Abstract

Incorporating graph side information into recommender systems has been widely used to better predict ratings, but relatively few works have focused on theoretical guarantees. Ahn et al. (2018) firstly characterized the optimal sample complexity in the presence of graph side information, but the results are limited due to strict, unrealistic assumptions made on the unknown latent preference matrix and the structure of user clusters. In this work, we propose a new model in which 1) the unknown latent preference matrix can have any discrete values, and 2) users can be clustered into multiple clusters, thereby relaxing the assumptions made in prior work. Under this new model, we fully characterize the optimal sample complexity and develop a computationally-efficient algorithm that matches the optimal sample complexity. Our algorithm is robust to model errors and outperforms the existing algorithms in terms of prediction performance on both synthetic and real data.

1 Introduction

Recommender systems provide suggestions for items based on users’ decisions such as ratings given to those items. Collaborative filtering is a popular approach to designing recommender systems [19, 39, 29, 35, 37, 38, 4, 12]. However, collaborative filtering suffers from the well-known cold start problem since it relies only on past interactions between users and items. With the exponential growth of social media, recommender systems have started to use a social graph to resolve the cold start problem. For instance, Jamali and Ester [23] provide an algorithm that handles the cold start problem by exploiting social graph information.

While a lot of works have improved the performance of algorithms by incorporating graph side information into recommender systems [21, 22, 23, 8, 51, 43, 44, 25], relatively few works have focused on justifying theoretical guarantees of the performance [10, 34, 5]. One notable exception is the recent work of Ahn et al. [5], which finds the minimum number of observed ratings for reliable recovery of the latent preference matrix with social graph information and partial observation of the rating matrix. They also provide an efficient algorithm with low computational complexity. However, the assumptions made in this work are too strong to reflect the real-world data. In specific, they assume that each user rates each item either +1 (like) or −1 (dislike), and that the observations are noisy so that they can be flipped with probability θ ∈ (0, 1/2). This assumption can be interpreted as each user rates each item +1 with probability 1 − θ or θ. Note that this parametric model is very limited, so the discrepancy between the model and the real world occurs; if a user likes item a, b and c with probability 1/4, 1/3 and 3/4 respectively, then the model cannot represent this case well (see Remark 3 for a detailed description).

This motivates us to propose a general model that better represents real data. Specifically, we assume that user i likes item j with probability $R_{ij}$, which we call user i’s latent preference level on item j, and $R_{ij}$ belongs to the discrete set $\{p_1, \ldots, p_d\}$ where $d \geq 1$ and $0 < p_1 < \cdots < p_d < 1$. As $d$ can be any positive integer, our generalized model can reflect various preference levels on different items. In addition to that, we assume that the social graph information follows the Stochastic Block Model (SBM) [20], and the social graph is correlated with the latent preference matrix $R$ in a specific way, which we will detail in Sec. 3. Under this highly generalized model, we fully characterize the optimal sample complexity required for estimating the latent preference matrix $R$. To the best of our knowledge, this work is the first theoretical work that
showing the optimal sample complexity of latent preference estimation with graph side information without making strict assumptions on the rating generation model, made in all the prior work [5, 45, 13, 48]. We also develop an algorithm with low computational complexity, and our algorithm is shown to consistently outperform all the proposed algorithms in the literature including those of [5] on synthetic/real data.

To further highlight the limitation of the proposed algorithms developed under the strict assumptions used in the literature, we present various experimental results in Fig. 1. (We will revisit the experimental setting in Sec. 6.) In Fig. 1a, we compare our algorithm with that of [5] on synthetic rating $N^\Omega$ and synthetic graph $G$. Here, we set $d = 2, p_1 = 0.3, p_2 = 0.62$, i.e., the symmetry assumption $p_1 + p_2 = 1$ does not hold anymore. We can see that our algorithm significantly outperforms the algorithm of [5] in terms of the estimation error for all tested values of $p$, where $p$ denotes the probability of observing each rating. This clearly shows that their algorithm quickly breaks down even when the modeling assumption is just slightly off. Shown in Fig. 1b is the performance of various algorithms on synthetic rating/real graph, and we observe that the estimation error of [5] increases as the observation rate $p$ increases unlike all the other algorithms. (We discuss why this unexpected phenomenon happens in more details in Sec. 6.) On the other hand, our algorithm outperforms all the existing baseline algorithms for almost all tested values of $p$ and does not exhibit any unexpected phenomenon. In Table 1 we observe that our algorithm outperforms all the other algorithms even on real rating/real graph data, although the improvement is not significant than the one for synthetic rating/real graph data. These results demonstrate the practicality of our new algorithm, which is developed under a more realistic model without limiting assumptions.

This paper is organized as follows. Related works are given in Sec. 2. We propose a generalized problem formulation for a recommender system with social graph information in Sec. 3. Sec. 4 characterizes the optimal sample complexity with main theorems. In Sec. 5, we propose an algorithm with low time complexity and provide a theoretical performance guarantee. In Sec. 6, experiments are conducted on synthetic and real data to compare the performance between our algorithm and existing algorithms in the literature. Finally, we discuss our results in Sec. 7. All the proofs and experimental details are given in the appendix.

Figure 1: Performance comparison of various algorithms for latent preference estimation with graph side information. The $x$-axis is the probability of observing each rating ($p$), and the $y$-axis is the estimation error measured in $\| \cdot \|_{\text{max}}$ or the mean absolute error (MAE). (a) Our algorithm vs [5] where $d = 2, p_1 = 0.3, p_2 = 0.62$. [5] performs badly due to the asymmetry of latent preference levels. (b) Our algorithm vs various algorithms proposed in the literature on real graph data and synthetic ratings. Observe that ours strictly outperforms all the existing algorithms for almost all tested values of $p$.

Table 1: MAE comparison with other algorithms on real $N^\Omega + \text{real } G$ [32, 33]

| ItemAvg | UserAvg | User k-NN | Item k-NN | BiasedMF | SocialMF | SoRec | SoReg | TrustSVD | Ahn’s | Ours |
|---------|---------|----------|----------|----------|----------|-------|-------|----------|-------|------|
| 0.547   | 0.731   | 0.614    | 0.664    | 0.592    | 0.591    | 0.576 | 0.567 | 0.567    | 0.540 |      |
1.1 Notation

Let \( [n] = \{1, 2, \ldots, n\} \) where \( n \) is a positive integer, and let \( 1(\cdot) \) be the indicator function. An undirected graph \( G \) is a pair \((V, E)\) where \( V \) is a set of vertices and \( E \) is a set of edges. For two subsets \( X \) and \( Y \) of the vertex set \( V \), \( e(X, Y) \) denotes the number of edges between \( X \) and \( Y \).

2 Related Work

Collaborative filtering has been widely used to design recommender systems. There are two types of methods commonly used in collaborative filtering: neighborhood-based method and matrix factorization-based method. The neighborhood-based approach predicts users’ ratings by finding similarity between users [19], or by finding similarity between items [39, 29]. In the matrix factorization-based approach, it assumes users’ latent preference matrix is of a certain structure, e.g., low rank, so the latent preference matrix can be decomposed into two matrices of low dimension [35, 37, 38, 4]. In particular, Davenport et al. [12] consider binary (1-bit) matrix completion and show that the maximum likelihood estimate is accurate under suitable conditions.

Since collaborative filtering relies solely on past interactions between users and items, it suffers from the cold start problem; collaborative filtering cannot provide a recommendation for new users since the system does not have enough information. A lot of works have been done to resolve this issue by incorporating social graph information into recommender systems. In specific, the social graph helps neighborhood-based method to find better neighborhood [21, 22, 43, 44]. Some works add social regularization terms to the matrix factorization method to improve the performance [8, 23, 31, 25].

Few works have been conducted to provide theoretical guarantees of their models that consider graph side information. Chiang et al. [10] consider a model that incorporates general side information into matrix completion, and provide statistical guarantees. Rao et al. [34] derive consistency guarantees for graph regularized matrix completion.

Recently, several works have studied the binary rating estimation problem with the aid of social graph information [5, 43, 47, 13, 48]. These works characterize the optimal sample complexity as the minimum number of observed ratings for reliable recovery of a latent preference matrix under various settings, and find how much the social graph information reduces the optimal sample complexity. In specific, Ahn et al. [5] study the case where users are clustered in two equal-sized groups, and Yoon et al. [45] generalize the results of [5] to the multi-cluster case. Zhang et al. [47, 48] study the problem where both user-to-user and item-to-item similarity graphs are available. Lastly, Elmahdy et al. [13] adopt the hierarchical stochastic block model to handle the case where each cluster can be grouped into sub-clusters. However, all of these works require strict assumptions on the rating generation model, which is too limited to well capture the real-world data.

Our problem can also be viewed as “node label inference on SBM,” where nodes are users, edges are for social connections, node labels are \( m \)-dimensional rating vectors (consisting of \(-1, 0, 1\)), and node label distributions are determined by the latent preference matrix. Various works have studied recovery of clusters in SBM in the presence of node labels [12, 30] or edge labels [18, 24, 46]. While their goal is recovery of clusters, Xu et al. [11] study “edge label inference on SBM” whose goal is to recover edge label distributions as well as clusters.

Remark 1. While our problem shares high similarities with “edge label” inference on SBM, studied in [11], there exist some critical differences. To see the difference, consider a very sparse graph where many nodes are isolated. Edge label inference is impossible in this regime since there is no observed information about those isolated nodes (see Thm. 2 in [11] for more details). On the other hand, in node labelled cases, we still observe information about isolated nodes from their node labels, so it is possible to infer node label distributions as long as we observe enough number of node labels.

3 Problem Formulation

Let \([n]\) be the set of users, and let \([m]\) be the set of items where \( m \) can scale with \( n \). For \( i \in [n] \) and \( j \in [m] \), \( R_{ij} \) denotes user \( i \)’s \textit{latent preference level} on item \( j \), that is, user \( i \)’s rating on item \( j \) is \(+1\) (like) with probability \( R_{ij} \) or \(-1\) (dislike) with probability \( 1 - R_{ij} \). We assume that latent preference levels take values
We denote the latent preference vector of the users in world, we estimate them with observed ratings on items and the social graph. Where $C = 2d$ can be interpreted as each user rates each item that the observations are noisy so that they can be flipped with probability $\alpha$. Ahn et al. [5] assume that each user rates each item either like or dislike, and that the observations are noisy so that they can be flipped with probability $\theta \in (0, \frac{1}{2})$. This assumption can be interpreted as each user rates each item $+1$ with probability $1 - \theta$ (when the user’s true rating is +1) or $\theta$ (when the user’s true rating is −1). Therefore, our model reduces to the model of [5] by setting $d = 2, p_1 = \theta, p_2 = 1 - \theta, K = 2, |C^{-1}(\{1\})| = |C^{-1}(\{2\})| = \frac{n}{2}$. As mentioned in Sec. [1], the parametric

Remark 2. (Why binary rating?) Binary rating has its critical applications such as click/impression-based advertisement recommendation, in which only −1 (shown, not clicked), 0 (not shown), 1 (shown, clicked) information is available. Moreover, binary rating is gaining increasing interests in the industry due to its simplicity and robustness. This is precisely why Youtube and Netflix, two of the largest media recommendation systems, have discarded their “star rating systems” and employed binary ratings in 2009 [15] and in 2017 [9], respectively.

Remark 3. Ahn et al. [6] assume that each user rates each item either +1 (like) or −1 (dislike), and that the observations are noisy so that they can be flipped with probability $\theta \in (0, \frac{1}{2})$. This assumption can be interpreted as each user rates each item $+1$ with probability $1 - \theta$ (when the user’s true rating is +1) or $\theta$ (when the user’s true rating is −1). Therefore, our model reduces to the model of [5] by setting $d = 2, p_1 = \theta, p_2 = 1 - \theta, K = 2, |C^{-1}(\{1\})| = |C^{-1}(\{2\})| = \frac{n}{2}$. As mentioned in Sec. [1], the parametric

![Figure 2: A toy example of our model where $n = 12, m = 8, d = 3, p_1 = 0.1, p_2 = \frac{1}{5}, p_3 = \frac{3}{4}, K = 3, C^{-1}(\{1\}) = \{1, 2, 3\}, C^{-1}(\{2\}) = \{4, 5, 6\}, C^{-1}(\{3\}) = \{7, 8, 9, 10, 11, 12\}, p = 0.5, \alpha = 0.6, \beta = 0.1.](image)
model used in [5] is very limited. For example, consider the following two latent preference matrices
\[ R_1 = \begin{bmatrix} 1/4 & 1/4 & 3/4 & 3/4 \\ 1/4 & 1/4 & 3/4 & 3/4 \\ 1/4 & 1/4 & 1/4 & 1/4 \\ 1/4 & 1/4 & 1/4 & 1/4 \end{bmatrix}, R_2 = \begin{bmatrix} 1/3 & 1/4 & 3/4 & 3/4 \\ 1/3 & 1/4 & 3/4 & 3/4 \\ 1/3 & 1/4 & 1/4 & 1/4 \\ 1/3 & 1/4 & 1/4 & 1/4 \end{bmatrix} \text{ where } n = 2, m = 4. \] Then \( R_1 \) can be represented by the model used in [Ahn et al., 2018] with \( \theta = 1/2 \), but \( R_2 \) cannot be handled by their model with any choice of \( \theta \) since there are more than two latent preference levels in \( R_2 \).

**Remark 4.** Without graph observation, our observation model reduces to a special case of the observation model for the binary (1-bit) matrix completion shown in Sec. 2.1. of [12].

### 4 Fundamental Limit on Sample Complexity

We now characterize the fundamental limit on the sample complexity. We first focus on the two equal-sized clusters case (i.e., \( K = 2, |C^{-1}(\{1\})| = |C^{-1}(\{2\})| = \frac{n}{2} \)) and will extend the results to the multi-cluster case. We use \( A_R \) and \( B_R \) for the ground-truth clusters and \( u_R \) and \( v_R \) for the corresponding latent preference vectors, respectively. We define the worst-case error probability as follows.

**Definition 1. (Worst-case probability of error for two equal-sized clusters)** Let \( \gamma \) be a fixed number in \( (0, 1) \) and \( \psi \) be an estimator that outputs a latent preference matrix in \( \{p_1, p_2, \ldots, p_d\}^{n \times m} \) based on \( N^\gamma \) and \( G \). We define the worst-case probability of error \( P^*_e(\psi) := \max \{ \Pr(\psi(N^\gamma, G) \neq R) : R \in \{p_1, p_2, \ldots, p_d\}^{n \times m}, \|u_R - v_R\|_0 = |\gamma m| \} \) where \( \| \cdot \|_0 \) is the Hamming distance.

A latent preference level \( p_i \in \{p_1, \ldots, p_d\} \) implies that the probability of choosing \((+1, -1)\) is \((p_i, 1 - p_i)\) respectively, so it corresponds to a discrete probability distribution \((p_i, 1 - p_i)\). For two latent preference levels \( p_i, p_j \in \{p_1, \ldots, p_d\} \), the Hellinger distance between two discrete probability distributions \((p_i, 1 - p_i)\) and \((p_j, 1 - p_j)\), denoted \( d_H(p_i, p_j) \), is

\[
\frac{1}{\sqrt{2}} \sqrt{(\sqrt{p_i} - \sqrt{p_j})^2 + (\sqrt{1 - p_i} - \sqrt{1 - p_j})^2}.
\]

Then, the minimum Hellinger distance of the set of discrete-valued latent preference levels \( \{p_1, \ldots, p_d\} \), denoted \( d_H^{\text{min}} \), is

\[
\min\{d_H(p_i, p_j) : i \neq j \in [d]\}.
\]

Below is our main theorem that characterizes a sharp threshold of \( p \), the probability of observing each rating of users, for reliable recovery as a function of \( n, m, \gamma, \alpha, \beta, d_H^{\text{min}} \).

**Theorem 1.** Let \( K = 2, |C^{-1}(\{1\})| = |C^{-1}(\{2\})| = \frac{n}{2}, \gamma \in (0, 1), m = \omega(\log n), \log m = o(n) \). \( I_1 := -2 \log (1 - d_H^{\text{min}}(\alpha, \beta)) \). Then, the following holds for arbitrary \( \epsilon > 0 \).

(I) if \( p \geq \left(\frac{\alpha \log n - 2L}{\gamma m}\right) \), then there exists an estimator \( \psi \) that outputs a latent preference matrix in \( \{p_1, p_2, \ldots, p_d\}^{n \times m} \) based on \( N^\gamma \) and \( G \) such that \( P^*_e(\psi) \to 0 \) as \( n \to \infty \).

(II) if \( p \leq \left(\frac{\alpha \log n - 2L}{\gamma m}\right) \), then \( P^*_e(\psi) \to 0 \) as \( n \to \infty \) for any \( \psi \).

**Remark 5.** We note that our technical contributions lie in the proof of Thm. 1. In specific, we find the upper bound of the probability of error in Lem. 3 by using the results of Lem. 1, 2, and we made nontrivial technical contributions as we need to handle a significantly larger set of candidate latent preference matrices.

---

1. Ahn et al. [5] made implicit assumptions that \( \alpha, \beta \to 0 \) and \( \frac{\alpha}{n} \to 1 \) as \( n \to \infty \). These assumptions are used when they approximate \(-2 \log (1 - d_H^{\text{min}}(\alpha, \beta)) \approx (1 + o(1))(\sqrt{\alpha} - \sqrt{\beta})^2 \). The approximation does not hold without above assumptions, in explicit, \(-2 \log (1 - d_H^{\text{min}}(\alpha, \beta)) \approx (\sqrt{\alpha} - \sqrt{\beta})^2 \left(\frac{\log n}{n}\right)^{1/2} + o(1) \) (see the appendix for the derivation). The MLE achievability part of our theorem does not make any implicit assumptions, and the results hold for any \( \alpha \) and \( \beta \) with our modified definition of \( I_1 := -2 \log (1 - d_H^{\text{min}}(\alpha, \beta)) \).
Definition 2. \( p^*_1 : = \frac{1}{(d_H^{min})^2} \max \left\{ \frac{\log n - \frac{d}{2} t \gamma m}{\gamma m}, \frac{2 \log m}{n} \right\} \) denotes the optimal observation rate. Then \( nmp^*_1 = \frac{1}{(d_H^{min})^2} \max \left\{ \frac{\log n - \frac{d}{2} t \gamma m}{\gamma m}, \frac{2 \log m}{n} \right\} \) denotes the optimal sample complexity for two-cluster cases.

The optimal sample complexity for two-cluster cases is written as a function of \( p_1, \ldots, p_d \), so the dependency on \( d \) is implicit. To see the dependency clearly, we can set \( p_1 = \frac{1}{d+1} \). This gives us \( p^*_1 \approx 2d^2 \max \left\{ \frac{\log n - \frac{d}{2} t \gamma m}{\gamma m}, \frac{2 \log m}{n} \right\} \), and \( p^*_1 \) increases as a quadratic function of \( d \).

Remark 6. (How does the graph information reduce the optimal sample complexity?) One can observe that \( I_s \) decreases as \( \alpha \) and \( \beta \) get closer to each other, and \( I_s = 0 \) when \( \alpha = \beta \). Hence \( I_s \) measures the quality of the graph information. If we consider the case that does not employ the graph information, it is equivalent to the case that \( \alpha = \beta \) (\( I_s = 0 \)) in our model, thereby getting the optimal sample complexity of \( \frac{1}{(d_H^{min})^2} \max \left\{ \frac{1}{\gamma} \log n, 2m \log m \right\} \). Therefore, exploiting the graph information results in the reduction of the optimal sample complexity by \( \frac{1}{(d_H^{min})^2} \frac{1}{\gamma} n^2 I_s \) provided that \( \frac{1}{\gamma} \log n > 2m \log m \). Note that the optimal sample complexity stops decreasing when \( I_s \) is larger than a certain threshold which implies the gain is saturated.

Remark 7. If we set \( d = 2, p_1 = \theta, p_2 = 1 - \theta \), then \( (d_H^{min})^2 = 1 - 2\sqrt{\theta(1 - \theta)} = (\sqrt{1 - \theta} - \sqrt{\theta})^2 \). Plugging this into the result of Theorem 1 we get \( p^*_1 = \frac{1}{(\sqrt{1 - \theta} - \sqrt{\theta})^2} \max \left\{ \frac{\log n - \frac{1}{2} t \gamma m}{\gamma m}, \frac{2 \log m}{n} \right\} \), recovering the main theorem of [5] as a special case of our result.

Our results can be extended to the case of multiple (possibly unequal-sized) clusters by combining the technique developed in Theorem 1 and the technique of [5]. Suppose \( d_H(p_1, p_2) \) achieves the minimum Hellinger distance when \( p_1 = p_{d_0}, p_2 = p_{d_0+1} \). Define \( p : \{p_1, \ldots, p_d\}^m \rightarrow \{p_{d_0}, p_{d_0+1}\}^m \) that maps a latent preference vector to a latent preference vector consisting of latent preference levels \( \{p_{d_0}, p_{d_0+1}\} \). In explicit, \( p \) sends each coordinate \( x_i \) of a latent preference vector to \( p_{d_0} \) if \( x_i \leq p_{d_0} \), \( p_{d_0+1} \) if \( x_i \geq p_{d_0+1} \). We now present the extended result below, while deferring the the proof to the appendix.

Theorem 2. Let \( m = \omega(\log n), \log m = o(n) \), \( c_k = |C^{-1}(\{k\})|, c_{i,j} = \frac{c_i + c_j}{2} \), \( \liminf_{m \rightarrow \infty} \frac{\|p(u_i) - p(u_j)\|_0}{m} > 0 \) for all \( k \in [K] \).

(1) (achievability)
If \( p \geq \frac{1}{(d_H^{min})^2} \max \left\{ \max_{i \neq j \in [K]} \left\{ \frac{1}{\|p(u_i) - p(u_j)\|_0} \right\}, \max_{k \in [K]} \left\{ \frac{(1+\epsilon) \log m}{c_k} \right\} \right\} \), then there exists an estimator \( \psi \) such that \( \Pr(\psi(N^{t_2}, G) \neq R) \rightarrow 0 \) as \( m \rightarrow \infty \).

(II) (impossibility)
Suppose \( R \in \{p_{d_0}, p_{d_0+1}\}^{n \times m} \), \( \alpha = O(\log n) \). If \( p \leq \frac{1}{(d_H^{min})^2} \max \left\{ \max_{i \neq j \in [K]} \left\{ \frac{1}{\|p(u_i) - p(u_j)\|_0} \right\}, \max_{k \in [K]} \left\{ \frac{(1-\epsilon) \log m}{c_k} \right\} \right\} \), then \( \Pr(\psi(N^{t_2}, G) \neq R) \rightarrow 0 \) as \( m \rightarrow \infty \) for any \( \psi \).

Remark 8. One can observe that Theorem 1 is a special case of Theorem 2 by setting \( K = 2, c_1 = c_2 = \frac{1}{2} \), \( \|p(u_1) - p(u_2)\|_0 = |\gamma m| \).

Remark 9. In light of Theorem 14 in [7], we conjecture that our results can be extended to asymmetric SBMs with a new definition of \( I_s \) involving Chernoff-Hellinger divergence.

5 Our Proposed Algorithm
In this section, we develop a computationally efficient algorithm that can recover the latent preference matrix \( R \) without knowing the latent preference levels \( \{p_1, \ldots, p_d\} \). We then provide a theoretical guarantee that if \( p \geq \frac{1}{(d_H^{min})^2} \max \left\{ \frac{(1+\epsilon) \log n - \frac{d}{2} t \gamma m}{\gamma m}, \frac{(1+\epsilon) \log m}{n} \right\} \) for some \( \epsilon > 0 \), then the proposed algorithm recovers the latent preference matrix with high probability. Now we provide a high-level description of our algorithm while deferring the pseudocode to the appendix.
Algorithm description

Input: $N^{\Omega} \in \{-1, 0, +1\}^{n \times m}$, $G = ([n], E)$, $K$, $d$, $\ell_{\text{max}}$

Output: Clusters of users $A_1^{(\ell_{\text{max}})}, \ldots, A_K^{(\ell_{\text{max}})}$, latent preference vectors $\hat{u}_1^{(\ell_{\text{max}})}, \ldots, \hat{u}_K^{(\ell_{\text{max}})}$

Stage 1. Partial recovery of clusters We run a spectral method [13] on $G$ to get an initial clustering result $A_1^{(0)}, \ldots, A_K^{(0)}$. Unless $\alpha$ is too close to $\beta$, this stage will give us a reasonable clustering result, with which we can kick-start the entire estimation procedure. Other clustering algorithms [2, 11, 27, 28] can also be used for this stage.

Stage 2 We iterate Stage 2-(i) and Stage 2-(ii) for $\ell = 1, \ldots, \ell_{\text{max}}$.

Stage 2-(i). Recovery of latent preference vectors In the $\ell$-th iteration step, this stage takes the clustering result $A_1^{(\ell-1)}, \ldots, A_K^{(\ell-1)}$ and rating data $N^{\Omega}$ as input and outputs the estimation of latent preference vectors $\hat{u}_1^{(\ell)}, \ldots, \hat{u}_K^{(\ell)}$.

First, for each cluster $A_k^{(\ell-1)}$, we estimate the latent preference levels for $d \lceil \log m \rceil$ randomly chosen items with replacement. The estimation of a latent preference level can be easily done by computing the ratio of “the number of +1 ratings” to “the number of observed ratings (i.e., nonzero ratings)” for each item within the cluster $A_k^{(\ell-1)}$. Now we have $Kd \lceil \log m \rceil$ number of estimations, and these estimations will be highly concentrated around the latent preference levels $p_1, \ldots, p_d$ under our modeling assumptions (see the appendix for the mathematical justifications). After running a distance-based clustering algorithm (see the pseudocode for details), we take the average within each cluster to get the estimations $\hat{p}_1, \ldots, \hat{p}_d$.

Given the estimations $\hat{p}_1, \ldots, \hat{p}_d$ and the clustering result $A_1^{(\ell)}, \ldots, A_K^{(\ell)}$, we estimate latent preference vectors $\hat{u}_1^{(\ell)}, \ldots, \hat{u}_K^{(\ell)}$ by maximizing the likelihood of the observed rating matrix $N^{\Omega}$ and the observed social graph $G = ([n], E)$. In specific, the $j$-th coordinate of $\hat{u}_k^{(\ell)}$ is $\arg \min \hat{L}(\hat{p}_h^{(\ell)}; A_k^{(\ell-1)}, j)$ where $\hat{L}(\hat{p}_h^{(\ell)}; A_k^{(\ell-1)}, j) := \sum_{i \in A_k^{(\ell-1)}} \{1(N_{ij}^{(\ell)} = 1)(-\log \hat{p}_h^{(\ell)}) + 1(N_{ij}^{(\ell)} = -1)(-\log (1 - \hat{p}_h^{(\ell)}))\}$.

Stage 2-(ii). Refinement of clusters In the $\ell$-th iteration step, this stage takes the clustering result $A_1^{(\ell-1)}, A_K^{(\ell-1)}$ as input and outputs the refined clustering result $A_1^{(\ell)}, \ldots, A_K^{(\ell)}$.

We first compute $\hat{\alpha}, \hat{\beta}$ that estimate $\alpha, \beta$ based on the clustering result $A_1^{(\ell-1)}, A_K^{(\ell-1)}$ and the number of edges within a cluster and across clusters. Let $A_k^{(\ell-1,0)} := A_k^{(\ell-1)}$ for $k \in [K]$. Then $A_k^{(\ell-1,0)}$’s are iteratively refined by $T = \lceil \log_2 n \rceil$ times of refinement steps as follows.

Suppose we have a clustering result $A_1^{(\ell-1,t-1)}$ is from the $(t-1)$-th refinement step where $t = 1, \ldots, T$. Given the estimations $\hat{\alpha}, \hat{\beta}$, the estimated latent preference vectors $\hat{u}_1^{(\ell)}, \ldots, \hat{u}_K^{(\ell)}$, and the clustering result $A_1^{(\ell-1,t-1)}, \ldots, A_K^{(\ell-1,t-1)}$, we find the refined clustering result $A_1^{(\ell-1,t)}, \ldots, A_K^{(\ell-1,t)}$ by updating each user’s affiliation. Specifically, for each user $i$, we put user $i$ to $A_k^{(\ell-1,t), i}$ when $k := \arg \min_{k \in [K]} \hat{L}(A_k^{(\ell-1,t-1), i})$ and

$\hat{L}(A_k^{(\ell-1,t-1), i}) := -\sum_{k \neq k} \left\{ \log(\hat{\beta})e(\{i\}, A_k^{(\ell-1,t-1)}) + \log(1 - \hat{\beta})(|A_k^{(\ell-1,t-1)}| - e(\{i\}, A_k^{(\ell-1,t-1)})) \right\} - \sum_{j: N_{ij}^{(\ell)} = 1} \log(\hat{\beta})e(\{i\}, A_k^{(\ell-1,t-1)}) - \log(1 - \hat{\alpha})(|A_k^{(\ell-1,t-1)}| - e(\{i\}, A_k^{(\ell-1,t-1)}))$.

$(\hat{u}_k^{(\ell)})_j$ denotes the $j$-th coordinate of $\hat{u}_k^{(\ell)}$. In each refinement step, the number of mis-clustered users will decrease provided that estimations $\hat{u}_k^{(\ell)}$’s, $\hat{\alpha}, \hat{\beta}$ are close enough to their true values (see the appendix for the mathematical justifications).

After $T$ times of refinement steps, we let $A_k^{(\ell)} := A_k^{(\ell-1,T)}$ for $k \in [K]$. Finally, this stage outputs the refined clustering result $A_1^{(\ell)}, \ldots, A_K^{(\ell)}$.

Remark 10. The computational complexity of our algorithm can be computed as follows; $O(|E| \log n)$ for Stage 1 via the power method [7], $O(|\Omega|)$ for Stage 2-(i), $O(|\Omega| + |E|) \log n)$ for Stage 2-(ii). As $\ell_{\text{max}}$ is constant, the linear factor of $\ell_{\text{max}}$ is omitted in the computational complexity of Stage 2-(i),(ii). Overall, our algorithm has low computational complexity of $O(|\Omega| + |E|) \log n)$. 

7
Remark 11. We note that our technical contributions lie in the analysis of Stage 2-(i) while the analysis of Stage 2-(ii) is similar to those in [5, 15]. In specific, we sample $O(\lceil \log m \rceil)$ number of items in Stage 2-(i) to get estimations of the latent preference levels and Lem. 8 ensures that those estimations are located in the $o(1)$-radius neighborhoods of ground-truth latent preference levels with high probability. Then Lem. 9 ensures that estimations of latent preference vectors converges to ground-truth latent preference vectors with high probability.

For the two equal-sized clusters case, the following theorem asserts that our algorithm will successfully estimate the latent preference matrix with high probability as long as the sampling probability is slightly above the optimal threshold. We defer the proof to the appendix.

**Theorem 3.** Let $\ell_{\max} = 1, K = 2, |C^{-1}(\{1\})| = |C^{-1}(\{2\})| = n^2/2, \gamma \in (0, 1), m = \omega(\log n), \log m = o(n)$, $\sqrt{\alpha - \sqrt{\beta}} = \omega(1/n), m = O(n)$, and $\alpha = O(\log n)$. Let $\phi_j$ be the ratio of the number of $p_i$'s among $(u_R)_1, \ldots, (u_R)_m, (v_R)_1, \ldots, (v_R)_m$ to $2m$ for $j = 1, \ldots, d$, and assume that $\phi_j \to 0$ as $n \to \infty$. If

$$p \geq \frac{1}{(d_{\min}^m)^2} \max \left\{ \frac{(1 + \epsilon) \log n - \frac{7}{2} I_s}{\gamma m}, \frac{2(1 + \epsilon) \log m}{n} \right\}$$

for some $\epsilon > 0$, then our algorithm outputs $\hat{R}$ where the following holds with probability approaching to 1 as $n$ goes to $\infty$: $\| \hat{R} - R \|_{\max} := \max_{(i,j) \in [n] \times [m]} |\hat{R}_{ij} - R_{ij}| = o(1)$.

**Remark 12.** As our algorithm makes use of only graph data at Stage 1, the initial clustering result highly depends on the quality of graph data $I_s$. In the extreme cases where only rating data are available, Stage 1 will output a meaningless clustering result. As the performance of Stage 2 depends on the success of Stage 1, our algorithm may not work well even if the observation rate $p$ is above the optimal rate. In Sec. 5 we suggest an alternative algorithm, which utilizes both rating and graph data at Stage 1. Analyzing the performance of this new algorithm is an interesting open problem.

### 6 Experimental Results

In this section, we run several experiments to evaluate the performance of our proposed algorithm. Denoting by $\hat{R}$ the output of an estimator, the estimation quality is measured by the max norm of the error matrix, i.e., $\| \hat{R} - R \|_{\max} := \max_{(i,j) \in [n] \times [m]} |\hat{R}_{ij} - R_{ij}|$. For each observation rate $p$, we generate synthetic data $(N^{12}, G)$ 100 times at random and then report the average errors.

#### 6.1 Non-asymptotic Performance of Our Algorithm

Shown in Fig. 3a is the probability of error $\Pr(\psi_1(N^{12}, G) \neq R)$ of our algorithm for $(n, m, K, d) = (10000, 5000, 2, 3)$ and various combinations of $(I_s, p)$. To measure $\Pr(\psi_1(N^{12}, G) \neq R)$, we allow our algorithm to have access to the latent preference levels $(p_1, p_2, p_3) = (0.2, 0.5, 0.7)$ in Stage 2. We draw $p_\gamma^*$ as a red line. While the theoretical guarantee of our algorithm is valid when $n, m$ go to $\infty$, Fig. 3a shows that Theorem 1 predicts the optimal observation rate $p_\gamma^*$ with small error for sufficiently large $n, m$. One can observe a sharp phase transition around $p_\gamma^*$.

#### 6.2 Limitation of the Symmetric Latent Preference Levels

As described in Sec. 1, the latent preference matrix model studied in [5] assumes that the latent preference level must be either $\theta$ or $1-\theta$ for some $\theta$, which is fully symmetric. In this section, we show that this model cannot be applied unless the symmetry assumption perfectly holds. Let $(K, d, n, m, \gamma, \alpha, \beta) = (2, 2, 2000, 1000, 1/2, 0.7, 0.3)$. Shown in Fig. 3b, Fig. 1a, Fig. 3c are the estimation errors of our algorithm and that of the algorithm proposed in [5] for various pairs of $(p_1, p_2)$. (1) Fig. 3b shows the result for $(p_1, p_2) = (0.3, 0.7)$ where the latent preference levels are perfectly symmetric, and the two algorithms perform exactly the same. (2) Fig. 1a shows the result for $(p_1, p_2) = (0.3, 0.62)$ where the latent preference levels are slightly asymmetric. The estimation error of the algorithm of [5] is much larger than ours for all tested values of $p$. (3) Shown in Fig. 3c...
The experimental result given in Sec. 6.3 motivated us to evaluate the performance of our algorithm when from LibRec [16], BiasedMF [26], SocialMF [23], SoRec [30], SoReg [31], Trust SVD [17]. Except for ours and that of [5], we adopt implementations shows that our algorithm does not work well with Remark 13. that the algorithm of [5] cannot properly handle of the optimal estimator (see the appendix for a detailed explanation) which means our algorithm shows baseline algorithms for almost all tested values of algorithm with other algorithms in the literature.

6.4 Real-World Data Experiments

The experimental result given in Sec. 6.3 motivated us to evaluate the performance of our algorithm when real-world graph data is given as graph side information. First, we take Facebook graph data [10] as graph side information (which has a 3-cluster structure) and generate binary ratings as per our discrete-valued latent preference model ( (p1, p2, p3) = (0.05, 0.5, 0.95) ). We use 80% (randomly sampled) of Ω as a training set (Ωtr) and the remaining 20% of Ω as a test set (Ωt). We use mean absolute error (MAE) \[ \frac{1}{|Ωt|} \sum_{(i,j) \in Ωt} \| N_{ij} - (2R_{ij} - 1) \| \] for the performance metric.\(^2\) Then we compare the performance of our algorithm with other algorithms in the literature\(^3\) Fig. 1b shows that our algorithm outperforms other baseline algorithms for almost all tested values of p. The red dotted line is the expected value of MAE of the optimal estimator (see the appendix for a detailed explanation) which means our algorithm shows near-optimal performance. Unlike other algorithms, MAE of [5] increases as p increases. One explanation is that the algorithm of [5] cannot properly handle d ≥ 3 cases due to its limited modeling assumption.

Remark 13. While our algorithm shows near-optimal performance with ℓ_{\text{max}} = 1 for synthetic data, Fig. 1b shows that our algorithm does not work well with ℓ_{\text{max}} = 1 for real-world data. This phenomenon can

\(^2\)We compute the difference between N_{ij} and 2R_{ij} - 1 for fair comparison since N_{ij} \in \{±1\}, R_{ij} \in [0,1].

\(^3\)We compare our algorithm with the algorithm of [5], item average, user average, user k-NN (nearest neighbors), item k-NN, BiasedMF [20], SocialMF [23], SoRec [30], SoReg [31], Trust SVD [17]. Except for ours and that of [5], we adopt implementations from LibRec [10].
We characterized the optimal sample complexity that guarantees perfect recovery of latent preference matrix. Although the improvement is not significant than the one for synthetic rating/real graph data, our algorithm achieves perfect recovery below the optimal sample complexity. We provided experimental results that corroborate our theoretical findings, highlight the importance of our relaxed modeling assumptions, and we can see that even a small increase in the quality of the graph can result in a significant decrease in error measured in $\|\cdot\|_{\text{max}}$.

Surprisingly, our algorithm shows near-optimal performance with $\ell_{\text{max}}^* = 1$ even for real-world graph data (see Fig. 11). Unlike ours, the algorithm of [5] shows no difference between $\ell_{\text{max}}^* = 1$ and $\ell_{\text{max}}^* = 2$.

Furthermore, we evaluate the performance of our algorithm on a real rating/real graph dataset called Epinions [32,33]. We use 5-fold cross-validation to determine hyperparameters. Then we compute MAE for a randomly sampled test set (with 500 iterations). Shown in Table 1 are MAE’s for various algorithms. Although the improvement is not significant than the one for synthetic rating/real graph data, our algorithm outperforms all the other algorithms. Note that all the experimental results presented in the prior work are based on synthetic rating [3,45,48], and this is the first real rating/real graph experiment that shows the practicality of binary rating estimation with graph side information.

### 6.5 Estimation Error with Different Values of $\gamma$ and $I_s$

We corroborate Theorem 3. More specifically, we observe how the estimation error behaves as a function of $p$ when $\gamma$ and $(\alpha, \beta)$ varies. Let $d = 3, p_1 = 0.2, p_2 = 0.5, p_3 = 0.7, n = 10000, m = 5000$. We first compare cases for $\alpha, \beta, \gamma = (0.26, 0.23, 0.5)$ and $\gamma = 0.26, 0.23, 0.25$. Shown in Fig. 13 is the estimation error as a function of $p$. We draw $p^*_s$ as dotted lines. One can see from the figure that the estimation error for $\alpha, \beta, \gamma = (0.26, 0.23, 0.5)$ is lower than that for $\alpha, \beta, \gamma = (0.26, 0.23, 0.25)$ for all tested values of $p$. This can be explained by the fact that $p^*_s$ decreases as $\gamma$ increases, as stated in Theorem 3. We also compare cases for $\alpha, \beta, \gamma = (0.26, 0.23, 0.25)$ and $0.27, 0.23, 0.25$. Note that the only difference between these cases is the value of $\alpha$. By Theorem 3, we have $p^*_s = 0.118$ for the former case, and $p^*_s = 0.081$ for the latter case. That is, a larger value of $\alpha$ implies a higher quality of graph side information, i.e., the graph side information is more useful for predicting the latent preference matrix $R$. Fig. 4c shows the estimation error as a function of $p$, and we can see that even a small increase in the quality of the graph can result in a significant decrease in $p^*_s$.

### 7 Conclusion

We studied the problem of estimating the latent preference matrix whose entries are discrete-valued given a partially observed binary rating matrix and graph side information. We first showed that the latent preference matrix model adopted in existing works is highly limited, and proposed a generalized data generation model. We characterized the optimal sample complexity that guarantees perfect recovery of latent preference matrix, and showed that this optimal complexity also serves as a tight lower bound, i.e., no estimation algorithm can achieve perfect recovery below the optimal sample complexity. We also proposed a computationally efficient estimation algorithm. Our analysis showed that our proposed algorithm can perfectly estimate the latent preference matrix if the sample complexity is above the optimal sample complexity. We provided experimental results that corroborate our theoretical findings, highlight the importance of our relaxed modeling assumptions,
imply the robustness of our algorithm to model errors, and compare our algorithm with other algorithms on real-world data.

Appendix

A Reproducing Our Simulation Results

We provide our Python implementation of our algorithm as well as that of [5] so that one can easily reproduce all of our experimental results. Our code is available at https://github.com/changhunjo0927/Discrete-Valued_Latent_Preference and one can easily reproduce any figure simply by opening the corresponding subfolder and run three or four Jupyter notebooks in order. (Click ‘Run All’ in each Jupyter notebook). Then, simulation results will be saved as a figure within the subfolder. While the values reported in our figures were the average performance over \( T = 100 \) random runs, the default configuration in our codes is \( T = 2 \). This way, one can quickly reproduce rough versions of our figures in a few minutes on a typical machine. If one wants to reproduce more precise simulations results, one may want to change the value of \( T \) from 2 to 100 by modifying the first cell of each Jupyter notebook.

B Pseudocode of Proposed Algorithm

See Alg. 1 for the pseudocode of our algorithm proposed in Sec. 5.

C Additional Experimental Details

In this section, we provide additional experimental details deferred to the appendix. Let \( 1_{k,l} \) be a \( k \times l \) matrix whose entries are all equal to 1.

C.1 Sec. 6.1

For Fig. 3a, we used

\[
R = \begin{bmatrix}
0.2 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.7 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250}
\end{bmatrix}
\]

as a latent preference matrix, and \((K, d, \ell_{\text{max}}) = (2, 3, 1)\).

C.2 Sec. 6.2

For Fig. 3b, we used

\[
R = \begin{bmatrix}
0.3 \cdot 1_{1000,250} & 0.3 \cdot 1_{1000,250} & 0.3 \cdot 1_{1000,250} & 0.3 \cdot 1_{1000,250} & 0.7 \cdot 1_{1000,250}
\end{bmatrix}
\]

as a latent preference matrix, and \((K, d, \ell_{\text{max}}) = (2, 2, 1)\).

For Fig. 4a, we used

\[
R = \begin{bmatrix}
0.3 \cdot 1_{1000,250} & 0.3 \cdot 1_{1000,250} & 0.3 \cdot 1_{1000,250} & 0.3 \cdot 1_{1000,250} & 0.62 \cdot 1_{1000,250}
\end{bmatrix}
\]

as a latent preference matrix, and \((K, d, \ell_{\text{max}}) = (2, 2, 1)\).

For Fig. 3c, we used

\[
R = \begin{bmatrix}
0.3 \cdot 1_{1000,250} & 0.3 \cdot 1_{1000,250} & 0.3 \cdot 1_{1000,250} & 0.3 \cdot 1_{1000,250} & 0.55 \cdot 1_{1000,250}
\end{bmatrix}
\]

as a latent preference matrix, and \((K, d, \ell_{\text{max}}) = (2, 2, 1)\).
Algorithm 1

Input: $X^T \in \{−1, 0, +1\}^{n \times m}$, $G = ([n], E), K, d, \ell_{\text{max}}$

Output: Clusters of users $A_1^{(\ell_{\text{max}})}$, $A_2^{(\ell_{\text{max}})}$, ..., $A_K^{(\ell_{\text{max}})}$
Latent preference vectors $\hat{u}_1^{(\ell_{\text{max}})}$, $\hat{u}_2^{(\ell_{\text{max}})}$, ..., $\hat{u}_K^{(\ell_{\text{max}})}$

Stage 1 (Partial recovery of clusters):
Run a spectral method on $G$, and get a clustering result $A_1^{(0)}$, $A_2^{(0)}$, ..., $A_K^{(0)}$.

for $\ell = 1$ to $\ell_{\text{max}}$ do

Stage 2-(i) (Recovery of latent preference vectors):

for $k = 1$ to $K$ do
  for $t = 1$ to $m_0(\coloneqq d\lfloor \log m \rfloor)$ do
    Sample $j^{(k)}_t \sim \text{unif}\{1, m\}$.
    \[
    \sum_{i \in A_{0}^{(\ell-1)}} \mathbb{1}(N_i^{(k)} = 1)
    \]
    \[
    a_{j^{(k)}_t} \leftarrow \frac{\sum_{i \in A_{0}^{(\ell-1)}} \mathbb{1}(N_i^{(k)} = \pm 1)}{\sum_{i \in A_{0}^{(\ell-1)}} \mathbb{1}(N_i^{(k)} = \pm 1)}
    \]
  end for

C.3 Sec. 6.3

For Fig. 3d we used

\[ R = \begin{bmatrix}
0.2 \cdot 1_{1000,250} & 0.5 \cdot 1_{1000,250} & 0.5 \cdot 1_{1000,250} & 0.7 \cdot 1_{1000,250} \\
0.2 \cdot 1_{1000,250} & 0.5 \cdot 1_{1000,250} & 0.5 \cdot 1_{1000,250} & 0.5 \cdot 1_{1000,250}
\end{bmatrix} \]

as a latent preference matrix, and \((K, d, \ell_{\text{max}}) = (2, 3, 1)\).

C.4 Sec. 6.4

Synthetic rating/real graph experiment

For Fig. 1b we take the Facebook graph data [40] as graph side information. In specific, we use the social graph of 1637 students in Vassar College; an edge is placed between two students if they are friends in Facebook. Students are clustered by the year they entered the college; 467, 590, 580 students in each year. On top of the social graph, we generate binary ratings as per our discrete-valued latent preference model. We used

\[ R = \begin{bmatrix}
0.05 \cdot 1_{1467,200} & 0.05 \cdot 1_{1467,200} & 0.5 \cdot 1_{1467,200} & 0.95 \cdot 1_{1467,200} & 0.95 \cdot 1_{1467,200} \\
0.05 \cdot 1_{590,200} & 0.95 \cdot 1_{590,200} & 0.05 \cdot 1_{590,200} & 0.05 \cdot 1_{590,200} & 0.05 \cdot 1_{590,200} \\
0.95 \cdot 1_{580,200} & 0.95 \cdot 1_{580,200} & 0.95 \cdot 1_{580,200} & 0.95 \cdot 1_{580,200} & 0.95 \cdot 1_{580,200}
\end{bmatrix} \]

as a latent preference matrix, and \((K, d, \ell_{\text{max}}) = (3, 3, 2)\).

We computed the expected value of MAE of the optimal estimator in Sec. 6.4 as follows. Suppose there exists an optimal estimator \( \psi^* \) in the sense that \( \psi^*(N^\Omega, G)_{ij} = R_{ij} \) for all \( i, j \). Then

\[
\text{the expected value of test MAE of } \psi^* = \mathbb{E} \left[ \frac{1}{|\Omega|} \sum_{(i,j) \in \Omega} |N^\Omega_{ij} - (2\psi^*(N^\Omega, G)_{ij} - 1)| \right]
\]

\[
= \mathbb{E} \left[ \frac{1}{|\Omega|} \sum_{(i,j) \in \Omega} |N^\Omega_{ij} - (2R_{ij} - 1)| \right]
\]

\[
= \frac{1}{|\Omega|} \sum_{(i,j) \in \Omega} \mathbb{E} \left[ |N^\Omega_{ij} - (2R_{ij} - 1)| \right]
\]

\[
= \frac{1}{|\Omega|} \sum_{(i,j) \in \Omega} \mathbb{E} \left[ |2\text{Bern}(R_{ij}) - 1 - (2R_{ij} - 1)| \right]
\]

\[
\left( \because \text{conditioned on } (i, j) \in \Omega, N^\Omega_{ij} = 2\text{Bern}(R_{ij}) - 1 \right)
\]

\[
= \mathbb{E} \left[ |2\text{Bern}(R_{ij}) - 1 - (2R_{ij} - 1)| \right]
\]

\[
= 2\mathbb{E} \left[ |\text{Bern}(R_{ij}) - R_{ij}| \right]
\]

\[
= 2 \cdot \frac{1}{1637 \cdot 1000} \sum_{1 \leq i \leq 1637, 1 \leq j \leq 1000} \{R_{ij} \cdot |1 - R_{ij}| + (1 - R_{ij}) \cdot |0 - R_{ij}| \}
\]

\[
\approx 0.236
\]

Real rating/real graph experiment

We used a real ratings/real graph dataset called Epinions [32, 33] that consists of 40163 users and 139738 items with rating and graph data. We preprocess this dataset as follows. First, the rating scale of this dataset is from +1 to +5, so we regard +1/2 as dislike(-1), +4/5 as like(+1) and ignore +3’s (i.e., we treat +3’s as unobserved ratings). After the first step, the observation rate of ratings is about 0.00012 which is too small for meaningful analysis. This is why we add the following preprocessing steps. 1) Find 100 most frequently rated items. 2) Find 1000 users who rated above 100 items most frequently. 3) Find a subset of users that shows a cluster structure via spectral clustering. As a result, we get a preprocessed dataset that consists of 290 users and 100 items.
C.5 Sec. 6.5

For the black curve with triangle markers in Fig. 4b, we used
\[
R = \begin{bmatrix}
0.2 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.7 \cdot 1_{5000,1250} \\
0.2 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} \\
0.2 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.7 \cdot 1_{5000,1250} \\
0.2 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250}
\end{bmatrix}
\]
as a latent preference matrix and \((K, d, \ell_{\max}, \alpha, \beta) = (2, 2, 1, 0.26, 0.23)\).
For the gray curve with square markers in Fig. 4b and Fig. 4c, we used
\[
R = \begin{bmatrix}
0.2 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.7 \cdot 1_{5000,1250} \\
0.2 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} \\
0.2 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.7 \cdot 1_{5000,1250} \\
0.2 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250}
\end{bmatrix}
\]
as a latent preference matrix and \((K, d, \ell_{\max}, \alpha, \beta) = (2, 2, 1, 0.26, 0.23)\).
For the yellow curve with circle markers in Fig. 4c, we used
\[
R = \begin{bmatrix}
0.2 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.7 \cdot 1_{5000,1250} \\
0.2 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} \\
0.2 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.7 \cdot 1_{5000,1250} \\
0.2 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250} & 0.5 \cdot 1_{5000,1250}
\end{bmatrix}
\]
as a latent preference matrix and \((K, d, \ell_{\max}, \alpha, \beta) = (2, 2, 1, 0.27, 0.23)\).

D Proof of Theorems

In this section, we provide proofs of theorems.

D.1 Proof of Theorem 1

We first recall some definitions and the main theorem.

**Definition 1** (Worst-case probability of error). Let \(\gamma\) be a fixed number in \((0, 1)\) and \(\psi\) be an estimator that outputs a latent preference matrix in \(\{p_1, p_2, \ldots, p_d\}^{n \times m}\) based on \(N^{11}\) and \(G\). We define the worst-case probability of error \(P^*_{\psi}(\gamma) := \max \{\Pr(\psi(N^{11}, G) \neq R) : R \in \{p_1, p_2, \ldots, p_d\}^{n \times m}, \|u_R - v_R\|_0 = \gamma m\}\) where \(\|\cdot\|_0\) is the hamming distance.

**Theorem 1.** Let \(K = 2, |C^{-1}(\{1\})| = |C^{-1}(\{2\})| = \frac{\gamma}{2}, \gamma \in (0, 1), m = \omega(\log n), \log m = o(n), I_s := -2 \log \left(1 - d^2_m(\alpha, \beta)\right)\). Then, the following holds for arbitrary \(\epsilon > 0\):

(I) if \(p \geq \frac{1}{(d^2_m)^2} \max \left\{\frac{1+(1+\epsilon)(\log n - 2I_s)}{\gamma m}, \frac{(1+\epsilon)(\log m n)}{n}\right\}\), then there exists an estimator \(\psi\) that outputs a latent preference matrix in \(\{p_1, p_2, \ldots, p_d\}^{n \times m}\) based on \(N^{11}\) and \(G\) such that \(P^*_{\psi}(\gamma) \rightarrow 0\) as \(n \rightarrow \infty\).

(II) if \(p \leq \frac{1}{(d^2_m)^2} \max \left\{\frac{1-\epsilon)(\log n - 2I_s)}{\gamma m}, \frac{(1-\epsilon)(\log m n)}{n}\right\}\) and \(\alpha = O\left(\frac{\log n}{n}\right)\), then \(P^*_{\psi}(\gamma) \rightarrow 0\) as \(n \rightarrow \infty\) for any \(\gamma\).

**Definition 2.** \(p^*_\psi(\gamma) := \frac{1}{(d^2_m)^2} \max \left\{\frac{\log n - 2I_s}{\gamma m}, \frac{2 \log m}{n}\right\}\) denotes the optimal observation rate.

Then \(nmp^*_\psi(\gamma) = \frac{1}{(d^2_m)^2} \max \left\{\frac{1}{\gamma} (n \log n - \frac{1}{2} n^2 I_s), 2 m \log m\right\}\) denotes the optimal sample complexity.

We will first show that the maximum likelihood estimator \(\psi_{ML}\) satisfies (I), and then show that there does not exist an estimator \(\psi\) satisfying (II).

**I) MLE Achievability**

**Overview of the proof:** We show that if the observation rate is above a certain threshold, then the worst-case probability of error approaches to 0 as \(n \rightarrow \infty\) for MLE. In specific, we show the following. Given observed ratings and graph side information, Lemma 1 shows the negative log-likelihood of a latent preference matrix can be written in a compact form. Then Lemma 2 represents the probability of the event “the likelihood of a candidate latent preference matrix is greater than that of the ground-truth latent preference matrix” in a compact form. In Lemma 3, we apply Chernoff bounds to the result of Lemma 2 to get an upper bound of the probability of error. Then we finally show that the worst case probability of error approaches to 0 as \(n \rightarrow \infty\) by applying the union bound. To get a tight bound, we enumerate all possible latent preference
matrices and group them into four distinct types based on Definition 3. Note that our technical contributions lie in the proofs of Lemma 1, Lemma 2 and Lemma 3 in which we must consider a significantly larger set of candidate latent preference matrices compared to the symmetric case. In Remark 4, we give a detailed explanation of our definition of $I_s$. The following diagram visualizes the proof dependencies.

![Proof dependencies diagram]

Let $R$ be an arbitrary ground-truth latent preference matrix satisfying $\|u_R - v_R\|_0 = \lceil \gamma m \rceil$ and assume our model is generated as per $R$ (i.e., user $i$ likes item $j$ with probability $R_{ij}$ and $n$ users are clustered into $A_R$ and $B_R$). By switching the order of items (columns of the latent preference matrix) if necessary, we can assume $(v_R)_j = (v_{R})_j$ for $j = 1, 2, \ldots, (m - \lceil \gamma m \rceil)$ and $(u_R)_j \neq (v_{R})_j$ for $j = (m - \lceil \gamma m \rceil) + 1, \ldots, m$. By switching the order of users (rows of the latent preference matrix) if necessary, we can also assume that $A_R = \lceil \frac{n}{2} \rceil$, $B_R = \lfloor n \rfloor \setminus \lceil \frac{n}{2} \rceil$. We will first find the upper bound of $\Pr(G_{ML}(N^\Omega, G) \neq R)$ for arbitrary $R$, and show that the upper bound approaches to 0 as $n$ approaches to infinity. We need following lemmas.

**Lemma 1.** Let $L(X)$ be the negative log-likelihood of a latent preference matrix $X$ for given $N^\Omega$ and $G$. Then

$$L(X) = \sum_{1 \leq i \leq d \land (i, j) \in \Omega_t} \left[ \sum_{1 \leq i \leq d \land (i, j) \in \Omega_t} \log \left\{ (1 - p)^{\gamma m - |\Omega|} N_i^\Omega \right\} \right] + \log \left( \frac{e^{(1 - \beta)}}{1 - \alpha} \right) e(A_X, B_X) + c,$$

where $c := -\log \left\{ (1 - p)^{nm - |\Omega|} p^{|\Omega|} \alpha e^{E} (1 - \alpha)^{2 \left( \frac{n}{2} \right)} (1 - \beta)^{\frac{p(n)}{2}} \right\}$, and $\Omega_t := \{(i, j) \in \Omega : X_{ij} = p_t\}$.

**Proof.** The likelihood of latent preference matrix $X$ given $N^\Omega$ and $G$ is $\Pr(N^\Omega, G | X) = \Pr(N^\Omega | X) \Pr(G | X)$. It is clear that

$$\Pr(N^\Omega | X) = (1 - p)^{nm - |\Omega|} p^{|\Omega|} \prod_{1 \leq i \leq d \land (i, j) \in \Omega_t} \left\{ p_t^{1(X^\Omega_i = 1)} (1 - p_t) \right\},$$

where $\Omega_t := \{(i, j) \in \Omega : X_{ij} = p_t\}$, and

$$\Pr(G | X) = \alpha e^{(A_X, B_X)} (1 - \alpha)^{2 \left( \frac{n}{2} \right)} (1 - \beta)^{\frac{p(n)}{2}} - (A_X, B_X) e^{(A_X, B_X)} (1 - \beta)^{\frac{p(n)}{2}}.$$

Then the negative log-likelihood of $X$ can be computed as follows.

$$L(X) = -\log(\Pr(N^\Omega, G | X)) = \sum_{1 \leq i \leq d \land (i, j) \in \Omega_t} \left[ \sum_{1 \leq i \leq d \land (i, j) \in \Omega_t} \log \left\{ (1 - p)^{\gamma m - |\Omega|} N_i^\Omega \right\} \right] + \log \left( \frac{e^{(1 - \beta)}}{1 - \alpha} \right) e(A_X, B_X) + c$$

where $c = -\log \left\{ (1 - p)^{nm - |\Omega|} p^{|\Omega|} \alpha e^{E} (1 - \alpha)^{2 \left( \frac{n}{2} \right)} (1 - \beta)^{\frac{p(n)}{2}} \right\}$. $\square$

**Definition 3.** (i) $\chi(k, a_1, a_2, b_1, b_2) := \left\{ X \in \{p_1, p_2, \ldots, p_d\}^{n \times m} : |A_X \setminus A_R| = |B_X \setminus B_R| = k, u_X \text{ differs from } u_R \text{ at } a_1 \text{ coordinates among the first } m - \lceil \gamma m \rceil \text{ coordinates}, u_X \text{ differs from } u_R \text{ at } a_2 \text{ coordinates among the last } \lceil \gamma m \rceil \text{ coordinates}, v_X \text{ differs from } v_R \text{ at } b_1 \text{ many coordinates among the first } m - \lceil \gamma m \rceil \text{ coordinates, and } v_X \text{ differs from } v_R \text{ at } b_2 \text{ many coordinates among the last } \lceil \gamma m \rceil \text{ coordinates.} \right\}$. (ii) Let $I$ be the index set of $X$, namely, $I := \{(k, a_1, a_2, b_1, b_2) \neq (0, 0, 0, 0, 0) : 0 \leq k \leq \frac{n}{4}, 0 \leq a_1, b_1 \leq m - \lceil \gamma m \rceil, 0 \leq a_2, b_2 \leq \lceil \gamma m \rceil \}$. Note that we can assume $k \leq \frac{n}{4}$ by switching the role of $A_X$ and $B_X$ if necessary.
Lemma 2. For $X \in \chi(k, a_1, a_2, b_1, b_2)$,

$$\Pr(L(X) \leq L(R)) = \Pr \left( \sum_{1 \leq a \leq d} \sum_{(i,j) \in Q_{ab}} \log \frac{P_{a,ij} \log \frac{P_{a,ij}}{p_a} + (1 - P_{a,ij}) \log \frac{1 - p_b}{1 - p_a}}{(1 - \alpha)\beta} \right),$$

where

$$Q_{ab} := \{(i, j) \in [n] \times [m] : R_{ij} = p_a, X_{ij} = p_b\},$$

and $A_i \overset{i.i.d.}{\sim} \text{Bern}(\alpha), B_i \overset{i.i.d.}{\sim} \text{Bern}(\beta), P_{ij} \overset{i.i.d.}{\sim} \text{Bern}(p), P_{a,ij} \overset{i.i.d.}{\sim} \text{Bern}(p_a)$.

Proof. By Lemma 1

$$L(R) = \sum_{1 \leq a \leq d} \sum_{(i,j) \in \Omega^{(R)}_a} \left( \mathbb{1}(N^{(R)}_{ij} = 1)(- \log p_a + \log(1 - p_a)) + \mathbb{1}(N^{(R)}_{ij} = -1)(- \log(1 - p_a) + \log(1 - p_b)) \right) + \log \left( \frac{\alpha(1 - \beta)}{(1 - \alpha)\beta} \right) e(A_R, B_R) + c$$

and

$$L(X) = \sum_{1 \leq a \leq d} \sum_{(i,j) \in \Omega^{(X)}_a} \left( \mathbb{1}(N^{(X)}_{ij} = 1)(- \log p_a + \log(1 - p_a)) + \mathbb{1}(N^{(X)}_{ij} = -1)(- \log(1 - p_a) + \log(1 - p_b)) \right) + \log \left( \frac{\alpha(1 - \beta)}{(1 - \alpha)\beta} \right) e(A_X, B_X) + c$$

where $\Omega^{(R)}_a := \{(i, j) \in \Omega : R_{ij} = p_a\}$ and $\Omega^{(X)}_a := \{(i, j) \in \Omega : X_{ij} = p_a\}$. Then

$$L(R) - L(X) = \sum_{1 \leq a \leq d} \sum_{(i,j) \in Q_{ab}} \left( \mathbb{1}(N^{(R)}_{ij} = 1)(- \log p_a + \log(1 - p_a)) + \mathbb{1}(N^{(R)}_{ij} = -1)(- \log(1 - p_a) + \log(1 - p_b)) \right)$$

$$+ \log \left( \frac{\alpha(1 - \beta)}{(1 - \alpha)\beta} \right) \{e(A_R, B_R) - e(A_X, B_X)\}$$

where $Q_{ab} := \{(i, j) \in [n] \times [m] : R_{ij} = p_a, X_{ij} = p_b\}, P_{ij} \overset{i.i.d.}{\sim} \text{Bern}(p), P_{a,ij} \overset{i.i.d.}{\sim} \text{Bern}(p_a)$.

Note that our ground-truth latent preference matrix is $R$, hence $\mathbb{1}(N^{(R)}_{ij} = 1) = P_{ij}P_{a,ij}$ and $\mathbb{1}(N^{(R)}_{ij} = -1) = P_{ij}(1 - P_{a,ij})$ for $(i, j) \in Q_{ab}$.

Note that $X \in \chi(k, a_1, a_2, b_1, b_2), |A_X \setminus A_R| = |B_X \setminus B_R| = k, |A_X \cap A_R| = |B_X \cap B_R| = \frac{k}{2} - k$,

$$e(A_R, B_R) = e(B_X \setminus B_R, B_X \cap B_R) + e(B_X \setminus B_R, A_X \setminus A_R) + e(A_X \cap A_R, B_X \cap B_R) + e(A_X \cap A_R, A_X \setminus A_R),$$

and

$$e(A_X, B_X) = e(B_X \setminus B_R, A_X \cap A_R) + e(B_X \setminus B_R, A_X \setminus A_R) + e(B_X \cap B_R, A_X \cap A_R) + e(B_X \cap B_R, A_X \setminus A_R),$$

so we can get

$$e(A_R, B_R) - e(A_X, B_X) = e(B_X \setminus B_R, B_X \cap B_R) + e(A_X \cap A_R, A_X \setminus A_R) - \{e(B_X \setminus B_R, A_X \cap A_R) + e(B_X \cap B_R, A_X \setminus A_R)\} = \sum_{1 \leq i \leq 2(\frac{k}{2} - k)} B_i - \sum_{1 \leq i \leq 2(\frac{k}{2} - k)} A_i,$$

where $A_i \overset{i.i.d.}{\sim} \text{Bern}(\alpha), B_i \overset{i.i.d.}{\sim} \text{Bern}(\beta)$.
Lemma 3. Let $X \in \chi(k, a_1, a_2, b_1, b_2), Q_{ab} := \{(i, j) \in [n] \times [m]: R_{ij} = p_a, X_{ij} = p_b\}, A_{i.i.d.} \sim \text{Bern}(\alpha), B_{i.i.d.} \sim \text{Bern}(\beta), P_{ij} \sim \text{Bern}(p), P_{a,ij} \sim \text{Bern}(p_a)$. Then $\text{Pr(} \sum \sum_{i,j \in Q_{ab}} P_{ij} \{P_{a,ij} \log \frac{p_b}{p_a} + (1 - P_{a,ij}) \log \frac{1 - p_b}{1 - p_a}\} \} + \log \left(\frac{1}{1 - \frac{\alpha(1 - \beta)}{(1 - \alpha)(1 - \beta)}\right) \leq 1 - p(d_H^{\min}(\alpha, \beta))^{D_x} \{1 - d_H^2(\alpha, \beta)\}^{4(\frac{1}{2} - k)k}$ where $D_x := |\{(i, j) \in [n] \times [m]: R_{ij} \neq X_{ij}\}|$.

Proof. Let

$$Z := \sum_{1 \leq a \neq b \leq d} \left[\sum_{(i,j) \in Q_{ab}} P_{ij} \{P_{a,ij} \log \frac{p_b}{p_a} + (1 - P_{a,ij}) \log \frac{1 - p_b}{1 - p_a}\} \right] + \log \left(\frac{\alpha(1 - \beta)}{(1 - \alpha)(1 - \beta)}\right) \leq 1 - p(d_H^{\min}(\alpha, \beta))^{D_x} \{1 - d_H^2(\alpha, \beta)\}^{4(\frac{1}{2} - k)k}$$

Then

$$\text{Pr}(Z \geq 0) = \text{Pr}(e^{\frac{1}{2}Z} \geq 1) \leq E[e^{\frac{1}{2}Z}] \leq \text{Markov}'s \text{ inequality}$$

$$= \prod_{1 \leq a \neq b \leq d} \prod_{(i,j) \in Q_{ab}} \left\{(1 - p) + p(\sqrt{p_a}p_b + \sqrt{1 - p_a}(1 - p_b))\right\} \leq 1 - p(d_H^{\min}(\alpha, \beta))^{D_x} \{1 - d_H^2(\alpha, \beta)\}^{4(\frac{1}{2} - k)k}$$

$$= \prod_{1 \leq a \neq b \leq d} \prod_{(i,j) \in Q_{ab}} \left\{1 - p(d_H^{\min}(\alpha, \beta))^{D_x} \{1 - d_H^2(\alpha, \beta)\}^{4(\frac{1}{2} - k)k}\right\}$$

Remark 14. We give a detailed explanation regarding the definition of $I_x$ in our paper. In the proof of Lemma 3 in [23], they made implicit assumptions that $\alpha, \beta \to 0$ and $\frac{\alpha}{\beta} \to 1$ as $n \to 0$, and used these assumptions when they approximate $-2 \log(1 - d_H^2(\alpha, \beta)) = (1 + o(1))(\sqrt{\alpha} - \sqrt{\beta})^2$. The approximation does not hold without above assumptions. In general,

$$1 - d_H^2(\alpha, \beta) = \sqrt{\alpha} - \sqrt{\beta} \leq 1 - \sqrt{\alpha(1 - \beta)(1 - \beta)}$$

$$= \sqrt{\beta + y\beta} + (1 - \beta) \sqrt{1 - \frac{y}{\beta}}$$

$$= \beta \left\{1 + \frac{y}{2\beta} - \frac{y}{8(1 - \beta)}\right\} + O(y^3)\} + (1 - \beta)\left\{1 - \frac{1}{2} + \frac{1}{1 - \beta} - \frac{1}{8(1 - \beta)^2} + O(y^3)\right\}$$

Assuming $\sqrt{\alpha} - \sqrt{\beta} = o(1)$ (which is true when $I_x = o(1)$),

$$-2 \log(1 - d_H^2(\alpha, \beta)) = -2 \left\{ \frac{\sqrt{\alpha} - \sqrt{\beta}}{8\beta(1 - \beta)} + O((\sqrt{\alpha} - \sqrt{\beta})^3)\right\}$$

$$= \log(1 + x) = x + O(x^2)$$

$$= (\sqrt{\alpha} - \sqrt{\beta})^2 \left\{ \frac{\sqrt{\alpha} + \sqrt{\beta}}{4\beta(1 - \beta)} + o(1)\right\}$$

20
Hence we get 

$$-2 \log \left(1 - d_H^2(\alpha, \beta)\right) = \frac{\log \left(1 - \frac{2}{\sqrt{|\beta|}} \frac{\sqrt{|\beta|} + \sqrt{|\beta|}}{2}\right)}{2} + o(1).$$

Note that if $\alpha, \beta \to 0$ and $\frac{2}{\sqrt{|\beta|}} \to 4$ as $n \to \infty$, then $-2 \log \left(1 - d_H^2(\alpha, \beta)\right) = \frac{\log \left(1 - \frac{2}{\sqrt{|\beta|}} \frac{\sqrt{|\beta|} + \sqrt{|\beta|}}{2}\right)}{2} + o(1)$ which is different from $\frac{\log \left(1 - \frac{2}{\sqrt{|\beta|}} \frac{\sqrt{|\beta|} + \sqrt{|\beta|}}{2}\right)}{2} + o(1)$.

This means the approximation used in [5] depends on the asymptotic behavior of $\alpha, \beta$. This is why we introduce a modified definition of $I_s := -2 \log \left(1 - d_H^2(\alpha, \beta)\right)$, then our achievability result holds for any $\alpha$ and $\beta$.

The event “$\psi_{ML}(N^\Omega, G) \neq R$” occurs only if there exists a latent preference matrix $X$ whose likelihood is greater than $R$’s (in other words, $L(X) \leq L(R)$ since $L(\cdot)$ is the negative log-likelihood). Let $[L(X) \leq L(R)]$ denotes the event “$L(X) \leq L(R)$”. Then

$$\Pr(\psi_{ML}(N^\Omega, G) \neq R) \leq \Pr(\bigcup_{X \neq R} [L(X) \leq L(R)])$$

union bound

$$\leq \sum_{X \neq R} \Pr(L(X) \leq L(R))$$

Lemma [2]

$$\leq \sum_{z \in I \in X(z)} \sum_{a \neq b \in \hat{D}} \sum_{1 \leq i \leq \alpha} \sum_{1 \leq j \leq 2} \left(1 - p(d_H^2(\alpha, \beta)) \right) \left(1 - d_H^2(\alpha, \beta)\right)^{2(\frac{2}{\sqrt{|\beta|}} - 2)k_z} k_z$$

where $D_X := \{(i, j) \in [n] \times [m] : R_{ij} \neq X_{ij}\}$ and $k_z$ is the first coordinate of $z = (k_z, a_1, a_2, b_1, b_2)$. A direct calculation yields $D_X \geq k_z(a_1 + (|\gamma| - - 2a_1) + b_1 + (|\gamma| - b_2)) + (2 - k_z)(a_1 + a_2 + b_1 + b_2) =: D_z$, so we have an upper bound of $\Pr(\psi_{ML}(N^\Omega, G) \neq R)$ as follows:

$$\Pr(\psi_{ML}(N^\Omega, G) \neq R) \leq \sum_{z \in I \in X(z)} \sum_{a \neq b \in \hat{D}} \sum_{1 \leq i \leq \alpha} \sum_{1 \leq j \leq 2} \left(1 - p(d_H^2(\alpha, \beta)) \right) \left(1 - d_H^2(\alpha, \beta)\right)^{2(\frac{2}{\sqrt{|\beta|}} - 2)k_z} k_z$$

We now show the upper bound of $\Pr(\psi_{ML}(N^\Omega, G) \neq R)$ approaches to 0 as $n \to \infty$. Note that

$$p \geq \frac{1}{(d_H^2)^2} \max \left\{ \frac{1 + \epsilon}{\gamma m} \log n - \frac{2}{\sqrt{|\beta|}} I, \frac{(1 + \epsilon) \log m}{n} \right\} \Leftrightarrow \frac{1}{2} n I_s + \gamma m p(d_H^2)^2 \geq (1 + \epsilon) \log m.$$ Since the RHS of (1) increases as $p$ decreases, it suffices to consider the case when $p = O(\frac{\log n}{m}) = o(1),$ which implies

$$\log(1 - p(d_H^2)^2) = -p(d_H^2)^2 + O(p^2) = -p(d_H^2)^2 (1 + o(1))$$

Hence the RHS of (1) can be represented as

$$\sum_{z \in I} \chi(z) e^{-D_z p(d_H^2)^2 (1 + o(1)) - 2(\frac{2}{\sqrt{|\beta|}} - 2)k_z k_z} I_s (1 + o(1)) = \sum_{z \in I} \chi(z) e^{(1 + o(1)) (I_s - 2(\frac{2}{\sqrt{|\beta|}} - 2)k_z k_z)} I_s$$

(2)

where $I_s := p(d_H^2)^2$. For a constant $\delta \in (0, \min\{\gamma, 1 - \gamma\})$ (the exact value of $\delta$ will be determined later), define

$$J := \{(k, a_1, a_2, b_1, b_2) \in I : a_1, b_1 < \delta m\}, K := \{(k, a_1, a_2, b_1, b_2) \in I : k < \delta n\}$$

Now we show the RHS of (2) approaches to 0 as $n \to \infty$ by dividing it into four partial sums over $I \setminus (J \cup K), J \setminus K, K \setminus J, J \cap K$.

- Case 1. $I \setminus (J \cup K)$: For $z = (k_z, a_1, a_2, b_1, b_2) \in I \setminus (J \cup K), \delta n \leq k_z \leq \frac{n}{4}$ since $z \notin K$. So $2(\frac{2}{\sqrt{|\beta|}} - 2)k_z \geq 2(\frac{2}{\sqrt{|\beta|}} - \frac{n}{4}) \delta n = \frac{4}{\sqrt{|\beta|}} n$. As $z \notin J$, we can assume $a_1 \geq \delta m$ without loss of generality, which
implies \( D_z = k_z \{ a_1 + \left( [\gamma m] - a_2 \right) + b_1 + \left( [\gamma m] - b_2 \right) \} + \left( \frac{n}{2} - k_z \right) (a_1 + a_2 + b_1 + b_2) \geq \left( \frac{n}{2} - k_z \right) a_1 \geq \left( \frac{n}{2} - \frac{n}{4} \right) \delta m = \frac{\delta}{4} \). Then

\[
\sum_{z \in \mathcal{I} \setminus (\mathcal{J} \cup \mathcal{K})} |\chi(z)| e^{(1+o(1))(-D_z I - 2(\frac{n}{2} - k_z) k_z I_s)}
\leq \sum_{z \in \mathcal{I} \setminus (\mathcal{J} \cup \mathcal{K})} |\chi(z)| e^{(1+o(1))(-\frac{\delta}{4} n m I_r - \frac{\delta}{4} n^2 I_s)}
= e^{(1+o(1))(-\frac{\delta}{4} n m I_r - \frac{\delta}{4} n^2 I_s)} \sum_{z \in \mathcal{I} \setminus (\mathcal{J} \cup \mathcal{K})} |\chi(z)|
\leq e^{(1+o(1))(-\frac{\delta}{4} n m I_r - \frac{\delta}{4} n^2 I_s)} \sum_{z \in \mathcal{I}} |\chi(z)|
\leq e^{(1+o(1))(-\frac{\delta}{4} n m I_r - \frac{\delta}{4} n^2 I_s)} 2^n d^m
\]

(\because \text{the total number of latent preference matrices is bounded by } 2^n d^m)

\[
\leq e^{(1+o(1))(-n(\frac{\delta}{4} n I_r + \frac{\delta}{4} m I_s) - m(\frac{\delta}{4} n I_r))} e^n \log 2 + 2m \log d
\]

\[
eq e^{(1+o(1))(-n(\Omega(\log n)) - m(\Omega(\log m))) + (n \log 2 + 2m \log d) \to 0 \text{ as } n \to \infty.}
\]

(\because \text{as } m = \omega(\log n), \to \infty \text{ as } n \to \infty)

Case 2. \( \mathcal{J} \setminus \mathcal{K} \): For \( z = (k_z, a_1, a_2, b_1, b_2) \in \mathcal{J} \setminus \mathcal{K}, \delta n \leq k_z \leq \frac{n}{4} \) since \( z \notin \mathcal{K} \). So \( 2(\frac{n}{2} - k_z) k_z \geq 2(\frac{n}{2} - \frac{n}{4}) \delta n = \frac{\delta}{4} n^2 \). As \( z \in \mathcal{J}, D_z = k_z \{ a_1 + ([\gamma m] - a_2) + b_1 + ([\gamma m] - b_2) \} + \left( \frac{n}{2} - k_z \right) (a_1 + a_2 + b_1 + b_2) \geq k_z \{ a_1 + ([\gamma m] - a_2) + b_1 + ([\gamma m] - b_2) \} \geq k_z \{ ([\gamma m] - \delta m) + ([\gamma m] - \delta m) \} \geq 2\delta (\gamma - \delta) n m. \) By applying the argument of Case 1, we have

\[
\sum_{z \in \mathcal{J} \setminus \mathcal{K}} |\chi(z)| e^{(1+o(1))(-D_z I - 2(\frac{n}{2} - k_z) k_z I_s)} \to 0 \text{ as } n \to \infty.
\]

Case 3. \( \mathcal{K} \setminus \mathcal{J} \): As \( z \in \mathcal{K}, k_z < \delta n \), which implies \( 2(\frac{n}{2} - k_z) k_z \geq 2(\frac{n}{2} - \delta n) k_z = k_z (1 - 2\delta) n \). As \( z \notin \mathcal{J} \), assume \( a_1 \geq \delta m \) without loss of generality. Then \( D_z = k_z \{ a_1 + ([\gamma m] - a_2) + b_1 + ([\gamma m] - b_2) \} + \left( \frac{n}{2} - k_z \right) (a_1 + a_2 + b_1 + b_2) \geq k_z \{ ([\gamma m] - \delta m) + ([\gamma m] - \delta m) \} + (\frac{n}{2} - \delta n)(a_1 + a_2 + b_1 + b_2) \geq 2k_z (\gamma - \delta) n m + (\frac{n}{2} - \delta n) (a_1 + a_2 + b_1 + b_2) \). Then

\[
\sum_{z \in \mathcal{K} \setminus \mathcal{J}} |\chi(z)| e^{(1+o(1))(-D_z I - 2(\frac{n}{2} - k_z) k_z I_s)}
\leq \sum_{z \in \mathcal{K} \setminus \mathcal{J}} |\chi(z)| e^{(1+o(1))\left[ -2k_z (\gamma - \delta) n m + \left( \frac{n}{2} - \delta n \right) (a_1 + a_2 + b_1 + b_2) \right]}
\leq \sum_{z \in \mathcal{K} \setminus \mathcal{J}} |\chi(z)| n^{2k_z (1 + \frac{\epsilon}{2}) (1 + o(1)) m^{(1 + \frac{\epsilon}{2}) (a_1 + a_2 + b_1 + b_2)}
\leq \sum_{z \in \mathcal{K} \setminus \mathcal{J}} |\chi(z)| n^{2k_z (1 + \frac{\epsilon}{2}) m^{-1}(1 + \frac{\epsilon}{2}) (a_1 + a_2 + b_1 + b_2)}
\leq (1 + \frac{\epsilon}{2}) (1 + o(1)) \geq (1 + \frac{\epsilon}{4}) \text{ for sufficiently large } n)
\]

\[
\sum_{z \in \mathcal{J} \cap \mathcal{K}} n^{2k_z m^{(1 + a_2 + b_1 + b_2)} (d - 1)^{a_1 + a_2 + b_1 + b_2} n^{2k_z (1 + \frac{\epsilon}{2}) m^{(1 + \frac{\epsilon}{2}) (a_1 + a_2 + b_1 + b_2)}}
= \sum_{z \in \mathcal{J} \cap \mathcal{K}} n^{2k_z m^{\frac{\epsilon}{4} (a_1 + a_2 + b_1 + b_2)} (d - 1)^{a_1 + a_2 + b_1 + b_2}}
\]
The worst-case probability of error does not approach to the maximum likelihood estimator. We need to show the following: for arbitrary $(\gamma, m, b_1, b_2)$, we have

\[
\frac{1}{n} \sum_{z \in \mathcal{F} \cap \mathcal{K}} n^{-\frac{1}{2}k_2} \{m^{-\frac{1}{2}}(d-1)\}^{(a_1 + a_2 + b_1 + b_2)} \lesssim \sum_{k_2 \in (0, \Delta_m]} n^{-\frac{1}{2}k_2} \left( \sum_{a_1 \in (0, \delta m]} \{m^{-\frac{1}{2}}(d-1)\}^{a_1} \right) \left( \sum_{a_2 \in (0, \delta m]} \{m^{-\frac{1}{2}}(d-1)\}^{a_2} \right) - 1 \to 0 \text{ as } n \to \infty.
\]

Here, three inequalities hold for the following reasons.

(i) It follows from the assumptions $\frac{1}{2} n I_n + \gamma m I_r \geq (1 + \epsilon) \log n, \frac{1}{2} n I_r \geq (1 + \epsilon) \log m$, and they imply $(\gamma - \delta) m I_r + \left( \frac{1}{2} - \delta \right) n I_n \geq (1 + \frac{\epsilon}{2}) \log n, \left( \frac{1}{2} - \delta \right) n I_r \geq (1 + \frac{\epsilon}{2}) \log m$ for sufficiently small $\delta$. In explicit, $\delta = \min\{ \frac{\epsilon}{4(1 + \epsilon)}, \gamma \frac{\epsilon}{1 + \epsilon} \}$ satisfies above inequalities.

(ii) For $z = (k_2, a_1, a_2, b_1, b_2)$, a direct calculation yields $|x(z)| = \left( \frac{\gamma m}{k_2} \right)^2 \left( \frac{m^{-\frac{1}{2}}(d-1)}{a_1} \right)^{a_1} \left( \frac{m^{-\frac{1}{2}}(d-1)}{b_1} \right)^{b_1}$ and it can be upper bounded by $n^{2k_2} \sum_{a_1 \in (0, \delta m]} \left( \frac{m^{-\frac{1}{2}}(d-1)}{a_1} \right)^{a_1} \left( \sum_{b_1 \in (0, \delta m]} \{m^{-\frac{1}{2}}(d-1)\}^{b_1} \right) - 1$ and the last $-1$ comes from the fact that $\phi(0, 0, 0, 0) \notin \mathcal{F} \cap \mathcal{K}$. Then apply $\sum_{a_1 \in (0, \delta m]} \left( \frac{m^{-\frac{1}{2}}(d-1)}{a_1} \right)^{a_1} = \sum_{b_1 \in (0, \delta m]} \{m^{-\frac{1}{2}}(d-1)\}^{b_1}.$

(II) MLE Converse

Overview of the proof: We show that if the observation rate is below a certain threshold, then the worst-case probability of error does not approach to 0 as $n \to \infty$ for any estimator. To begin with, Lemma 4 shows that it suffices to prove the statement above for the constrained version of MLE. Then the rest of the proof is similar to the proof in [6]. Specifically, we consider a genie-aided MLE by providing the constrained MLE with additional information of a small set where the ground-truth latent preference matrix lies. First make our analysis tractable by designing a proper set that reveals a just-about-right amount of information about the ground-truth latent preference matrix. We then show that the error probability for the genie-aided MLE becomes strictly larger than 0. Since the error probability of a genie-aided MLE is always lower than that of MLE, we can conclude the error probability of the constrained MLE does not approach to 0 as $n \to \infty$.

The following diagram visualizes the proof dependencies.

**Proof dependencies:**

(II) of Theorem 1 ← Lemma 4, Case 1, 2

Case 1 ← Lemma 5

Case 2 ← Lemma 6, 7

We need to show the following: for arbitrary $\epsilon > 0$, if $p \leq \frac{1}{(d_m)^2} \max \left\{ \frac{(1-\epsilon) \log n - \frac{2}{\gamma} L_n}{\gamma m}, \frac{(1-\epsilon) 2 \log m}{n} \right\}$, then $P^*_c(\psi) \to 0$ as $n \to \infty$ for any $\psi$. To prove the statement for any $\psi$, we need to consider the constrained maximum likelihood estimator.

Suppose $d_H(p_i, p_j)$ achieves the minimum Hellinger distance when $p_i = p_{d_0}, p_j = p_{d_0 + 1}$. Let $\mathcal{D}^\gamma := \left\{ X \in \{p_{d_0}, p_{d_0 + 1}\}^{[n] \times [m]} : \| u_{X} - v_{X} \|_0 = \gamma m \right\}$. Consider the maximum likelihood estimator $\psi_{\text{MLE}, \mathcal{D}^\gamma}$ whose output is constrained in $\mathcal{D}^\gamma$. Let $R'$ be a ground-truth latent preference matrix chosen in $\mathcal{D}^\gamma$ where $A' = \left[ \frac{1}{2} \right], B' = \left[ \frac{a_1}{2} \right], (u_{R'})_j = (v_{R'})_j = p_{d_0}$ for $j = 1, 2, \ldots, (m - \gamma m)$ and $(u_{R'})_j = p_{d_0}, (v_{R'})_j = p_{d_0 + 1}$ for $j = (m - \gamma m) + 1, \ldots, m$.

**Lemma 4.** $\inf_{\psi} P^*_c(\psi) \geq \Pr(\psi_{\text{MLE}, \mathcal{D}^\gamma}(N^\Omega, G) \neq R|R = R')$. 

23
Proof.\\n\[
\inf_{\psi} P_{\epsilon}^\gamma(\psi) = \inf_{\psi} \max \left\{ \Pr(\psi(N, G) \neq R) : R \in \{p_1, p_2, \ldots, p_d\}^{n \times m}, \|u_R - v_R\|_0 = [\gamma m] \right\} \\
\geq \inf_{\psi} \Pr(\psi(N, G) \neq R|R = R') \\
= \inf_{\psi : \psi(N, G) \in D^\gamma} \Pr(\psi(N, G) \neq R|R = R') \\
\left( \therefore \text{if there exist } N_0, G_0 \text{ such that } \psi(N_0^\Omega, G_0) \notin D^\gamma, \text{ we can decrease} \right. \\
\Pr(\psi(N, G) \neq R|R = R') \text{ by replacing } \psi(N_0^\Omega, G_0) \text{ with any element in } D^\gamma.\right) \\
= \Pr(\psi_{ML,D^\gamma}(N, G) \neq R|R = R'). \\
\left( \therefore \text{maximum likelihood estimator is optimal under uniform prior.} \right)
\]

By Lemma 4 it suffices to show that \(\Pr(\psi_{ML,D^\gamma}(N, G) \neq R|R = R') \to 0 \text{ as } n \to \infty.\) Let \(S := X \notin R' \cap X \notin D^\gamma \) be the success event of \(\psi_{ML,D^\gamma} \) where \(R = R'.\) Then it suffices to prove \(\Pr(S) \to 0.\) \(\therefore \text{Pr}(S) \to 0 \implies \Pr(S \cap (\psi_{ML,D^\gamma}(N, G) \neq R|R = R')) \geq \frac{1}{2} \Pr(S \cap (S \neq 1)).\) The last inequality comes from the fact that \(\Pr(\psi_{ML,D^\gamma}(N, G) \neq R|R = R') \geq \frac{1}{2} \text{ conditioned on } S^c.\)

Now we consider genie-aided ML estimators to prove \(\Pr(S) \to 0; \psi_{ML}^{(i)} \) is given with the information that the ground-truth latent preference matrix belongs to \(D^\gamma \cap \chi(0,0,0,1,1)\), and \(\psi_{ML}^{(2)} \) is given with the information that the ground-truth latent preference matrix belongs to \(D^\gamma \cap \chi(1,0,0,0,0)\). Let \(S^{(i)} \) be the success event of \(\psi_{ML}^{(i)} \) for \(i = 1, 2\). Then \(S^{(1)} = X \notin D^\gamma \cap \chi(0,0,0,1,1) \) and \(S^{(2)} = X \notin D^\gamma \cap \chi(1,0,0,0,0) \) are straightforward that \(\Pr(S) \leq \Pr(S^{(1)}) \) and \(\Pr(S) \leq \Pr(S^{(2)}).\) Note that \(p \leq \frac{(1 - \epsilon) \log n - \frac{4L}{\gamma m}}{\gamma m} \leq \frac{1}{2} \log(p^{\min}_{H})^2 \leq (1 - \epsilon) \log n \) and \(\frac{1}{2} n I_s + \gamma mp(d_H^{\max})^2 \leq (1 - \epsilon) \log n.\) It is enough to show the following: (i) if \(\frac{1}{2} n I_s + \gamma mp(d_H^{\max})^2 \leq (1 - \epsilon) \log n,\) then \(\Pr(S^{(1)}) \to 0 \text{ as } n \to \infty.\) (ii) if \(\gamma mp(d_H^{\max})^2 \leq (1 - \epsilon) \log n,\) then \(\Pr(S^{(2)}) \to 0 \text{ as } n \to \infty.\)

**Case 1.** \(\frac{1}{2} n I_s + \gamma mp(d_H^{\max})^2 \leq (1 - \epsilon) \log n.\)

We first need to observe the following fact. Consider \(X \in \chi(0,0,0,0,1) \cap D^\gamma, \) where \(v_{X_3} \) differs from \(v_{X'} \) at \(i_1\)-th coordinate, \(v_{X_2} \) differs from \(v_{X'} \) at \(i_2\)-th coordinate, \(v_{X_3} \) differs from \(v_{X''} \) at \(i_1\)-th and \(i_2\)-th coordinate, \(v_{X_2} \) differs from \(v_{X''} \) at \(i_1\)-th coordinate, \(v_{X_3} \) differs from \(v_{X''} \) at \(i_1\)-th coordinate, and \(X_j \in \chi(0,0,0,0,1) \cap D^\gamma \) where \(v_{X_{3,j}} \) differs from \(v_{X'} \) at \(m - [\gamma m] + j\)-th coordinate \((j = 1, \ldots, [\gamma m]).\) Using the observation above and the fact that \(L(X_3) > L(R') \) (by the assumption together), we can conclude that \(L(X_3) > L(R') \) for all \(j = 1, \ldots, [\gamma m].\) Applying the union bound, we get \(\Pr(\bigcup_{X \in \chi(0,0,0,1,0) \cap D^\gamma} [L(X) > L(R')] \leq \Pr(\bigcup_{X \in \chi(0,0,0,0,1) \cap D^\gamma} [L(X) > L(R')] + \Pr(\bigcup_{X \in \chi(0,0,0,0,1) \cap D^\gamma} [L(X) > L(R')]) \to 0 \text{ as } n \to \infty.\) (Identical argument can be applied to \(\Pr(\bigcup_{X \in \chi(0,0,0,1,0) \cap D^\gamma} [L(X) > L(R')] \to 0 \text{ as } n \to \infty.\))

**Lemma 5.** For integers \(K, L > 0,\) Let \(\{A_i\}_{i=1}^K \overset{i.i.d.}{\sim} \text{Bern}(\alpha), \{B_i\}_{i=1}^K \overset{i.i.d.}{\sim} \text{Bern}(\beta), \{F_i\}_{i=1}^L \overset{i.i.d.}{\sim} \text{Bern}(p), \{F_{do,i}\}_{i=1}^L \overset{i.i.d.}{\sim} \text{Bern}(\rho_{do}).\) Assume that \(\alpha, \beta, p = o(1) \) and \(\max\{\sqrt{\alpha K}, KL\} = o(1).\) Then the following holds for sufficiently
large \( K \) if \( \sqrt{\alpha \beta} K > pL \); sufficiently large \( L \) otherwise:
\[
\Pr \left( \log \left( \frac{(1-\beta)}{(1-\alpha)\beta} \right) \sum_{1 \leq i \leq L} (B_i-A_i) + \sum_{1 \leq i \leq L} \mathbb{P}_i \{ \mathbb{P}_{d_0,i} \log \left( \frac{p_{d_0+1}}{p_d} \right) + (1-\mathbb{P}_{d_0,i}) \log \left( \frac{1-p_{d_0+1}}{1-p_d} \right) \} \geq 0 \right) \geq \frac{1}{4} e^{-\left(1+o(1)\right)(KL+IL_r)}
\]
where \( I_s := -2 \log \left( 1 - d_H^2(\alpha,\beta) \right) \), \( I_r = p(d_H^{\text{min}})^2 \).

**Proof.** Can be proved similarly by applying the argument of Lemma 4 in [5]. \( \Box \)

Then
\[
\Pr \left( \bigcap_{X \in \chi(0,0,0,1,0) \cap D^\gamma} \left[ L(X_1) > L(R') \right] \right)
= \prod_{X \in \chi(0,0,0,1,0) \cap D^\gamma} \Pr \left( \left[ L(X_1) > L(R') \right] \right) \quad (\because \{ \left[ L(X_1) > L(R') \right] \} \text{ is mutually independent.})
= \prod_{X \in \chi(0,0,0,1,0) \cap D^\gamma} \left( 1 - \Pr \left( \left[ L(X_1) > L(R') \right] \right) \right)
= \prod_{X \in \chi(0,0,0,1,0) \cap D^\gamma} \left( 1 - \frac{1}{4} e^{-\left(1+o(1)\right)(L_{L_r})} \right) \quad (\because \text{apply Lemma 4 with } K = 0, L = \frac{n}{2})
\leq \prod_{X \in \chi(0,0,0,1,0) \cap D^\gamma} e^{-\frac{1}{4} e^{-\left(1+o(1)\right)(L_{L_r})}} \quad (\because 1 - x \leq e^{-x})
= \exp \left\{ -\frac{1}{4} (\chi(0,0,0,1,0) \cap D^\gamma) e^{-\left(1+o(1)\right)(L_{L_r})} \right\}
= \exp \left\{ -\frac{1}{4} (1-\gamma) me^{-\left(1+o(1)\right)(L_{L_r})} \right\}
= \exp \left\{ -\frac{1}{4} (1-\gamma)e^{-\left(1+o(1)\right)(L_{L_r})}+\log m \right\} \to 0 \text{ as } n \to \infty \quad (\because \frac{1}{2}nI_r \leq (1-\epsilon) \log m)
\]

**Case 2.** \( \frac{1}{2}nI_s + \gamma m I_r = \frac{1}{2}nI_s + \gamma mp(d_H^{\text{min}})^2 \leq (1-\epsilon) \log n \):

From the assumption, \( \alpha, \beta = O(\frac{\log n}{n}) \).

**Lemma 6.** Suppose \( \alpha = O(\frac{\log n}{n}) \), and consider the following procedure:
1) For \( r = \frac{n}{\log^2 n} \), let \( T := \{1, 2, \ldots, 2r\} \cup \left\{ \frac{n}{2} + 1, \frac{n}{2} + 2, \ldots, \frac{n}{2} + 2r \right\} \).
2) Within \( T \), we will delete every pair of two nodes which are adjacent.
3) Denote the remaining nodes by \( U \).

Then the above procedure results in \( |U| \geq 3 \frac{n}{\log^2 n} \), with probability approaching to 1.

**Proof.** Lemma 5 in [5]. \( \Box \)

Let \( \Delta \) be the event \( \left[ |U| \geq 3 \frac{n}{\log^2 n} \right] \). Let \( \Psi \) be the event \( \left[ \text{there exist subsets } A_P \subset A_R \text{ and } A_Q \subset B_R \text{ such that } (i) \ |A_P| = |A_Q| = \frac{n}{\log^2 n} \text{ and } (ii) \text{ there is no edge between nodes in } A_P \cup A_Q \right] \). One can show that \( \Delta \subset \Psi \). As \( \Pr(\Delta) = 1 - o(1) \) by Lemma 6 \( \Pr(\Psi) = 1 - o(1) \).

Let \( X^{(i)} \) be the latent preference matrix obtained from \( X \) by replacing \( i \)-th row with \( u_X \) if \( i \in A_X \); with \( u_X \) otherwise. In explicit, \( A_X^{(i)} = A_X \triangle \{i\} \) and \( B_X^{(i)} = B_X \triangle \{i\} \).

**Lemma 7.** Suppose that \( L(R^{(i)}) \leq L(R) \) and \( L(R^{(j)}) \leq L(R) \) hold for \( i \in A_P \) and \( j \in A_Q \). Then, conditioned on \( \Psi \), \( L((R^{(i)})^{(j)}) \leq L(R) \).

**Proof.** Lemma 6 in [5]. \( \Box \)

Now we can find the upper bound of \( \Pr \left( S^{(2)} \right) = \Pr \left( \bigcap_{X \in D^\gamma \cap \chi(1,0,0,0,0)} \left[ L(X) > L(R') \right] \right) \) as follows.
\[
\Pr \left( S^{(2)} \right) = \Pr \left( \bigcap_{X \in D^\gamma \cap \chi(1,0,0,0,0)} \left[ L(X) > L(R') \right] \right)
= \Pr \left( \left\{ \left( \bigcap_{X \in D^\gamma \cap \chi(1,0,0,0,0)} \left[ L(X) > L(R') \right] \right) \cap \Psi \right\} \cup \left\{ \left( \bigcap_{X \in D^\gamma \cap \chi(1,0,0,0,0)} \left[ L(X) > L(R') \right] \right) \cap \Psi^c \right\} \right)
\]
The upper bound of \( \Pr \left( [L(R^1) > L(R^r)] \mid \Psi \right) ^{|A_P|} \) can be computed as follows. Let \( c_s := \log \left( \frac{\alpha(1-\beta)}{(1-\beta)^3} \right) \)

\[
\Pr \left( L(R^1) > L(R^r) \right) \mid \Psi \right) ^{|A_P|} \\
\leq \left[ \Pr \left( c_s \left\{ e(A_R, B_R) - e(A_R^{(1)}, B_R^{(1)}) \right\} + \sum_{1 \leq i \leq \gamma m} P_i \left\{ P_{d_0, i} \log \left( \frac{p_{d_0 + 1}}{p_{d_0}} \right) + (1 - P_{d_0, i}) \log \left( \frac{1 - p_{d_0 + 1}}{1 - p_{d_0}} \right) \right\} < 0 \mid \Psi \right) \right] ^{|A_P|} \\
\leq \left[ \Pr \left( c_s \left\{ e(\{1\}, B_R) - e(\{1\}, A_R \Delta \{1\}) \right\} + \sum_{1 \leq i \leq \gamma m} P_i \left\{ P_{d_0, i} \log \left( \frac{p_{d_0 + 1}}{p_{d_0}} \right) + (1 - P_{d_0, i}) \log \left( \frac{1 - p_{d_0 + 1}}{1 - p_{d_0}} \right) \right\} < 0 \mid \Psi \right) \right] ^{|A_P|} \\
\leq \left\{ 1 - \frac{1}{4} e^{-(1+o(1))(\frac{2}{L} - r) I_s - (1+o(1)) \gamma m I_r} \right\} ^{|A_P|} \quad (\because \text{apply Lemma} 5 \text{ with } K = \frac{n}{2} - r \text{ and } L = \gamma m) \\
\leq \left[ \exp \left\{ - \frac{1}{4} e^{-(1+o(1))(\frac{2}{L} - r) I_s - (1+o(1)) \gamma m I_r} \right\} \right] ^{|A_P|} \quad (\because 1 - x \leq e^{-x}) \\
= \exp \left\{ - \frac{n}{\log^3 n} \right\} ^{|A_P|} \quad (\because |A_P| = \frac{n}{\log^3 n}) \\
\leq \exp \left\{ - \frac{n}{4} e^{-(1+o(1))(\frac{2}{L} - r) I_s - (1+o(1)) \gamma m I_r} \right\} \quad \text{for sufficiently large } n \\
\leq \exp \left\{ - \frac{n}{4} e^{-(1+o(1))(\frac{2}{L} - r) I_s - (1+o(1)) \gamma m I_r} \right\} \quad (\because (1+o(1))(\frac{n}{2} - r) I_s - (1+o(1)) \gamma m I_r \geq - (1 - \frac{\epsilon}{2}) \log n \quad \text{for sufficiently large } n) \\
= \exp \left\{ - \frac{n}{4} e^{-(1+o(1))(\frac{2}{L} - r) I_s - (1+o(1)) \gamma m I_r} \right\} \to 0 \text{ as } n \to \infty
\]

Hence we can conclude that \( \Pr \left( S^{(2)} \right) \to 0 \text{ as } n \to \infty. \)

### D.2 Proof of Theorem 2

**Overview of the proof:** The proof of Theorem 2 consists of two parts: MLE achievability and MLE converse. Both parts can be proved by combining the technique developed in the proof of Theorem 1 and the technique of [15].
In this section, we provide the full statement and the proof of Theorem 2. Recall that $R \in \{p_1, p_2, \ldots, p_d\}^{n \times m}$ is a ground-truth latent preference matrix, $C : [n] \rightarrow [K]$ is a cluster assignment function, $u_k \in \{p_1, \ldots, p_d\}^m$ is a latent preference vector whose cluster assignment is $k \in [K]$, $c_k := |C^{-1}(\{k\})|$, $c_{ij} := \frac{c_i + c_j}{2}$, $d_0 := \arg \max_{i \in \{1,2,\ldots,d-1\}} \left(\sqrt{p_i p_{i+1}} + \sqrt{(1-p_i)(1-p_{i+1})}\right)$. Define $\mathcal{P} : \{p_1, \ldots, p_d\}^m \rightarrow \{p_{d_0}, p_{d_0+1}\}^m$ that sends each coordinate $x_i$ to $p_{d_0}$ if $x_i \leq p_{d_0}$; $p_{d_0+1}$ if $x_i > p_{d_0+1}$.

**Theorem 2.** Let $D$ be a ground-truth latent preference matrix, $Q : [n] \rightarrow [K]$ is a cluster assignment function, $u_k \in \{p_1, \ldots, p_d\}^m$ is a latent preference vector whose cluster assignment is $k \in [K]$, $c_k := |C^{-1}(\{k\})|$, $c_{ij} := \frac{c_i + c_j}{2}$, $d_0 := \arg \max_{i \in \{1,2,\ldots,d-1\}} \left(\sqrt{p_i p_{i+1}} + \sqrt{(1-p_i)(1-p_{i+1})}\right)$. Define $\mathcal{P} : \{p_1, \ldots, p_d\}^m \rightarrow \{p_{d_0}, p_{d_0+1}\}^m$ that sends each coordinate $x_i$ to $p_{d_0}$ if $x_i \leq p_{d_0}$; $p_{d_0+1}$ if $x_i > p_{d_0+1}$.

(1) If $p \geq \left(\frac{\sum_{i \neq j} |C^X_{i,j}| - |C^X_{i,j}|}{\|p(u_i) - p(u_j)\|_2} \right)$, then there exists an estimator $\hat{\psi}$ such that $\Pr(\hat{\psi}(N^G, G) \neq R) \rightarrow 0$ as $n \rightarrow \infty$.

(2) Suppose $R \in \{p_{d_0}, p_{d_0+1}\}^{n \times m}$, $\alpha = \Omega(n)$, $\beta = \Omega(n)$. If $p \leq \left(\frac{\sum_{i \neq j} |C^X_{i,j}| - |C^X_{i,j}|}{\|p(u_i) - p(u_j)\|_2} \right)$, then $\Pr(\hat{\psi}(N^G, G) \neq R) \rightarrow 0$ as $n \rightarrow \infty$ for any $\hat{\psi}$.

We will first show that the maximum likelihood estimator $\hat{\psi}_{ML}$ satisfies (1), and then show that there does not exist an estimator $\hat{\psi}$ satisfying (2).

**I. MLE Achievability.**

We introduce a few more notations that will be used in the proof. For an arbitrary latent preference matrix $X$, let $C^X : [n] \rightarrow [K]$ be a cluster assignment function, $u_k \in \{p_1, \ldots, p_d\}^m$ be a latent preference vector whose cluster assignment is $k \in [K]$, $C_k := (C^X)^{-1}(\{k\})$, $C_{k+} := C_k \cap C^X$. Then $C_{k+} : 1 \leq i, j \leq K$ is a $K^2$-partition of $[n]$. In light of the proof of Claim 1 in [10], together with Lemma 2, we get

$$
\Pr(L(X) \leq L(R)) = \Pr \left( \sum_{1 \leq a \neq b \leq d} \left[ \sum_{(i,j) \in Q_{ab}} \mathbb{P}_{a,i,j} \log \frac{p_a}{p_b} + (1 - \mathbb{P}_{a,i,j}) \log \frac{1 - p_a}{1 - p_b} \right] 
\right.
+ (N_B - N_A) \log \frac{(1 - \alpha)}{(1 - \beta)} + \log \left( \frac{\alpha(1 - \beta)}{(1 - \alpha)\beta} \left( \sum_{1 \leq i \leq N_B} B_i - \sum_{1 \leq i \leq N_A} A_i \right) \geq 0 \right)
$$

where $Q_{ab} := \{(i,j) \in [n] \times [m] : R_{ij} = p_{ab}, X_{ij} = p_k\}$, $N_A := \sum_{i,j,k \in [K], j \neq k} |C^X_{i,j}| - |C^X_{i,j}|$, $N_B := \sum_{i,j,k \in [K], j \neq k} |C^X_{i,j}|$, and $A_i \stackrel{i.i.d.}{\sim}$ Bern($\alpha$), $B_i \stackrel{i.i.d.}{\sim}$ Bern($\beta$), $\mathbb{P}_{a,i,j} \stackrel{i.i.d.}{\sim}$ Bern($p$), $\mathbb{P}_{a,i,j} \stackrel{i.i.d.}{\sim}$ Bern($p_a$). Applying the technique of Lemma 2 in [10], together with Lemma 3, we get

$$
\Pr(L(X) \leq L(R)) \leq \{1 - p(\frac{d_{\min}^2}{d_{\min}^2})\} \exp \left( - \frac{N_A + N_B}{2} I_s \right)
$$

where $D_X := \{(i,j) \in [n] \times [m] : R_{ij} \neq X_{ij}\}$. Then

$$
\Pr(\hat{\psi}_{ML}(N^G, G) \neq R) \leq \Pr \left( \bigcup_{X \neq R} \left[ \left( \sum_{X \neq R} \Pr(L(X) \leq L(R)) \right) \sum_{X \neq R} \Pr(L(X) \leq L(R)) \right] \right.
$$

$$
\leq \sum_{X \neq R} \{1 - p(\frac{d_{\min}^2}{d_{\min}^2})\} \exp \left( - \frac{N_A + N_B}{2} I_s \right)
$$

Let $\mathcal{X} := \{X \neq R : X$ is a latent preference matrix with $K$ clusters$\}$. It suffices to show that the last summation converges to 0 as $n \rightarrow \infty$. We divide it into three partial sums over subsets $X_1 := \{X \in \mathcal{X} : \exists i, j \neq k \in [K]$ such that $|C^X_{i,j}|, |C^X_{i,k}| \geq \delta m\} \cup \{X \in \mathcal{X} : \exists i \neq k \in [K]$ such that $|C^X_{i,k}|, |C^X_{i,k}| \geq \delta m\}$,

$$
X_2 := \{X \in \mathcal{X} \setminus X_1 : \exists i \in [K]$ such that $\|p(u_i) - p(u_j)\|_2 \geq \delta m\}, X_3 := \mathcal{X} \setminus (X_1 \cup X_2).$$

Applying the technique used in the proof of Claim 1 in [10], one can show that each partial sum converges to 0 as $n \rightarrow \infty$.

**II. MLE Converse.**

$R \in \{p_{d_0}, p_{d_0+1}\}^{n \times m}$ by the assumption. Let $\mathcal{D} := \{p_{d_0}, p_{d_0+1}\}^{n \times m}$. In light of Lemma 4, one can show that $\Pr(\hat{\psi}(N^G, G) \neq R) \geq \Pr(\hat{\psi}_{ML}|_{\mathcal{D}}(N^G, G) \neq R)$ where $\hat{\psi}_{ML}|_{\mathcal{D}}$ is the maximum likelihood estimator whose output is constrained in $\mathcal{D}$. Hence it suffices to show that $\Pr(\hat{\psi}_{ML}|_{\mathcal{D}}(N^G, G) \neq R) \rightarrow 0$ as $n \rightarrow \infty$. Let $S := \bigcap_{X \neq R, X \in \mathcal{D}} \left[ L(X) > L(R) \right]$ which is the success event of $\hat{\psi}_{ML}|_{\mathcal{D}}$. Then one can observe that $\Pr(S) \rightarrow 0$.
implies $\Pr(\psi_{ML} | D(\mathcal{N}, G) \neq R) \to 0$.

Note that $p \leq \frac{1}{(d_H^{\min})^2} \max\{ \max_{i \neq j \in [K]} \{ (1-\epsilon) \log n - c_{i,j} I_s \}, \max_{k \in [K]} \{ (1-\epsilon) \log m \} \} \Leftrightarrow p(d_H^{\min})^2 ||p(u_i) - p(u_j)||_0 + c_{i,j} I_s \leq (1 - \epsilon) \log n$ for some $i \neq j \in [K]$ or “$c_k p(d_H^{\min})^2 \leq (1 - \epsilon) \log m$ for some $k \in [K]$”.

- **Case 1.** $p(d_H^{\min})^2 ||p(u_i) - p(u_j)||_0 + c_{i,j} I_s \leq (1 - \epsilon) \log n$ for some $i \neq j \in [K]$; Without loss of generality, assume that $i = 1, j = 2$. We consider a genie-aided ML estimator $\psi_{ML}^{(1)}$, which is given with the information that the ground-truth latent preference matrix belongs to $D_1 := \{ X \in D : C^0_Y \cup C^1_Y \cup C^0_X \cup C^1_X = 1 \}$, $C^0_Y \cup C^1_Y \cup C^0_X \cup C^1_X = C^0_i$ for $i = 3, \ldots, K$. Then one can show that $\Pr(S) := \Pr(\bigcap_{X \neq R, X \in D} [L(X) > L(R)]) \leq \Pr(\bigcap_{X \neq R, X \in D} [L(X) > L(R)]) \to 0$ by using the technique developed in [15].

- **Case 2.** $c_k p(d_H^{\min})^2 \leq (1 - \epsilon) \log m$ for some $k \in [K]$; Without loss of generality, assume that $k = 1$. We consider a genie-aided ML estimator $\psi_{ML}^{(2)}$ which is given with the information that the ground-truth latent preference matrix belongs to $D_2 := \{ X \in D : \|u_i^X - u_k^R\|_0 = 1, u_i^X = u_k^R \}$. Then one can show that $\Pr(S) := \Pr(\bigcap_{X \neq R, X \in D} [L(X) > L(R)]) \leq \Pr(\bigcap_{X \neq R, X \in D} [L(X) > L(R)]) \to 0$ by using the technique developed in [15].

### D.3 Proof of Theorem 3

**Overview of the proof:** For Stage 1, we make use of the standard performance guarantee of spectral clustering algorithms, and this step is identical to the argument in [3]. Our theoretical contribution lies in the analysis of Stage 2-(i). In [3], the authors have considered the symmetric case with $d = 2$, i.e., $p_1 + p_2 = 1$. Thus, one just needs to estimate a single parameter $p_1$, making the entire parameter estimation part straightforward. On the other hand, we do have to estimate $d$ parameters $p_1, p_2, \ldots, p_d$, making our estimation algorithm more complicated and complicating our analysis.

To obtain a theoretical guarantee of Stage 2-(i), we first show that $2d[\log m]$ number of estimations $a_j$’s and $a_j'$’s satisfy the following in Lemma 8 (i) every $p_j \in \{p_1, \ldots, p_d\}$ will be estimated by at least one of $a_j$’s or $a_j'$’s with probability approaching 1 as $n \to \infty$, (ii) $a_j$’s and $a_j'$’s are located in the $o(1)$-radius neighborhoods of ground-truth latent preference levels $p_1, \ldots, p_d$ with probability approaching 1 as $n \to \infty$. The next step is a distance-based clustering on the distribution of $p_1, \ldots, p_d$ which will give us $\tilde{p}_1, \ldots, \tilde{p}_d$ where $\tilde{p}_k$ is indeed the average of numbers whose distance from $p_k$ can be arbitrarily small as $n \to \infty$. Then for each pair of cluster and column, we assign one of $\tilde{p}_1, \ldots, \tilde{p}_d$ whose likelihood is maximum for that pair. This gives us $u_R, v_R$ which are the estimations of latent preference vectors, and Lemma 9 ensures that $u_R^{(j)} \to u^{(j)}_R$, $v_R^{(j)} \to v^{(j)}_R$ for all $j = 1, \ldots, m$ with probability approaching 1 as $n \to \infty$.

**Stage 2-(ii)** is a local refinement step in which we compare estimated likelihood values and update cluster assignments, and the analysis is similar to the proof in [3]. We prove that under the conditions of Thm. 2 the number of wrongly classified users can be halved in each iteration, and hence one can successively improve the quality of the estimation, eventually achieving the perfect recovery. Note that the proof procedure is based on a standard successive refinement technique. The following diagram visualizes the proof dependencies.

**Proof dependencies:**
- **Theorem 3** ← **Analysis of Stage 1, 2-(i), 2-(ii)**
  - **Analysis of Stage 2-(i)** ← **Lemma 8, 9**
  - **Analysis of Stage 2-(ii)** ← **Lemma 10, 11, 12**

**Theorem 3.** Let $\ell_{\max} = 1, K = 2, |C^{-1}(\{1\})| = |C^{-1}(\{2\})| = \frac{\gamma}{2}, \gamma \in (0, 1), m = \omega(\log n), \log m = o(n), (\sqrt{\alpha} - \sqrt{\beta})^2 = o(\frac{1}{n}), m = O(n)$, and $\alpha = O(\frac{\log n}{n})$. Let $\phi_j \cdot 2m$ be the number of $p_j$’s among $(u_R)_1, \ldots, (u_R)_m, (v_R)_1, \ldots, (v_R)_m$ for $j = 1, \ldots, d$, and assume that $\phi_j \to 0$ as $n \to \infty$. If

\[
p \geq \frac{1}{(d_H^{\min})^2} \max\left\{ \frac{(1+\epsilon)\log n - \frac{\gamma}{2} I_s}{\gamma m}, \frac{2(1+\epsilon)\log m}{n} \right\}
\]
for some \( \varepsilon > 0 \), then our algorithm outputs \( \hat{R} \) where the following holds with probability approaching to 1 as \( n \) goes to \( \infty \): \( \| \hat{R} - R \|_\text{max} := \max_{(i,j) \in [n] \times [m]} |\hat{R}_{ij} - R_{ij}| = o(1) \).

In Algorithm 1, (Stage 1) we first use spectral clustering to get \( A_R^{(0)}, B_R^{(0)} \), (Stage 2-(i)) then get almost exact recovery of latent preference vectors \( u_R, v_R \), (Stage 2-(ii)) and eventually get exact recovery of clusters \( A_R, B_R \).

**Analysis of Stage 1.** Let \( \eta := |A_R^{(0)} \setminus A_R| \). Then \( \eta \to 0 \) as \( n \to \infty \) with probability approaching to 1.

**Proof.** Since \( (\sqrt{n} - \sqrt{\eta})^2 = \omega(\frac{1}{n}) \) satisfies the assumption of Theorem 6 in [14], \( \eta \to 0 \) as \( n \to \infty \) with probability approaching to 1.

**Analysis of Stage 2-(i).** Under the success of Stage 1, \( u_R \to u_R, v_R \to v_R \) as \( n \to \infty \) with probability approaching to 1.

**Proof.** It follows directly from Lemma 9 and we need to prove Lemma 8 first.

**Lemma 8.** Sample \( m_0 := d[\log m] \) elements \( j_1, \ldots, j_{m_0} \) from \( m \) with replacement. Define \( a_j = \frac{\sum_{i \in A_R^{(0)}} \mathbb{1}(N_{ij}^\delta = 1)}{\sum_{i \in A_R^{(0)}} \mathbb{1}(N_{ij}^\delta = 1 \text{ or } -1)} \) and \( a_j' = \frac{\sum_{i \in A_R^{(0)}} \mathbb{1}(N_{ij}^\delta = 1)}{\sum_{i \in A_R^{(0)}} \mathbb{1}(N_{ij}^\delta = 1 \text{ or } -1)} \) for \( j = j_1, \ldots, j_{m_0} \). Let \( q_1, \ldots, q_{2m_0} \) be ground-truth latent preference levels corresponding to \( a_1, \ldots, a_{m_0}, a_1', \ldots, a_{m_0}' \) respectively. (i) Then \( \{q_1, \ldots, q_{2m_0}\} = \{p_1, \ldots, p_d\} \) with probability approaching to 1 as \( n \to \infty \). (ii) Moreover, for any constant \( \delta > 0 \), the following holds with probability approaching to 1 as \( n \to \infty \): for all \( i = 1, \ldots, m_0 \), \( |a_i - q_i| < \delta \) and \( |a_i' - q_i| < \delta \).

**Proof.** (i) As there are \( \phi_j \cdot 2m p_j \)'s among \( (u_R)_1, \ldots, (u_R)_m, (v_R)_1, \ldots, (v_R)_m \), \( \Pr \left( \left. \left\{ p_j \notin \{q_1, \ldots, q_{2m_0}\} \right\} \right| (1 - \phi_j)^{2m_0} \leq (1 - \phi_n)^{2m_0} \right) \geq \min\{\delta_1, \ldots, \delta_d\} \). By union bound, \( \Pr \left( \left. \{q_1, \ldots, q_{2m_0}\} \neq \{p_1, \ldots, p_d\} \right\} \leq \sum_{1 \leq j \leq d} \Pr \left( \left. \{p_j \notin \{q_1, \ldots, q_{2m_0}\} \right\} \right) \leq \sum_{1 \leq j \leq d} (1 - \delta_0)^{2m_0} = d(1 - \delta_0)^{2m_0} \to 0 \text{ as } n \to \infty \). So \( \{q_1, \ldots, q_{2m_0}\} = \{p_1, \ldots, p_d\} \) with probability approaching to 1 as \( n \to \infty \).

(ii) For \( j = j_1 \), \( \Pr(\{a_j - q_j \geq \delta\}) = \Pr(\{a_j - q_j \geq \delta\}) + \Pr(\{a_j - q_j \leq \delta\}) \). We first find the upper bound of \( \Pr(\{a_j - q_j \geq \delta\}) \).

\[
Pr(a_j - q_j \geq \delta) = Pr(a_j \geq q_j + \delta) = Pr \left( \sum_{i \in A_R^{(0)} \setminus A_R} \mathbb{1}(N_{ij}^\delta = 1) \geq q_j + \delta \right) = Pr \left( \sum_{i \in A_R^{(0)} \setminus A_R} \mathbb{1}(N_{ij}^\delta = 1 \text{ or } -1) \geq q_j + \delta \right)
\]

(\( P_i \sim \text{Bern}(p), Q_{i,j} \sim \text{Bern}(q_1), Q_{i,j} \sim \text{Bern}(p_f) \) where \( q_1, p_f \) are ground-truth latent preference levels of \( j_1 \)-th column of \( A_R, B_R \) respectively.)

\[
= Pr \left( \sum_{i \in A_R^{(0)} \setminus A_R} P_i(Q_{i,j} - q_j) \geq 0 \right) = Pr \left( Y \geq 0 \right)
\]

(\( Y := \sum_{i \in A_R^{(0)} \setminus A_R} P_i(Q_{i,j} - q_j) \geq 0 \))

\[
= Pr(Y \geq 0) \leq \inf_{t>0} \mathbb{E}[e^{tY}] \quad \left( \because \text{Markov's inequality} \right)
\]

\[
\leq \mathbb{E}[e^{t_0 Y}] \quad \left( t_0 := \log \left( \frac{q_j + \delta}{q_j} \right) \left( 1 - q_j \right) \right)
\]
Moreover, as there are finite number of choices for k, the following holds with probability approaching to 

\[ \Pr(\hat{L}_1 > n, L_2 := |A_R^{(0)} \setminus A_R| = \eta n) \]

\[ = \prod_{1 \leq i \leq L_1} (1 - a_\delta p) \prod_{1 \leq i \leq L_2} e^{b \delta p} \]

\[ \text{for some constant } a_\delta \in (0, 1) \]

\[ \leq \prod_{1 \leq i \leq L_1} (1 - a_\delta p) \prod_{1 \leq i \leq L_2} \left( 1 + b_\delta p \right) \]

\[ \text{(by calculating } \prod_{1 \leq i \leq L_2} e^{b \delta p} \text{ directly, it is clear that such } b_\delta \text{ exists.)} \]

\[ = e^{\left( \frac{1}{2} - \eta \right) n \log(1 - a_\delta p) + o(1)} \]

\[ \leq e^{\left( \frac{1}{2} - \eta \right) n \log m} \]

\[ \leq e^{- \frac{\alpha_\delta}{d_{\min}} (1 + \epsilon) \log m} \]

\[ \text{(} \because \text{ note that } \frac{\alpha_\delta}{d_{\min}} \geq 1 - \frac{G(q_1)}{G(q_1 + \delta)} \text{ for some constant } \alpha_\delta \geq 0 \text{ which means } a_\delta = \frac{G(q_1)}{G(q_1 + \delta)} \in (0, 1). \]

\[ \text{So we get } \Pr(a_{j_i} - q_i \geq \delta) = o(m^{-A}) \text{ for some } A > 0, \text{ and similarly, } \Pr(a_{j_i} - q_i \leq \delta) = o(m^{-B}) \text{ for some } B > 0. \text{ Hence } \Pr \left( \{a_{j_i} - q_i \geq \delta\} \right) = o(m^{-A}) \text{ and } \Pr \left( \{a_{j_i} - q_i \leq \delta\} \right) = o(m^{-B}). \]

\[ \text{We have the following with probability approaching to 1 as } n \to \infty: \]

\[ 1 - \Pr \left( \bigcup_{1 \leq i \leq m_0} [a_{j_i} - q_i < \delta] \cap \bigcup_{1 \leq i \leq m_0} [a_{j_i}' - q_{m_0+i} < \delta] \right) \]

\[ \leq \sum_{1 \leq i \leq m_0} \Pr([a_{j_i} - q_i \geq \delta] \cap [a_{j_i}' - q_{m_0+i} \geq \delta]) \]

\[ = \sum_{1 \leq i \leq m_0} o(m^{-A_\delta}) + \sum_{1 \leq i \leq m_0} o(m^{-A_\delta}) \]

\[ = 2m_0 \cdot o(m^{-A_\delta}) = 2d \log m \cdot o(m^{-A_\delta}) \to 0 \text{ as } n \to \infty \]

\[ \text{So we can conclude that } \Pr \left( \bigcap_{1 \leq i \leq m_0} [a_{j_i} - q_i < \delta] \cap \bigcup_{1 \leq i \leq m_0} [a_{j_i}' - q_{m_0+i} < \delta] \right) \to 1 \text{ as } n \to \infty. \]

\[ \square \]
Note that $\frac{2}{\pi}$ and $\frac{1}{\pi}$ are continuous functions on $\mathbb{R}^2 \setminus \{(x, y) | x \neq 0, x \neq 1\}$. Together with the facts that $0 < p_1, \ldots, p_d < 1$ and that there are finite number of choices for $(i, j)$ where $1 \leq i, j \leq d$, the following holds with probability approaching to 1 as $n \to \infty$:

$$\hat{p}_i = \frac{p_i}{1 - p_i} (1 + o(1)) \quad \text{and} \quad \frac{1 - \hat{p}_i}{1 - p_i} = \frac{1 - p_i}{1 - p_i} (1 + o(1)) \quad \text{for all } i, j = 1, \ldots, d.$$

(4)

Lemma 9. Define $u_R^{(j)} = \arg\min_{\hat{p}_k \in [d]} \{ \sum_{i \in A_R^{(j)}} \{ 1(N_{ij}^\Omega = 1)(-\log \hat{p}_k) + \mathbb{1}(N_{ij}^\Omega = -1)(-\log (1 - \hat{p}_k)) \} \}$, and $v_R^{(j)} = \arg\min_{\hat{p}_k \in [d]} \{ \sum_{i \in B_R^{(j)}} \{ 1(N_{ij}^\Omega = 1)(-\log \hat{p}_k) + \mathbb{1}(N_{ij}^\Omega = -1)(-\log (1 - \hat{p}_k)) \} \}$ for $j = 1, \ldots, m$. Then the following holds with probability approaching to 1 as $n \to \infty$ : for all $j = 1, \ldots, m$, $u_R^{(j)} \to u_R^{(j)}, v_R^{(j)} \to v_R^{(j)}$.

Proof. Without loss of generality, assume $u_R^{(j)} = p_1$. Let $L_{u_R^{(j)}}(\hat{p}_k) := \sum_{i \in A_R^{(j)}} \{ \mathbb{1}(N_{ij}^\Omega = 1)(-\log \hat{p}_k) + \mathbb{1}(N_{ij}^\Omega = -1)(-\log (1 - \hat{p}_k)) \}$. Then

$$\Pr(u_R^{(j)} \neq \hat{p}_1) \leq \sum_{2 \leq k \leq d} \Pr \left( L_{u_R^{(j)}}(\hat{p}_k) \leq L_{u_R^{(j)}}(\hat{p}_1) \right) \quad \text{(\because Union bound)}$$

$$= \sum_{2 \leq k \leq d} \left\{ \Pr \left( \sum_{i \in A_R^{(j)} \cap A_R} \{ 1(N_{ij}^\Omega = 1) \log \frac{\hat{p}_k}{p_1} + 1(N_{ij}^\Omega = -1) \log \frac{1 - \hat{p}_k}{1 - p_1} \} \geq 0 \right) 
+ \Pr \left( \sum_{i \in A_R^{(j)} \cap A_R} \{ 1(N_{ij}^\Omega = 1) \log \frac{\hat{p}_k}{p_1} + 1(N_{ij}^\Omega = -1) \log \frac{1 - \hat{p}_k}{1 - p_1} \} \geq 0 \right) \right\}$$

$$= \sum_{2 \leq k \leq d} \left\{ \Pr \left( \sum_{i \in A_R^{(j)} \cap A_R} \{ P_i \log \frac{\hat{p}_k}{p_1} + P_i(1 - P_{1, i}) \log \frac{1 - \hat{p}_k}{1 - p_1} \} \geq 0 \right) 
+ \Pr \left( \sum_{i \in A_R^{(j)} \cap A_R} \{ P_i \log \frac{\hat{p}_k}{p_1} + P_i(1 - P_{1, i}) \log \frac{1 - \hat{p}_k}{1 - p_1} \} \geq 0 \right) \right\}$$

where $p_f$ is the ground-truth latent preference level corresponding to $j$-th column of $B_R$

$$= \sum_{2 \leq k \leq d} \left\{ \Pr(\hat{z}_{k, 1} \geq 0) + \Pr(\hat{z}_{k, 2} \geq 0) \right\} = \sum_{2 \leq k \leq d} \left\{ \Pr(e^{\hat{z}_{k, 1}} \geq 1) + \Pr(e^{\hat{z}_{k, 2}} \geq 1) \right\}$$

$$\leq \sum_{2 \leq k \leq d} \left( \mathbb{E}[e^{\hat{z}_{k, 1}}] + \mathbb{E}[e^{\hat{z}_{k, 2}}] \right) \quad \text{(\because Markov’s inequality)}$$

$$= \sum_{2 \leq k \leq d} \left[ \prod_{i \in A_R^{(j)} \cap A_R} \left\{ p_{1, i} \frac{\hat{p}_k}{p_1} + p(1 - p_{1, i}) \sqrt{\frac{1 - \hat{p}_k}{1 - p_1} + (1 - p)} \right\} \prod_{i \in A_R^{(j)} \setminus A_R} \left\{ p_{1, i} \frac{\hat{p}_k}{p_1} + p(1 - p_{1, i}) \sqrt{\frac{1 - \hat{p}_k}{1 - p_1} + (1 - p)} \right\} \right]$$

$$= \sum_{2 \leq k \leq d} \left[ \prod_{i \in A_R^{(j)} \cap A_R} \left\{ p_{1, i} \frac{\hat{p}_k}{p_1} + p(1 - p_{1, i}) \sqrt{\frac{1 - \hat{p}_k}{1 - p_1} + (1 - p)} \right\} \right. \cdot \prod_{i \in A_R^{(j)} \setminus A_R} \left\{ p_{1, i} \frac{\hat{p}_k}{p_1} + p(1 - p_{1, i}) \sqrt{\frac{1 - \hat{p}_k}{1 - p_1} + (1 - p)} \right\} \quad \text{(\because 4)}$$

$$= \sum_{2 \leq k \leq d} \left[ \prod_{i \in A_R^{(j)} \cap A_R} \left\{ p_{1, i} \frac{\hat{p}_k}{p_1} + p(1 - p_{1, i}) \sqrt{\frac{1 - \hat{p}_k}{1 - p_1} + (1 - p)} \right\} \right. \cdot \prod_{i \in A_R^{(j)} \setminus A_R} \left\{ p_{1, i} \frac{\hat{p}_k}{p_1} + p(1 - p_{1, i}) \sqrt{\frac{1 - \hat{p}_k}{1 - p_1} + (1 - p)} \right\}$$

$$\leq \sum_{2 \leq k \leq d} \prod_{i \in A_R^{(j)} \setminus A_R} \left\{ p(1 - (\hat{p}_k)^2)(1 + o(1)) + (1 - p) \right\} \cdot \prod_{i \in A_R^{(j)} \setminus A_R} \left( 1 + B_k p \right) \quad \text{(it is clear that such } B_k > 0 \text{ exists)}$$

31
\[= \sum_{2 \leq k \leq d} e^{(\frac{1}{2} - \eta)n \log p(1 - (d_H^{\min})^2(1 + o(1)) - (1 - p))} \cdot e^{\eta n \log (1 + B_k p)}\]

\[= \sum_{2 \leq k \leq d} e^{\eta n (1 - o(1))I_r e^{\eta n (\frac{R_k}{d_H^{\min}})^2 + o(1))I_r}}\]

\[\left(\cdots \log (1 - p(1 - 1 - (d_H^{\min})^2(1 + o(1)))\right) = -p(d_H^{\min})^2(1 + o(1)) + O(p^2) = I_r(-1 + o(1)) \text{ where } I_r = p(d_H^{\min})^2\]

\[\leq \sum_{2 \leq k \leq d} e^{-(1/2) \log m} \left(\cdots - nI_r\left(\left(\frac{1}{2} - \eta(1 + o(1)) - \eta\left(\frac{B_k}{(d_H^{\min})^2} + o(1)\right)\right) \geq (1 + \frac{\epsilon}{2}) \log m \quad \text{for sufficiently large } n\right)\]

\[\leq \sum_{2 \leq k \leq d} O(m^{-1/2}) = O(m^{-1/2})\]

If we set \(u_R^{(j)} = p_{a_j}, v_R^{(j)} = \hat{p}_{b_j}\) for \(j = 1, \ldots, m\), above result means \(Pr(u_R^{(j)} \neq \hat{p}_{a_j}) = O(m^{-1/2})\) for \(j = 1, \ldots, m\). Similarly, \(Pr(v_R^{(j)} \neq \hat{p}_{b_j}) = O(m^{-1/2})\) for \(j = 1, \ldots, m\). Then

\[\sum_{1 \leq j \leq m} \left\{ Pr(u_R^{(j)} \neq \hat{p}_{a_j}) + Pr(v_R^{(j)} \neq \hat{p}_{b_j}) \right\} = 2m \cdot O(m^{-1/2}) = o(1)\]

which implies \(u_R^{(j)} = \hat{p}_{a_j}, v_R^{(j)} = \hat{p}_{b_j}\) for all \(j = 1, \ldots, m\) with probability approaching 1 as \(n \to \infty\). As \(p_{a_j} \to p_{a_j}, \hat{p}_{b_j} \to p_{b_j}\) for all \(j = 1, \ldots, m\) with probability approaching 1 as \(n \to \infty\) by (6), we can conclude that \(u_R^{(j)} \to p_{a_j}(= u_R^{(j)}), v_R^{(j)} \to p_{b_j}(= v_R^{(j)})\) for all \(j = 1, \ldots, m\) with probability approaching 1 as \(n \to \infty\). \(\square\)

Lemma 9 implies the success of Stage 2-(i).

\[\square\]

**Analysis of Stage 2-(ii).** With probability approaching to 1 as \(n \to \infty\), \(T := \lceil \log n \rceil\) iterations ensure that \(A_R\) and \(B_R\) will be recovered exactly.

**Proof.** Let \(L(i; A, B) := -\log \left(\frac{\alpha(1 - \beta)}{\beta(1 - \alpha)}\right) e(\{i\}, A) - \left[ \sum_{j:N_{ij}^{(j)} = 1} \log(u_R^{(j)}) + \sum_{j:N_{ij}^{(j)} = -1} \log(1 - u_R^{(j)})\right] + \log \left(\frac{\alpha(1 - \beta)}{\beta(1 - \alpha)}\right) e(\{i\}, B) + \left[ \sum_{j:N_{ij}^{(j)} = 1} \log(v_R^{(j)}) + \sum_{j:N_{ij}^{(j)} = -1} \log(1 - v_R^{(j)})\right]

\text{and } \hat{L}(i; A, B) := -\log \left(\frac{\hat{\alpha}(1 - \hat{\beta})}{\hat{\beta}(1 - \hat{\alpha})}\right) e(\{i\}, A) - \left[ \sum_{j:N_{ij}^{(j)} = 1} \log(u_R^{(j)}) + \sum_{j:N_{ij}^{(j)} = -1} \log(1 - u_R^{(j)})\right] + \log \left(\frac{\hat{\alpha}(1 - \hat{\beta})}{\hat{\beta}(1 - \hat{\alpha})}\right) e(\{i\}, B) + \left[ \sum_{j:N_{ij}^{(j)} = 1} \log(v_R^{(j)}) + \sum_{j:N_{ij}^{(j)} = -1} \log(1 - v_R^{(j)})\right].

There are \(T\) iterations in Stage 2-(ii), and at \(t\)-th iteration, Algorithm 1 updates every user’s affiliation by the following rule: put user \(i\) to \(A_R^{(t)}\) if \(\hat{L}(i; A_R^{(t-1)}, B_R^{(t-1)}) < 0\); put user \(i\) to \(B_R^{(t)}\) otherwise. In Lemma 11, we show the following holds with probability approaching 1 as \(n \to \infty\): if we use \(L(i; A, B)\) instead of \(\hat{L}(i; A, B)\), \(A_R, B_R\) will be recovered exactly within 1 iteration of Stage 2-(ii).

**Lemma 10.** Suppose \(\frac{1}{2}nI_s + \gamma mp(d_H^{\min})^2 \geq (1 + \epsilon) \log n\). Then there exist a constant \(\tau > 0\) such that \(L(i; A_R, B_R) < -\tau \log n\) if \(i \in A_R\); \(L(i; A_R, B_R) > \tau \log n\) if \(i \in B_R\) with probability \(1 - O(n^{-2})\).

**Proof.** This lemma can be proved similarly by applying the argument of Lemma 9 in [5]. \(\square\)

Our goal is to show \(A_R, B_R\) can be recovered exactly by using \(\hat{L}(i; A, B)\) in Stage 3. Define \(Z_\delta := \{(A, B) : A \cup B = \{n\}, A \cap B = \emptyset, |A \triangle A_R| = |B \triangle B_R| < \delta n\}\) for \(\delta \in \left(\frac{1}{4}, \frac{1}{2}\right)\).

**Lemma 11.** Suppose \(\alpha = \Theta(\frac{\log n}{n})\) For arbitrary \(\tau > 0\), there exists \(\delta_0 < \frac{1}{2}\) such that if \(\delta < \delta_0\), the following holds with probability \(1 - O(n^{-1})\): for all \((A, B) \in Z_\delta, |L(i; A, B) - L(i; A_R, B_R)| \leq \frac{\tau}{2} \log n\), for all except \(\frac{\tau}{2}\) many \(i\)’s.
Proof. This lemma can be proved similarly by applying the argument of Lemma 10 in [5]. □

Lemma 12. Suppose \( \alpha = \Theta \left( \frac{\log n}{n} \right), \rho = \Theta \left( \frac{\log n}{m} + \frac{\log m}{n} \right), m = O(n) \). For arbitrary \( \tau > 0 \), the following holds with probability approaching to 1 as \( n \to \infty \): for all \( A, B \subset [n] \), and \( i \in [n] \), \( |\hat{L}(i; A, B) - L(i; A, B)| \leq \frac{\tau}{2} \log n \).

Proof. This lemma can be proved similarly by applying the argument of Lemma 11 in [5]. □

By Lemma 11, there exists \( \delta_0 < \frac{1}{2} \) such that if \( \delta < \delta_0 \), the following holds with probability \( 1 - O(n^{-1}) \): for all \( (A, B) \in Z_\delta \), \( |L(i; A, B) - \hat{L}(i; A, B)| \leq \frac{\tau}{2} \log n \), for all except \( \frac{n}{2} \) many \( i \)'s. At the same time, by applying Lemma 12 to \( (A, B) \in Z_\delta \), the following holds with probability approaching to 1 as \( n \to \infty \): for all \( (A, B) \in Z_\delta \), and \( i \in [n] \), \( |\hat{L}(i; A, B) - L(i; A, B)| \leq \frac{\tau}{2} \log n \). Combining these two results, the following holds with probability approaching to 1 as \( n \to \infty \): for all \( (A, B) \in Z_\delta \), \( |\hat{L}(i; A, B) - L(i; A, B)| \leq \frac{\tau}{2} \log n \). Then together with Lemma 10, we eventually get the following holds with probability approaching to 1 as \( n \to \infty \): for all \( (A, B) \in Z_\delta \),

\[
\hat{L}(i; A, B) = \begin{cases} 
\leq L(i; A_R, B_R) + |\hat{L}(i; A, B) - L(i; A_R, B_R)| < -\tau \log n + \tau \log n = 0 & \text{if } i \in A_R; \\
\geq L(i; A_R, B_R) - |\hat{L}(i; A, B) - L(i; A_R, B_R)| > \tau \log n - \tau \log n = 0 & \text{if } i \in B_R;
\end{cases}
\]

for all except \( \frac{n}{2} \) many \( i \)'s. This means that at each iteration of Stage 2-(ii), every user’s affiliation will be updated to the correct one except for \( \frac{n}{2} \) many \( i \)'s. So the following holds with probability approaching to 1 as \( n \to \infty \): whenever \( (A, B) \) belongs to \( Z_\delta \), the result of single iteration of Stage 2-(ii) belongs to \( Z_\delta \). Then \( T = \lceil \frac{\log(\delta_0 n)}{\log 2} \rceil \) iterations guarantee the exact recovery of \( A_R, B_R \). □

E An Alternative Algorithm

As we mentioned in Remark 12, we suggest an alternative algorithm, which utilizes both rating and graph data at Stage 1. Analyzing the performance of this new algorithm is an interesting open problem.

Algorithm 2

Input: \( N \in \{ -1, 0, +1 \}^{n \times m} \), \( G = ([n], E) \), \( K \), \( d \)

Output: Clusters of users \( A_1^{(1)}, \ldots, A_K^{(1)} \), latent preference vectors \( \hat{u}_1^{(1)}, \ldots, \hat{u}_K^{(1)} \)

Preprocessing: We first concatenate \( G \) and \( N \) to get a new matrix \( [G, N] \in \{ -1, 0, +1 \}^{n \times (n+m)} \). We denote \([G, N]\) by \( I_0 \). To make Stage 1 and Stage 2-(i) independent, we split the information of \( I_0 \) by using the technique used in [3]. In specific, we generate a matrix \( M_1 \in \{ 0, +1 \}^{n \times (n+m)} \) where each entry is drawn independently from the Bernoulli distribution with parameter \( \frac{1}{\sqrt{\log n}} \). A matrix \( M_2 \in \{ 0, +1 \}^{n \times (n+m)} \) is defined as \( (I_n, (n+m) - M_1) \). Then, we let \( I_1 = I_0 \odot M_1 \) and \( I_2 = I_0 \odot M_2 \), where \( \odot \) is the Hadamard product.

Stage 1. Partial recovery of clusters We apply Part I of the algorithm proposed in [6] to \( I_1 \): (i) we project \( I_1 \) onto the subspace spanned by the top \( K \) singular vectors, and we denote the projected matrix by \( \tilde{I}_1 \); (ii) run a 10-approximate \( k \)-means algorithm on \( \tilde{I}_1 \), and obtain an initial clustering result \( A_1^{(0)}, \ldots, A_K^{(0)} \).

Stage 2-(i) Run Stage 2-(i) of Alg. 1 on \( I_2 \).
Stage 2-(ii) Run Stage 2-(ii) of Alg. 1 on \( I_0 \).
