right]} s, \quad \text{if } \nu \neq 1, 2, 3. \]  

(21)

We argue that the expression (21), on which the entire

convergence analysis is based, is an unreliable approximation
of the solution to (20). In fact, by separation of variables, (20)

renders

\[ \ln |s(t) - s^{\nu}| = \frac{s^{\nu}}{s(t) - s^{\nu}} e^{\left( -\frac{2\mu \nu}{(3 - \nu)v(s^{\nu})^{\nu-1}} \right)} + \mathcal{C}, \]  

(1')

where \( \mathcal{C} \) is the constant of integration whose value can be
determined by the initial input \( s_0 = s(0) \). Specifically,

\[ \mathcal{C} = \ln |s_0 - s^{\nu}| - \left[ \frac{s^{\nu}}{s_0(s^{\nu})} - s^{\nu} \right]. \]  

(2')

Substituting (2') in (1') and setting \( s(t) = s_k \), one gets

\[ (s_k - s^{\nu}) \equiv (s_0 - s^{\nu}) e^{\left( -\frac{2\mu \nu}{(3 - \nu)v(s^{\nu})^{\nu-1}} \right)} e^{\left( -\frac{s^{\nu}}{s_0(s^{\nu})} \right)} s^{\nu}. \]  

(21*)

Remark that (21*) is different from the correct solution (21')
to the ODE (20). In fact, if one chooses \( \mathcal{C} = 0 \) and neglects

the second term on the LHS of (1') while solving ODE (20),
one gets (21). In Section III we substantiate that \( \mathcal{C} \)
cannot be simply neglected under the parametric setting of
[1]. Moreover, the removal of the second term leads to an
unreliable estimation of the rate of convergence.
B. Technical Flaw in the Algorithmic Design

The FAL approach in [1] is proposed for seeking a minimizer \( s^{*\nu} \) of the energy norm [1, Eq. (6)] in the real domain \( \mathbb{R} \). Both negative and positive minimizers are sought in [1]. However, the update equation (19) of the FAL algorithm contains a fractional power of \( s_k \) which becomes complex whenever \( s_k < 0 \). In particular, \( d^\nu E / ds^\nu \) for \( \nu = 1/2 \) and \( 3/2 \) is pure imaginary. In this situation, \( s_{k+1} \) will be complex since (19) is also derived from \( d^\nu E / ds^\nu \). Consequently, the FAL method is not expected to converge to a real value. In order to elaborate on this point, we evaluate \( d^\nu E / ds^\nu \) (based on [1, Eq. (8)]) using the same parameters as in [1, Sect. IV-B], i.e., we set \( E_1^{\min} = 10, \eta = 2, \) and \( s^{1.55} = 5, 1 < \nu \leq 2, \) and the domain \(-4 < s < 8 \) as used for [1, Figs. 2(e), 2(d)]. Then, for \( \nu = 3/2, \)
\[
\frac{d^{3/2}E}{ds^{3/2}} = - \frac{1}{\sqrt{\pi}} \left( 30s^{-3/2} + 20s^{-1/2} - 8s^{1/2} \right),
\]
which contains fractional powers of \( s \in (-4, 8) \). In particular, at \( s = -1, \)
\[
\frac{d^{3/2}E}{ds^{3/2}} \bigg|_{s=-1} = - \frac{2}{\sqrt{\pi}},
\]
(2')
where \( t = \sqrt{-1} \). Similarly, the \( 1/2 \)-order derivative of the energy norm (based on [1, Eq. (8)]) can be calculated as
\[
\frac{d^{1/2}E}{ds^{1/2}} = \frac{4}{3\sqrt{\pi}} \left( 45s^{-1/2} - 30s^{1/2} + 4s^{3/2} \right),
\]
with parameters as in [1, Fig. 2(a)]. Especially, at \( s = -1, \)
\[
\frac{d^{1/2}E}{ds^{1/2}} \bigg|_{s=-1} = - \frac{316t}{3\sqrt{\pi}},
\]
(5')
As a result, (19) is also complex since it is based on the same expression of the fractional derivative. Consequently, the future updates \( s_{k+1} \) will be complex and the algorithm will not converge to a real value as anticipated. In order to substantiate this, we plotted the expressions (2') and (4') in Fig. 1 over the domain \((-4, 8)\) using same parameters as in [1, Fig. 2]. It is observed that \( d^\nu E / ds^\nu \) is real as long as \( s > 0 \) and is pure imaginary for \( s < 0 \). Note also that \( d^\nu E / ds^\nu \) is singular at \( s = 0 \) which actually justifies that \( s_0 = 0 \).

III. DISCUSSION

A. Reliability of the Rate of Convergence

Let us discuss some consequences of the flaws indicated in Section III-A. First, it is worthwhile precising that the FAL approach is based on left Riemann-Liouville fractional derivative [1, Eq. (3)] (instead of Grünwald-Letnikov derivative as pretended in [1]) with \( a = 0 \). Therefore, FAL is valid only for \( s > 0 \) and \( s_0 = 0 \). Consequently, Eq. (2) suggests that \( C \simeq \ln|s^{*\nu}| + 1 \). Since \( s^{*\nu} \) is unknown sought value, one cannot simply set \( C \equiv 0 \) in [1] to get (21).

On the other hand, the approximation (21), derived from (21') by ignoring \( \exp(s^{*\nu}/(s_k - s^{*\nu})) \) and choosing \( C \equiv 0 \), is highly unreliable. The convergence analysis in [1] is based entirely on the estimate (21). By choosing \( \mu \) such that
\[
\lim_{k \to \infty} k^\chi = +\infty, \quad \text{with} \quad \chi := \frac{2\mu}{\Gamma(3 - \nu)(s^{*\nu})^{\nu-1}} > 0, \quad (6')
\]
it is suggested in [1] that the algorithm converges at the rate \( \exp(-\chi k) \). In fact, since \( (s_k)_{k \in \mathbb{N}} \) is assumed to be convergent to \( s^{*\nu} \), \( (s_k - s^{*\nu}) \to 0 \) as \( k \to +\infty \). Hence, \( s^{*\nu}/(s_k - s^{*\nu}) \to +\infty \) and consequently, \( \exp(s^{*\nu}/(s_k - s^{*\nu})) \to +\infty \) when \( s^{*\nu}/(s_k - s^{*\nu}) \) is positive and \( k \to +\infty \). Therefore, the product \( \exp(-\chi k) \exp(s^{*\nu}/(s_k - s^{*\nu})^{-1}) \) has an indeterminate form \( 0 \times \infty \). One cannot guarantee that it will approach to 0. Even if it does, the factor \( \exp(s^{*\nu}/(s_k - s^{*\nu})^{-1}) \) will severely impede the decay of \( \exp(-\chi k) \), which will be grandiloquent as the rate of convergence of FAL.

In order to elaborate on this point, we have compared the rates of convergence based on estimates (19), (21), and (21') in Fig. 2. We choose same parameters as in [1, Fig.5(a)]. The computational results indicate that the FAL (with update rule (19)) converges at a very slow rate as compared to that predicted by (21). When \( \chi = 0.25 \), (21) suggest that FAL converges to the sought value \( s^{*\nu} = 4.2856 \) after only 29 iterations with \( s_{29} \approx 4.2856 \). On contrary, (19) suggests that after \( k = 1948 \) iterations \( s_k \approx 4.3166 \). On the other hand, (21') predicts that a steady state is achieved at \( k = 414 \) with \( s_{414} \approx 4.2856 \). Similarly, when \( \chi = 1.75 \), the actual number of iterations for FAL to achieve a steady state is \( k = 1741 \) whereas (21) and (21') predict \( k = 5 \) and \( k = 56 \), respectively.

Following remarks are in order. First, (21) does not provide any reliable estimate for the rate of convergence as the actual convergence is roughly two orders of magnitude slower than the predicted rate. Second, (21') also predicts a convergence almost an order of magnitude faster than the actual rate, yet, it provides much superior estimation than (21). Thirdly, based on these observations, it seems inappropriate to consider \( s_k \) as a discrete sample of a continuous function \( s(t) \) based on which both (21) and (21') are derived.
B. Consequences of the Flaw in Algorithmic Design

In view of the remarks in Section II-B it is clear that for negative sought values, the FAL update weight $s_{k+1}$ in (19) becomes complex and cannot converge to a real negative desired output. As mentioned above, the fractional gradient (11, Eq. (8)) is valid over the domain $[0, s)$. Therefore, the algorithm cannot be used for negative values of the independent variable. This is the main reason that the fractional derivative appears to be complex for $s < 0$. As a consequence, almost every simulation in (1) is affected and is unreliable.

1) [1, Figs. 2(a), (b), (d), (e), (g), and (h)] are counterfactual as the fractional derivative in all these cases is complex. Particularly for $v = 1/2$ or $3/2$, the fractional derivative is pure imaginary (see, for example, (2)–(5) or Fig. 1 in this note). For $v = 0$ (i.e., no derivative is taken), the quadratic energy function (11, Eq. (6)) is expected to have a parabolic graph. However, in (1) Fig 2(h)], it appears to be a straight line, which is impossible. Similar observations also hold for (1) Figs. 2(b), (d), (e), and (g)].

2) In (1) Fig. 3(b)], the fractional derivative is evaluated over the domain $s < 0$. Therefore, derivative should be complex valued.

3) In (1) Fig. 4(b)], a negative optimal value $s_{20}^* = -0.6406$ is sought. In fact, with initial step $s_{20} = -0.25$ and the parameters for (1) Fig. 4(b)], even $s_{21}$ becomes complex if (11, Eq. (19)] is used. If (11, Eq. (21)] is used then the exponent on the RHS becomes complex (due to the term $(s_{21}^{(*)})^{-1}$).

4) In (1) Fig. 5], the rate of convergence is evaluated for different choices of $\mu$ and $\gamma$. As discussed in Section III-A the displayed results are misleading and grandiloquent (see Fig. 2 in this note). Note that $s_0 = 15$ is assumed for (1) Fig. 5] whereas $s_0 = 0$ is tacitly assumed in the derivation of the FAL algorithm.

5) The results in (1) Fig. 6] are also affected by the complex outputs when the $x$ or the $y$ component is varying over a part of the negative axis as multi-dimensional FAL is essentially a generalization of the 1-D FAL.

C. Comparison to [3]

In [3], Bershad, Wen, and Cheung So, have already debated the unsuitability of fractional learning frameworks for adaptive signal processing [4]. Theoretical observations in this note can be compared to those made in (3) through a variety of experimental results (see [3] Sect. 1 and Remark 1]). In fact, it is well-known that the LMS algorithm is a stochastic version of the steepest descent algorithm when the statistics of the input are unknown. Thus, (3, Eq. (1)] can be compared directly to (11, Eq. (19)].

Based on extensive experiments, the following conclusions have been drawn in [3, Page 225].

1) The fractional variants of the LMS are only useful when all the update weights are positive but their performance is comparable to that of the LMS. That is, under no conditions fractional variants of LMS perform better than the standard LMS.

2) In case when some of the update weights are negative, the fractional variants of LMS render complex outputs (see [3, Remark 1]). Moreover, even when the absolute operator is employed in the fractional algorithms (see, for instance, Refs. 3 and 5 in [3]), their performance is inferior than standard LMS. Finally, if only the real part of the complex update weight is employed, the fractional LMS reduces to LMS with a slower convergence rate.

Observe that the FAL method proposed in [1] has similar drawbacks as highlighted in [3] for fractional frameworks for adaptive signal processing. Precisely, as debated in Sections III-A and III-B the FAL method has limited applicability for broad spectrum of adaptive learning problems due to complex outputs and has slow convergence rate when the update iterates remain real.

IV. Conclusion

In this comment, some serious concerns over the derivation of the rate of convergence of Fractional Adaptive Learning (FAL) approach proposed in [1] were raised. It is established that the convergence analysis performed in (1) is unreliable in general and the FAL algorithm converges much slower than anticipated. It was also highlighted that the FAL method can practically work only for positive domains. Over negative domains or whenever its iterative update becomes negative, the FAL algorithm furnishes a complex output due to the presence of fractional powers in its update rule. In this situation, the algorithm is not expected to converge to a real sought value. Moreover, thanks to the analogy of the FAL algorithm with fractional variants of Least Mean Squares (LMS) for adaptive signal processing [4], the analysis performed by Bershad, Wen, and Cheung So [3] suggests that FAL is not better than LMS under any condition. Their performances are nearly the same but the FAL approach is much more complicated than LMS. Finally, it is needless to say that the multi-dimensional variant of the FAL also inherits the same flaws and is unreliable.
