ABSTRACT

The Marinoan panglaciation (ca 650 to 635 Ma) is represented in north-east Svalbard by the 130 to 175 m thick Wilsonbreen Formation which contains syn-glacial carbonates in its upper 100 m. These sediments are now known to have been deposited under a CO₂-rich atmosphere, late in the glaciation, and global climate models facilitate testing of proposed analogues. Precipitated carbonates occur in four of the seven facies associations identified: Fluvial Channel (including stromatolitic and intraclastic limestones in ephemeral stream deposits); Dolomitic Floodplain (dolomite-cemented sand and siltstones, and microbial dolomites); Calcareous Lake Margin (intraclastic dolomite and wave-rippled or aeolian siliciclastic facies); and Calcareous Lake (slump-folded and locally re-sedimented rhythmic/stromatolitic limestones and dolomites associated with ice-rafted sediment). There is no strong cyclicity, and modern analogues suggest that sudden changes in lake level may exert a strong control on facies geometry. Both calcite and dolomite in stromatolites and rhythms display either primary or early diagenetic replacive growth. Oxygen isotope values (−12 to +15‰VPDB) broadly covary with δ¹³C. High δ¹³C values of +3.5 to +4.5‰ correspond to equilibration with an atmosphere dominated by volcanically degassed CO₂ with δ¹³C of −6 to −7‰. Limestones have consistently negative δ¹⁸O values, while rhythmic and playa dolomites preserve intermediate compositions, and dolocretes possess slightly negative to strongly positive δ¹⁸O signatures, reflecting significant evaporation under hyperarid conditions. Inferred meltwater compositions (−8 to −15.5‰) could reflect smaller Rayleigh fractionation.
related to more limited cooling than in modern polar regions. A common pseudomorph morphology is interpreted as a replacement of ikaite (\(\text{CaCO}_3 \cdot \text{H}_2\text{O}\)), which may also have been the precursor for widespread replacive calcite mosaics. Local dolomitization of lacustrine facies is interpreted to reflect microenvironments with fluctuating redox conditions. Although differing in (palaeo)latitude and carbonate abundance, the Wilsonbreen carbonates provide strong parallels with the McMurdo Dry Valleys of Antarctica.

**INTRODUCTION**

The second of two Neoproterozoic glaciations, in which ice sheets reached sea-level in the tropics, terminated 635 Myr ago at the base of a transgressive cap carbonate defining the Cryogenian–Ediacaran System boundary (Table 1). Deposits of Cryogenian ice ages are preserved on most continents and are commonly interpreted as glacimarine (Arnaud *et al.*, 2011). However, in north-east Svalbard, the Marinoan-aged, 130 to 175 m thick Wilsonbreen Formation (Halverson, 2011) uniquely contains non-marine carbonates as well as subglacial tillites (Fig. 1). These evince hyperarid terrestrial environments (Fairchild *et al.*, 1989) and an atmosphere rich in carbon dioxide during glaciation (Bao *et al.*, 2009), the latter conclusion fulfilling a prediction of the Snowball Earth hypothesis (Kirschvink, 1992; Hoffman *et al.*, 1998). Because Wilsonbreen Formation outcrops are restricted to remote icefield nunataks on Spitsbergen (Fig. 2) and coastal eastern Nordaustlandet, they have rarely been visited, and hence current knowledge of the sedimentary architecture has been incomplete. Wilsonbreen Formation carbonates contain the highest carbonate and sulphate \(\delta^{18}\text{O}\) values and lowest sulphate \(\Delta^{17}\text{O}\) signatures so far discovered in the geological record, features which evoke one of the most extreme climatic events in Earth history (Bao *et al.*, 2009; Benn *et al.*, 2015). This article characterizes a range of non-marine environments in which the carbonates were precipitated using a combination of field, petrographic and stable isotope evidence, and scrutinizes their analogy to the extreme terrestrial environments of the modern McMurdo Dry Valley region of Antarctica (Fairchild *et al.*, 1989).

The study area in the Svalbard mainland of Spitsbergen (Figs 1 and 2) and the basin continuation to the north-east have long been recognized as classic areas for late Precambrian glaciation (Kulling, 1934). The first detailed description of the Wilsonbreen Formation was by Wilson & Harland (1964), although carbonates were discussed only in terms of its bounding dolomites which serve as stratigraphic markers. A later sedimentological synthesis (Hambrey, 1982; Fairchild & Hambrey, 1984) showed that evidence of glacial activity was confined to two glacial units in the Polarisbreen Group: the Wilsonbreen Formation, and a newly discovered, thin, older unit in the Elbobreen Formation (Petrovbreen Member also known as E2; Table 1). Several distinctive forms of carbonate occur in association with the glacial deposits. Dolomitic glacial rock flour was first demonstrated in ultra-thin sections (Fairchild, 1983). Subsequent stable isotope studies showed the presence of glacimarine precipitates in the Petrovbreen Member and glaciolacustrine deposits in the Wilsonbreen Formation (Fairchild & Hambrey, 1984; Fairchild & Spiro, 1987; Fairchild *et al.*, 1989). It was also shown that these carbonates contrast with a distinctive marine transgressive ‘cap carbonate’ (following Williams, 1979) over the Wilsonbreen Formation. Halverson *et al.* (2004) provided a much more detailed chemostratigraphic framework for the Polarisbreen Group and postulated that both diamictite units belonged to the same, Marinoan glaciation. However, new chemostratigraphic data led to a reversion to the previous two-fold glaciation interpretation of older literature (Halverson, 2006; Hoffman *et al.*, 2012). No direct geochronological constraints exist on Svalbard, but the low \(^{87}\text{Sr}/^{86}\text{Sr}\) values at the base of the Polarisbreen Group correlate well with those associated with the first evidence of Neoproterozoic glaciation elsewhere (Halverson *et al.*, 2010). Also, the transgressive–regressive succession above the Wilsonbreen Formation closely resembles the basal Ediacaran facies succession globally (Halverson *et al.*, 2004). The end of Marinoan glaciation, and hence the top
Table 1. Neoproterozoic chronostratigraphy and north-east Svalbard lithostratigraphy (after Halverson, 2011, updated by unpublished data). Glacial units are highlighted in red. This paper deals with the Wilsonbreen Formation, representing the younger of the two Cryogenian glaciations.

of the Wilsonbreen Formation is 635 Ma (Roo ney et al., 2015, and references therein). Palaeomagnetic constraints suggest that north-east Svalbard lay in the subtropics throughout the Cryogenian (Li et al., 2013) as part of Laurentia, which spanned the equator in the centre of the fragmenting Rodinia supercontinent.

The closely similar stratigraphy in central East Greenland (now officially redesignated as North-east Greenland; Hambrey & Spencer, 1987; Moncrieff & Hambrey, 1990) indicates that it represents a basin continuation (Hambrey, 1983; Knoll et al., 1986; Fairchild & Hambrey, 1995), subsequently offset to the south by left-lateral strike-slip faulting (Harland, 1997). The distinct Neoproterozoic succession in western Svalbard cannot easily be correlated with its counterpart in north-east Svalbard and was probably deposited in a separate basin (Harland et al., 1993).

Cryogenian events and panglaciation

Harland (1964) championed the idea of low-latitude late Proterozoic glaciation based on globally distributed diamictites that were considered to be glacigenic and correlative. However, firmly establishing the glacial affinity of these units, determining their low-latitude origin, and confirming their correlation required another four decades (Fairchild & Kennedy, 2007). Despite the complexity of individual successions, as summarized in Arnaud et al. (2011), it is now widely recognized that two panglacial events occurred during the Cryogenian period (ca 720 to 635 Ma), referred to as the Sturtian (or early Cryogenian) and Marinoan (or late Cryogenian) glaciations (Halverson et al., 2005; MacDonald et al., 2010; Hoffman et al., 2012; Calver et al., 2013; Lan et al., 2014; Rooney et al., 2014, 2015). The traditional geological interpretation of Cryogenian glaciation invoked low atmospheric CO₂ levels, but it was not until whole-Earth energy balance models emerged (for example, to study a future ‘nuclear winter’) that it became understood that a frozen, high-albedo planet represents a stable climatic state (Budyko, 1969). Kirschvink (1992) first applied this model to interpreting the geological record, suggesting a Neoproterozoic Snowball Earth that was facilitated by low palaeolatitudes of the continents at this time and that the key to escape from the Snowball state was the build-up of volcanically derived CO₂ (Caldeira & Kasting, 1992), which at sufficiently high levels would overcome the control of the albedo of Earth’s icy surface on global energy balance and trigger deglaciation. Hoffman et al. (1998) and Hoffman & Schrag (2002) subsequently elaborated upon the Snowball Earth model and provided the first sedimentological, stratigraphic and geochemical evidence in its support. Snowball Earth theory stimulated data-collection and modelling which have significantly clarified the criteria for attribution of a suite of phenomena to Snowball Earth conditions. Neoproterozoic glaciations are associated with negative carbon isotope anomalies (Knoll et al., 1986; Kaufman et al., 1997) and Hoffman et al. (1998) argued that the anomaly apparently encompassing the Marinoan glacial period reflected low organic productivity as a result of glacial climate and an ocean that became isolated from the atmosphere. Additionally, the post-glacial cap carbonates and the associated negative carbon isotope anomalies were regarded as a positive test of the Snowball Earth hypothesis, reflecting rapid meltdown and re-equilibration of oceanic and atmospheric CO₂ during a post-Snowball, ultra-greenhouse environment. However, subsequent work implies a more nuanced scenario and the interpretations

Fig. 1. Reconstruction of the sedimentary architecture and palaeoenvironments of the Wilsonbreen Formation and its constituent members (W1 to W3). Precipitated carbonate is present in the palaeoenvironmental group called ‘Carbonate Fluvial and Lacustrine’ throughout W2 (except locally at the top and base), also in W3 and at one of the locations in W1 as listed in Table 2. The Svalbard archipelago is shown bottom right and Spitsbergen is the main island of the group, while Nordaustlandet is the island to the north-east. The rectangle on the Svalbard map shows the study area as enlarged upper right with Wilsonbreen Formation outcrops (red) within nunataks (grey) rising from the highland snowfield. From north to south, study locations are: DRA (Dracoisen); here the main section is located on a nunatak informally known as Multikolorfjellet with some additional sampling from W2 at a second nunatak termed Topthatten 1 km to the north; DIT (Ditlovtoppen); AND (East Andromedafjellet); REIN (a ridge on South Andromedafjellet informally known as Reinsryggen); KLO (South Klofjellet); with some additional observations from a partial W2 section 1 km away, at North Klofjellet; McD (MacDonaldryggen); GOL (Golitsynfjellet, intermediate between McD and BAC) – a partial W2 section was illustrated by Fairchild et al. (1989); BAC (Backlundtoppen-Kvitfjellet ridge); PIN (an unnamed nunatak informally termed Pinsvinryggen); SLA (Southeast Slangen) and ORM (South Ormen).

of both the pre-glacial and post-glacial anomalies remain disputed (Kennedy et al., 2001a,b; Halverson et al., 2002; Hoffman & Schrag, 2002; Schrag et al., 2002; Trindade et al., 2003; Hoffman et al., 2007, 2012; Le Hir et al., 2008, 2009; Kennedy & Christie-Blick, 2011). Early articulation of the Snowball Earth model lacked a framework for interpreting the glacial formations and their relevance for the theory. In the original ‘hard’ Snowball, a universally thick, ice cover on the oceans, composed of an upper zone of glacier ice and lower zone of frozen seawater was envisaged (Pierrehumbert, 2005; Pierrehumbert et al., 2011). In this scenario, sea-level should have been greatly lowered and marine ice margins should have occurred far below the shallow-water pre-glacial sediments. Evidence to support this hypothesis was found in Namibia. On platform tops, glaciogenic deposits are rare, whereas on platform margins tidewater-glacier grounding-line phenomena are inferred to be some hundreds of metres lower topographically (Hoffman, 2011; Domack & Hoffman, 2013). On the other hand, most glacial sedimentologists opposed the Snowball theory, commonly citing evidence of repeated glacial advances and retreats in marine environments, and wave-generated and storm-generated structures indicating open water inconsistent with the hard Snowball scenario (Xiao et al., 2004; Etienne et al., 2007; Allen & Etienne, 2008; Le Heron et al., 2011, 2013). Apparent support from models showing equatorial open water (e.g. Hyde et al., 2000) faced the problem that the simulated climate solutions were unstable. Hence, Hoffman (2011) responded that: “counter arguments [to the Snowball model] based on temperate-type glacial sedimentology fail to grasp that the preserved glacial sedimentary record reflects the end of the Snowball Earth, when melting was bound to emerge triumphant”.

New modelling that showed stable, long-lived ice-free regions (‘Waterbelts’) in the tropics has motivated rethinking the Snowball glacial record (Pierrehumbert et al., 2011). Abbot et al. (2011) proposed the term ‘Jormangund’ state to describe a stable, ice-free equatorial fringe achieved as the result of the low albedo of low-latitude sea ice. Alternatively, Rose (2015) argued for an entirely new climatic state in which convergence of ocean heat transport at tropical ice edges stabilizes a belt of open water straddling the equator. Hoffman et al. (2012) noted that although the Jormangund state preserved the pattern of modern low-latitude climate belts, with a moister equatorial region, the hard Snowball climatic pattern (Pierrehumbert et al., 2011) would result in higher precipitation minus evaporation in the subtropics and an extremely arid equatorial zone. This important distinction draws attention to the need to study low-latitude continental glacial deposits such as the Wilsonbreen Formation where more direct evidence of climatic conditions can be obtained.

The surviving essential predictions of Snowball Earth theory can be summarized as follows: (1) globally, glaciations must occur synchronously, (2) they must be long-lasting (>1 Ma) to allow (3) the build-up of atmospheric CO2 to high levels when (4) sedimentation occurs in a brief period prior to termination. Although earlier geochronological compilations had legitimate doubts about (1) and (2) (Allen & Etienne, 2008), they are now more firmly established (Rooney et al., 2015), although the duration of the Marinoan glaciation (5 to 15 Myr) is imprecisely known. The Wilsonbreen Formation has now permitted positive tests of (3) and (4).

Compared to the Cenozoic, Neoproterozoic strata offer limited options for determining atmospheric CO2 concentrations. Bao et al. (2008) proposed a bold new approach based on processes occurring during stratospheric ozone formation which results in an enrichment in the isotope 17O in ozone and carbon dioxide and depletion in oxygen (O2). This non-mass-depen-

Fig. 2. Examples of studied section outcrops. dent effect does not influence \(^{18}\)O abundances. The \(^{17}\)O signal can be preserved in the oxygen atoms of sulphate in rocks if atmospheric oxygen is used to oxidize sulphides on the land surface. Sulphate has the fortuitous property of not exchanging oxygen atoms with other species over 1000 Myr timescales at surface conditions, provided it is not subject to microbial redox cycling. Bao et al. (2008) showed that at time periods when atmospheric PCO\(_2\) was enhanced, sulphate in the geological record was \(^{17}\)O-depleted. The most significant anomaly was discovered in barite crystal fans within the carbonate succession overlying Marinoan glacial diamictites in South China.

Bao et al. (2009) subsequently found more profound \(^{17}\)O-deficiencies in carbonate-associated sulphate (CAS) in lacustrine limestone of the central part (member W2) of the Wilsonbreen Formation, consistent with very high atmospheric PCO\(_2\) actually during glaciation. More recent studies in other geographic regions, coupled with process modelling approaches, have supported evidence for high PCO\(_2\) during deposition of Marinoan cap carbonates (Bao et al., 2012; Cao & Bao, 2013; Killingsworth et al., 2013; Bao, 2015), but the Wilsonbreen Formation remains the only unit where PCO\(_2\) can be estimated during glaciation.

Benn et al. (2015) applied the same approach to a much larger data set of limestones from members W2 and W3 to argue that similar high PCO\(_2\) values (estimated at 10 to 100 mbar atmospheric CO\(_2\)) occurred throughout the deposition of the Wilsonbreen Formation. Because it would have taken a long time to accumulate CO\(_2\), these authors inferred that the bulk of the Wilsonbreen Formation was deposited in a relatively short period near the end of the glaciation. In turn, this implies an extended hiatus early in the glaciation, which manifested as a permafrosted horizon at the base of the Wilsonbreen Formation.

Coupled ice sheet and atmospheric general circulation model results in Benn et al. (2015), using Snowball Earth boundary conditions at 20 mbar atmospheric PCO\(_2\), display thick glaciers on the continents coexisting with extensive areas of bare ground and widespread hyperaridity. Under these conditions, the climatic consequences of orbital precession cycles is to force ice margins to migrate by at least hundreds of kilometres, and the present authors link this cyclicity to the presence of distinct ice advances within the Wilsonbreen Formation (Fig. 1). The presence of an arid tropical continent during the Marinoan ice age is also consistent with observations of periglacial structures, aeolian, fluvial and evaporative floodplain facies in the Australian Marinoan successions (Williams, 2008; Ewing et al., 2014; Retallack et al., 2015). Although conclusions based on the Marinoan glaciation should not necessarily apply to the much longer Sturtian glaciation, the new results provide a way to reconcile the opposed positions stated in Allen & Etienne (2008), of temperate glacial conditions during panglaciation, and Hoffman (2011), of sediment deposition occurring rapidly during meltdown (Allen, 2015). The purpose of this contribution is to provide a detailed sedimentological analysis of the Wilsonbreen Formation as template for glacial sedimentation in the terrestrial realm during Snowball glaciation and to investigate the geomorphic-climatic system in which the Wilsonbreen carbonates were deposited. This analysis begins by examining the most plausible modern analogue.

The Antarctic McMurdo Dry Valleys as analogues for the Wilsonbreen Formation carbonates

Walter & Bauld (1983) were the first to attempt to compare the frigid, arid Dry Valleys region with carbonates and associated facies in Neoproterozoic successions, but the Australian examples chosen were either postglacial or had an uncertain relationship with glaciation. Later, Fairchild et al. (1989) made a more specific comparison with member W2 of the Wilsonbreen Formation. Conversely, leading workers on the Dry Valleys (Lyons et al., 2001) commented that they might compare with Proterozoic Snowball Earth; they have also been used as analogues for the Martian surface (Marchant & Head, 2007; Dickson et al., 2013). The local ‘Alpine’ glaciers of the Dry Valleys are cold-based, but outlet glaciers such as the Taylor Glacier are warm-based, albeit because of sitting in a saline basin (Mikucki & Priscu, 2007). Given the criteria for recognition of a glacial thermal regime presented by Hambrey & Glasser (2012), warm-based analogues are needed to understand much of the glaciogenic facies of the Wilsonbreen Formation (Fleming et al., 2016). Nevertheless, for the carbonate facies, the context of the Dry Valley region provides unique parallels for the following evidence provided by Fairchild et al. (1989): (i) a record of extreme evaporation with
an interpreted up to 20% difference in δ¹⁸O between input waters and those responsible for the precipitation of the carbonates with heaviest δ¹⁸O signatures; and (ii) alternating deposition of glacial sediment and continental deposits indicating ice advance and retreat, specifically including rhythmic and microbial, presumed lacustrine carbonates and evidence of former evaporites.

Figure 3 illustrates the geographical context of the Dry Valleys region, which has been studied extensively over several decades by groups led from New Zealand, Japan and the USA, with Taylor Valley being the focus since 1993 of the McMurdo Dry Valleys Long-term Ecosystem Research Program of the National Science Foundation. The Dry Valleys occupy 4800 km² in the Transantarctic Mountains between the East Antarctic Ice Sheet (EAIS) and the Ross Sea. The individual valleys mostly trend east–west, are up to 80 km long and 15 km wide and are internally drained, commonly with several discrete lake basins in each valley. Two outlet glaciers from the EAIS (Wright Upper and Taylor glaciers) only just cross the regional bedrock divide into the eastward-draining catchments, while Ferrar Glacier flows all the way to the coast (Fig. 3). Local valley glaciers extend from the mountains into dry valleys, for example, Canada Glacier in Taylor Valley (inset in Fig. 3) and ephemeral streams develop in summer. A variety of lakes occur, including those occupied by ice frozen to the bed in the relatively high-altitude Victoria Valley, highly saline lakes with no ice cover (for example, Don Juan Pond, Upper Wright Valley) and finally lakes with a 3 to 5 m ice cover (for example, Lakes Brownsworth and Vanda in Wright Valley, and Lakes Bonney, Hoare and Fryxell in Taylor Valley), which melt only in a marginal moat in summer (Green & Lyons, 2009; Dickson et al., 2013). Microbe-dominated biotas flourish wherever and whenever liquid water is present, including as mats on stream and lake beds. Photosynthesizing algae are important in lakes during the spring season (Fountain et al., 1999). Microbial mats consume nutrients rapidly from stream water, and biogeochemical cycling in these systems is strongly influenced by exchange of hyporheic waters with stream water (McKnight et al., 1999).

Microclimates in the Dry Valleys comprise a coastal zone, with soils that transiently thaw in summer, and a stable cold upland zone with particularly low relative humidity (Marchant & Head, 2007; Marchant et al., 2013). The intervening valleys have a mean annual temperature of −16 to −21°C and the maximum average daily temperature is below zero throughout the year (Fountain et al., 1999). The valleys receive less than 10 mm water-equivalent of precipitation per year, almost always as snow. Because of the prevailing low relative humidities (for example, between 50% and 60% in Taylor Valley, Fountain et al., 1999), ablation (mostly as sublimation) greatly exceeds precipitation. Wilson (1981) described the consequences of this geographic configuration and climatology using physical and chemical principles. The amount of precipitation rises with altitude, but falls inland further from the Ross Sea. The snowline marks the boundary where ablation exceeds precipitation and it rises inland as precipitation declines. Wilson (1981) attempted to explain the distribution of salts based on an understanding of downslope-increasing aridity, but it seems that variable meteorology confounds the predictions in detail. Nevertheless, it is the case that deliquescent salts flow downhill in the subsoil above a permanently frozen layer. Lakes with a lid of ice maintain mass balance between ablation at the surface and freezing of lake water at the base of the lid, replenished seasonally by stream inflow. Once snow is removed by ablation, sunlight penetrates through vertical ice crystals and significant solar heating of lakes can occur. The present configuration of salts allows deductions of both long-term and short-term history. Specifically, spatial variability in salts requires a long-term (10⁵ to 10⁶ years) stability of the ice-free subaerial valley sides. On the other hand, some lakes have a basal brine layer, which diffusion modelling shows originated ca 1200 years ago when some lakes were ice-free shallow brines, before being re-filled by fresh meltwater.

Wilson (1981) did not address the effect of wind on aridity and salt distribution. Katabatic winds flowing down the East Antarctic Ice Sheet strongly enhance aridity regionally. As this air warms adiabatically, humidity decreases, particularly in winter (Nylen et al., 2004). It is now clear that the episodically strong summer winds are actually warm foehn winds, which arise from strong pressure gradients that arise during cyclonic development over the Ross Sea, governed by hemispheric climatic anomalies. These topographically enhanced and channelled winds typically flow at >5 m s⁻¹ westerly along the Dry Valleys and cause very large intra-annual
Fig. 3. (A) Oblique aerial view of the McMurdo Dry Valleys (01/01/1999 imagery from US Geological Survey via Google Earth) with location arrowed in inset of Antarctica (upper right). EAIS = East Antarctic Ice Sheet. LGM = Last Glacial Maximum. Abbreviations on upper right inset: EA = East Antarctica, WA = West Antarctica, RIS = Ross Ice Shelf. The lower left inset shows an oblique aerial photograph looking west up Taylor Valley with cold-based valley glaciers on hillside on left, ice-covered Lake Bonney (valley floor, right) with the tip of the Taylor Glacier beyond. (B) Despite sub-zero temperatures, runoff occurs from the Lower Wright Glacier (an outlet glacier of the coastal Wilson Piedmont Glacier) and feeds the Onyx River. This stream flows inland to the west, eventually to Lake Vanda, visible in (A) in the central part of the valley. Note the aeolian sands banked against the glacier. (C) Oblique aerial view of Victoria Lower Glacier (eastern end of Victoria Valley) which feeds a stream flowing inland, westward to Lake Vida, seen in the distance. Aeolian dunes transverse to the stream are visible on the right-side of the valley.
and inter-annual increases in meltwater production and streamflow (Doran et al., 2008; Speirs et al., 2013). The high incidence of these winds in summer 2001/2002, when positive degree days increased by an order of magnitude, led to rises in lake level of 0.5 to 1.0 m, effectively wiping out the previous 14 years of lowering of lake level in a period of three months (Doran et al., 2008). These details effectively demonstrate the sensitivity of the environment to climatic changes, which in turn will strongly influence sedimentary facies.

The Dry Valleys region and the adjacent offshore area, seaward of Ferrar Glacier, demonstrate a 34 Myr history of glaciation. Cores from several offshore drillholes indicate that the first evidence of glaciation was at the Eocene/Oligocene boundary, and that the thermal characteristics of the glaciers changed from temperate (associated with abundant flora), through polythermal conditions to the predominantly cold glaciers of today (Hambrey & Barrett, 1993; Hambrey et al., 2002; Barrett, 2007; Naish et al., 2008). The McMurdo region has generated considerable controversy concerning the timing of the switch to cold, arid conditions, specifically whether the switch took place in Miocene or Late Pliocene time; these views have been reviewed and re-evaluated by Barrett (2013). Evidence for landscape evolution based on the position of Miocene volcanic ash deposits clearly demonstrates that, after the establishment of the current large, cold, and stable East Antarctic Ice Sheet in the Miocene, only surficial landscape modification has occurred (Sugden et al., 1995; Lewis et al., 2007). Importantly, the cold, dry climates of the Dry Valleys remained stable, even during significant warming events recorded in the Ross Sea during the Pliocene. This long-term climatic stasis can be compared with the predicted long-term hydrological inactivity anticipated on a Snowball Earth as carbon dioxide levels slowly rose.

Large lakes formed during the Last Glacial Maximum in all the major Dry Valleys – this required two conditions: (i) expansion of the Ross Sea Ice sheet to block the marine margins of the Dry Valleys (Hendy, 1980; Hall et al., 2013); and (ii) increased meltwater production in the valley (by wind-induced melting, Doran et al., 2008), despite significantly colder conditions. Conversely, dating of aragonitic lacustrine deposits shows that Taylor Glacier (with characteristically light oxygen isotope values) expanded during interglacial periods, as did local valley-side glaciers, which have heavier isotope values (Hendy, 1979, 1980). These phenomena presumably reflect higher snow accumulation on the EAIS, enhanced meltwater production and partial blockage of the valley by ice. Importantly, these inferences draw attention to the potential anti-phasing of global temperature and local glacier advance, and the greater importance of regional humidity controls on Milankovitch timescales.

In the current paper, a wealth of new data on the Wilsonbreen Formation carbonates are presented which allows the analogies previously made to be tested and evaluated in depth. The interpretation of these data is assisted by modern analogues and new computer simulation studies of Neoproterozoic climates (Pierrehumbert et al., 2011; Benn et al., 2015).

**METHODS**

Fieldwork (2010/2011) was supported by helicopter and by snow scooter. Sections, including six entirely new locations, were measured by 30 m tape, orientated by compass and Abney level, and linked to bedding dips, with total thickness checked by GPS with uncertainty of around 5%. The best available sections in each region were logged (Figs 1 and 2), although they vary in quality from almost complete exposure, to intermittent outcrop separated by ground-level frost-shattered regolith. The carbonate rocks are chemically fresh, but laboratory study of cut or sectioned samples was necessary to identify facies in many cases. Over 350 samples were sawn, 210 of which were thin-sectioned; 60 of these were stained with Alizarin Red-S and potassium ferricyanide, and over 30 polished sections were studied by cold-cathode cathodoluminescence (CL) at 15 kV.

Carbon and oxygen stable isotope data are presented here as δ13C and δ18O in parts per thousand with respect to the VPDB (Vienna Pee Dee Belemnite) standard. Differences between laboratories are insignificant in relation to the wide range of isotope values (29‰ in δ18O and 8‰ in δ13C) in this study. Supplementary data in Bao et al. (2009) included methods and all data collected to that date. New data were obtained at the University of Birmingham using a continuous-flow Isoprime IRMS (isotope ratio mass spectrometer; Isoprime Limited, Stockport, UK), with a multifold preparation system. Samples of between 80 to 250 µg powdered carbonate were reacted with phosphoric acid at 90°C for at least
90 min. Results were calibrated using IAEA (International Atomic Energy Agency) standards NBS-18 and NBS-19 (National Bureau of Standards) and repeatability on an internal standard was better than 0.1‰ for δ13C and 0.15‰ for δ18O. A fluid inclusion study is reported in the supplementary information. Sulphate oxygen and sulphur isotopes are presented in Benn et al. (2015). The present study draws on previously presented trace element data from the carbonate fraction soluble in dilute nitric acid (Fairchild & Spiro, 1987; Fairchild et al., 1989; Bao et al., 2009), while new trace element and other isotope analyses will be presented elsewhere.

In figure captions, the location and stratigraphic position are given in a standard format. For example, ‘W2, Dracoisen, 70 m’ refers to a sample from member W2 from the Dragoisen section, 70 m above the base of the Formation (or the base of the section where the base is not seen). The context and oxygen isotope composition of the carbonate from that horizon can be found in the stratigraphic section diagrams: Fig. 4 for Dragoisen and supplementary Figs 1 to 6 for the other sections. Carbonates in members W1 and W3 are summarized only in Table 2, but full stratigraphic logs of the Wilsonbreen Formation are given in Benn et al. (2015, fig. S1).

WILSONBRENN FORMATION ARCHITECTURE, COMPOSITION AND POST-DEPOSITIONAL HISTORY

The Wilsonbreen Formation, dominated lithologically by sandy diamicrites, contains a wealth of evidence indicating that it is largely glaciogenic, and was deposited in both aqueous and subglacial settings (Hambrey, 1982; Fairchild et al., 1993). New work (Benn et al., 2015; Fleming et al., 2016), including five previously undescribed sections, has resulted in a coherent stratigraphic-facies reconstruction (Fig. 1). This paper focuses on beds (sandstones, rhythmites and mudrocks) containing precipitated carbonate; the presence of such strata was originally used to define member W2 (Hambrey, 1982). In the northernmost section (Dragoisen), W2 is readily distinguished by three such carbonate-bearing beds separated by diamicrites (Fig. 2A), and overall a similar pattern applies in other sections (Fig. 1). However, thin rhythmite units also occur in member W1, one containing precipitated carbonate, and most of the thin non-diamicite (sandstone and rhythmites) beds in member W3 contain such carbonate facies (Table 2). Although glacialic rocks continue NNE to the coast and to Nordaustlandet, these were not included in this study because diamicrites are thinner and less well exposed, and precipitated carbonates are absent (Halverson et al., 2004; Hoffman et al., 2012). Neither do such carbonates occur in the equivalent Storeelv Formation of Northeast Greenland, representing the south-western continuation of the basin (Hambrey & Spencer, 1987; Moncrieff & Hambrey, 1990; Hoffman et al., 2012; Fleming, 2014).

Terrigenous detritus

Clarifying the nature of reworked (terrigenous) clastic material is important for the petrological study of the Wilsonbreen Formation. Harland et al. (1993) summarized information from five sites, determining that carbonate clasts make up 40 to 85%, igneous and metamorphic clasts 5 to 33%, and sandstones and quartzites 10 to 20% of stones (i.e. gravel-sized debris); the basement lithologies are primarily granitoids and gneisses, with some basalt in which ferromagnesian minerals are commonly chloritized. In the wider context of terranes affected by the Caledonian orogen, detrital zircon studies indicate provenance from Archaean and Palaeoproterozoic rocks of the cratonic interior, and Mesoproterozoic detritus derived from the eroded remnants of the Grenville–Sveconorwegian orogen (Cawood et al., 2007). A systematic study of carbonate clast compositions will be presented elsewhere, but in summary 80% of pebbles are dolomite rock and 20% are limestone. Many of these carbonates resemble units from the underlying succession (Table 1) in lithology and isotope composition, but no stratigraphic trends in clast type or isotope composition were found. The sand fraction is dominated by quartz and feldspar with subordinate dolomite and limestone and the mud fraction likewise comprises quartzo-feldspathic debris and dolomite (Fig. 5). The dominance of silt in the mud fraction is shown in graded rhythmites (Fig. 5C and D); notably detrital calcite occurs in the mud fraction only locally and the proportion of clay minerals is very low. The dolomite matrix of Polarisbreen Group diamicites is predominantly the result of glacial transport and comminution, as shown by the presence of sub-micron relic rock flour (Fairchild, 1983) in which clay minerals are virtually absent (Fig. 5D). This detrital
matrix contains a complex mixture of both bright and dully luminescent red dolomite when viewed in CL (Fig. 5A). The mean carbon and oxygen isotope compositions of dolomitic matrix in diamictites and wackes (n = 43) are +2.4 ± 1.3‰ and −3.5 ± 1.8‰, respectively, which are slightly lower values than for dolomite pebbles (Fig. 6A). This matrix composition forms a useful reference point for comparison with precipitated carbonates in the Wilsonbreen Formation.

**Burial diagenetic modification**

The Wilsonbreen Formation is overlain by a marine transgressive succession but, above the transgressive–regressive cycle of the lower Dracoisen Formation, most Ediacaran strata (Table 1) are non-marine playa lake facies, in turn overlain by 950 m of Cambro–Ordovician platform carbonates (Harland, 1997), indicating a minimum burial of 1.5 km. Late Silurian Caledonian folding and local thrusting followed (Fig. 2), but small-scale folding is generally absent, as is penetrative deformation. The Wilsonbreen Formation lies outside the thermal aureoles of Devonian granite plutons in the fold belt (Harland, 1997). Pores in the cap carbonate are filled with traces of bitumen, indicating that the sediments passed through the oil window, but good preservation is indicated by the ability to remove individual striated clasts from diamictite matrix (Hambrey, 1982) and some unusually high oxygen isotope compositions of dolomites (Fairchild et al., 1989; Bao et al., 2009). A fluid inclusion study (see supplementary information) indicates that initial pore fluids were advectively replaced by a typical meteoric fluid with δ²H in the range −60 to −100‰ and that ²H is slightly enriched by exchange with the solid phase. However, fluid inclusion volumes are orders of magnitude too small to have affected the bulk solid composition. Physical compaction effects are not noticeable because of the low clay content of the sediments and early cementation of the carbonates, but very locally lamina boundaries are stylolitic. Uncemented sandstones exhibit straight to concavo-convex boundaries between quartz grains.

Many Wilsonbreen Formation outcrops are reddened, and even in unreddened facies, organic carbon contents are low (below detection levels of 0.2% on three W2 carbonates). Fairchild & Hambrey (1984) regarded the hematite pigment as post-depositional based on the occurrence of Liesegang band structures. Ongoing palaeomagnetic studies may further elucidate the timing of this hemitization. Reddening is less pervasive in clean sandstones, implying that the source of iron in reddened zones is the fine fraction. The low preservation of organic carbon may reflect low abundance of clay (Kennedy et al., 2006) as well as a low-productivity continental setting. In either case, it permitted the diagenetic reddening, which contrasts with the dark-coloured early Cryogenian glacimarine deposits in the study area (Member E2, Table 1).

Burial cements are minor and readily distinguished from syn-depositional phenomena. Limited quartz overgrowths are common in sandstones and on sand grains floating in dolomites, while some sandstones display partial poikilotopic calcite cement. Ferroan saddle dolomite and ferroan calcite occlude larger primary pores, in dolomites and limestones, respectively. These carbonate phases also occur, locally together with quartz and white mica in crystal pseudomorphs. Saddle dolomite averages −12.2 ± 1.5‰ in δ¹⁸O and −18 ± 1.5‰ in δ¹³C and calcite spar −10.5 ± 1.6‰ and +2.0 ± 1.5‰, respectively (Bao et al., 2009).

**FACIES ANALYSIS**

**Facies Associations**

Following Benn et al. (2015) seven facies associations (FAs) are recognized in the Wilsonbreen Formation. Table 3 presents summary descriptions and interpretations, whereas Fig. 7 illustrates inferred environments. The glacial and
periglacial facies associations (FA1, 6 and 7) are discussed in Hambrey (1982), Fairchild & Hambrey (1984), Benn et al. (2015) and Fleming et al. (2016), and only a few salient points are mentioned here. Two distinct glacier advances from the south are recognized, just below and above member W2, by occurrences of FA1: sheared diamictite, sandstones and gravels, locally resting on highly deformed rhythmites (glacitectonites) or striated clast pavements (Fig. 1, labelled ‘FA1 subglacial’). The bulk of the Wilsonbreen Formation is, however, composed of weakly stratified diamictites (FA6) with decimetre to metre-scale lenses of rhythmites (with precipitated carbonate in members W2 and W3). Local presence of dropstones or isolated gravel clasts (lonestones), till pellets and stratification, and the absence of subglacial shearing phenomena, point to a subaqueous ice-rafted origin. Local lensing conglomerates are interpreted as sediment-gravity flows which, at Dracoisen, comprise a conspicuous low-angle cross-stratified unit (Fig. 1, labelled ‘FA6 proximal’), interpreted as a grounding-line fan (Benn et al., 2015; Fleming et al., 2016).

Gravel with ventifacts overlying shattered dolomite represents the Periglacial Facies Association (FA7) at the base of the Wilsonbreen Formation, interpreted as a multi-million year continental hiatus (Benn et al., 2015). Facies Association 7 also occurs at the base of W2 where a periglacial exposure horizon with sandstone wedges penetrating subglacial till is found (Fig. 1) at South Ormen, South Klofjellet and Ditlovtoppen and also at the Golitsynfjellet section (Fairchild et al., 1989), which is between McDonaldryggen and the Backlundtoppen–Kvitfjella Ridge (BAC). The periglacial horizon is overlain by sandstones correlated with those at the base of W2 at Dracoisen (DRA).

The other four facies associations contain precipitated carbonate and are described in detail below with summaries presented in Table 3 and Fig. 7. Each of the facies associations occurs as units 0·1 to 4·0 m in thickness (Fig. 4 and supplementary information Figs S1 to S6).

**Facies Association 2 (Facies 2S and 2T)**

**Description**

This facies association is represented by erosionally based, fining-upward tabular sandstone beds, 0·5 to 4·0 m in thickness. Facies 2T typically

| Detailed facies analysis in Fleming et al. (2016) |                                                                                                                                                                                                                      |                                                                      |
| FA2: Fluvial Channel                  | 2S: Beds of 0.5 to 4.0 m very fine to medium-grained, locally cross-stratified sandstone with erosional conglomeratic base. Some variants have low-angle accretion surfaces with silt-dominated beds. Stromatolitic limestone is either absent or abundant, forming decimetre-scale packages with millimetre to centimetre-scale laminae separated by sand laminae and laterally eroded into trains of intraclasts. 2T: As above, but lacking carbonate precipitates. | Ephemeral stream channel sands with strongly seasonal flows. In some cases there is a widespread carpet of calcified microbial mats. |
| FA3: Dolomitic Floodplain             | All facies contain dolomite with a positive $\delta^{18}$O composition that actively cements, displaces and/or upwardly accretes the sediment. 3D: Nodules, centimetre to decimetre-scale of dolomite-cemented silts and sands transitional to structureless decimetre to metre-scale beds with floating silt and sand in dolomite, internal nodules and calcite-cemented fractures. 3S: Stromatolitic dololaminites, decimetre-scale and millimetre-laminated. | Dolocretes representing soil horizons, typically above fluvial deposits, with locally raised water table. 3N: Nodular dolocrete 3D: Bedded dolocrete 3S: Subaerial stromatolites. |
| FA4: Calcareous Lake Margin           | 4R: Rhythmites with millimetre-scale dolomite, limestone or mixed-mineralogy laminae, commonly desiccated, alternating with 1 to 10 mm wavy cross-laminated silty sandstones. Carbonate laminae are often stromatolitic. Almost invariably reddened. 4I: Intraclastic, decimetre-scale, very fine to medium-grained sandstones. Very locally contain ooids. 4S: Indistinctly horizontally stratified well-sorted fine to medium-grained sandstone, with well-rounded grains, locally with centimetre-scale dolomite laminae. | 4R: Shallow lake to playa environment with wave-reworked sediment alternating with microbial mat accretion. 4I: Discrete storm horizons in shallow lake/playa reworking sand and stromatolitic carbonate. 4S: Aeolian sandflat deposits. |
| FA5: Carbonate Lake                   | 5R: Rhythmites with millimetre-scale limestone, dolomite or mixed-mineralogy laminae, usually with stromatolitic microstructure and locally building decimetre stromatolites with centimetre-scale relief. Alternate with 0.1 to 5.0 mm laminae of diamictite/wacke, commonly with till pellets and occasional limestones. Slump folding and brecciation common. 5D: Discrete gravel to diamictite units with significant intraclastic debris in addition to terrigenous gravel. | 5R: Carbonate microbial mat deposits in lacustrine environment subject to seasonal ice-rafting and slope instability 5D: Slope-related resedimentation. |
| FA6: Glacilacustrine – Detailed facies analysis in Fleming et al. (2016) | Dominated by massive and stratified diamictites with common limestones and till pellets. Decimetre to metre-scale intervals of silty rhythmites occur locally, especially in member W1. May contain lenses of conglomerate, sometimes channelled, and lenses or thin beds of sandstone forming packages which can be inclined at up to 20°. | Ice-raftered glacilacustrine sediment locally reworked as sediment-gravity flows. Inclined packages form grounding-line fans (termed proximal glacilacustrine on Fig. 1) and rhythmites likewise reflect ice-margin retreat. |
| FA7: Periglacial – See Fairchild & Hambrey (1984) and Benn et al. (2015) | Decimetre-wide sandstone wedges penetrating up to 2 m into underlying sediment from a discrete surface that may have a gravel lag. At base of Wilsonbreen Formation, gravel with ventifacts overlying shattered dolostone. | Exposed periglacial bedrock and sand wedges from exposed periglacial environment. |
comprises moderately sorted very fine to medium-grained sandstone with a basal erosional surface capped by a gravel lag. Internal cross-stratification is tabular, typically with low-angle accretion surfaces and set thickness of 0.5 to 1.0 m. This facies is seen at the base of the W2 section at Ditlovtoppen (Fig. S1), South Ormen (Fig. S2), East Andromedafjellet (Fig. S3) and Reinsryggen (Fig. S4), and is also prominent near the top of the member at Dracoisen (Fig. 8H) and at Ditlovtoppen, where thin siltstone beds define low-angle accretion surfaces (Fig. 8G).

Facies 2S is distinguished from Facies 2T by the presence of limestone laminae and intraclasts, and reduced silt content. The best-exposed example is a 4 m thick unit that forms the basal part of member W2 at Dracoisen (Figs 2A and 4), resting on massive diamictite with decimetre-scale erosional relief. A thin basal pebble conglomerate passes up into 0.7 m of pebbly sandstone, whereas the main, central part of the bed is very fine to medium-grained sandstone with local tabular cross-stratification, with set thickness up to 15 cm and current ripples (Fig. 8D). At both levels, there are abundant (ca 25 to 50%) layers of limestone, with individual laminae typically 1 to 3 mm thick (Fig. 8A). Universal features of the limestone are domed growth morphologies (Fig. 8A) and differentiated microstructures (Fig. 8B) with well-developed slightly irregular laminae of micrite, microspar and detritus-rich carbonate with regular millimetre-scale fenestrae (Fairchild, 1991; Riding, 2000). In one case a pervasive vertical structure reminiscent of cyanobacterial or algal filament moulds (Knoll et al., 1993) was observed (Fig. 9B). All limestone occurrences are laterally discontinuous, and grade laterally to trains of intraclasts that are locally stacked at high angles. In places, extensive crusts, up to 0.5 to 6.0 mm thick, of radiaxial calcite

Fig. 7. Summary cartoon of facies associations. Facies Associations 2 to 5 are colour-coded here and in isotope plots. The margin of an ice sheet is depicted, terminating partly on land and, in the foreground, in the lake. Facies Association 1 is shown in a subglacial environment (subglacial sediments are coloured brown); periglacial phenomena are also grouped in this facies association. Facies Associations 2 and 3 both occur in a fluvial setting (sediments coloured yellow), while FA5 and FA6 were deposited in lakes (sediments coloured light brown). Facies Association 4 includes both shallow lacustrine and coastal sediments.

© 2015 The Authors. Sedimentology © 2015 International Association of Sedimentologists, Sedimentology, 63, 443–497
cement develop, also broken to form intraclasts (Fig. 8C).

Under CL, intraclasts fluoresce uniformly brightly, whereas later vein cements show more variable characteristics (Fig. 9A). This pattern is mirrored geochemically in high Mn contents of several thousand ppm and exceptionally high Mn/Fe of 1 (Bao et al., 2009) of the intraclasts. Strontium contents are 150 to 300 ppm, while Mg is 4000 to 6000 ppm (Bao et al., 2009), equivalent to ca 2 mole % MgCO$_3$. The radiaxial fabrics appear pristine and microdolomite inclusions are absent. Sulphate content is high (2000 to 5000 ppm, Bao et al., 2009), whereas the preservation of a negative $\Delta^{18}$O anomaly demonstrates that the sulphate has not undergone redox cycling (Bao et al., 2009; Benn et al., 2015). Stable isotope data from stromatolitic limestones define a coherent field (Fig. 6A) with $\delta^{18}$O ranging from $-10.5$ to $-3.4$$_{\text{oo}}$ and $\delta^{13}$C from $+0.9$ to $+4.6$$_{\text{oo}}$, weighted towards higher values, with overall isotopic covariation (Fig. 6B). A micromill traverse through syndepositional calcite reveals ‘lamina to lamina’ variations of $2.0$$_{\text{oo}}$ in $\delta^{18}$O and $0.5$$_{\text{oo}}$ in $\delta^{13}$C, without strong covariation (Fig. 8E and F). The clear petrographic distinction between syn-depositional and later calcite spar cement is reflected also in the low $\delta^{18}$O signature of the spar of $-10$ to $-12$$_{\text{oo}}$ (Fig. 8F).

**Interpretation**

Facies Association 2 is distinguished by tractional sediment transport. The consistent presence of laterally extensive basal erosion surfaces imply channelization, while for Facies 2T the low-angle accretion surfaces with thin silt beds suggests migrating point-bar deposits (Davies & Gibling, 2010), although confirmation would require more extensive exposures. The presence of high-angle cross-stratification, good sorting and disrupted intraclasts in Facies 2S are characteristics found in either tidal sand flats or in low sinuosity fluvial channels. The limestones contain two features typical of Neoproterozoic microbial deposits: macroscopically domed laminae and differentiated microstructures formed by periodic variations in phenomena such as a sediment trapping, gas generation and carbonate precipitation, fulfilling criteria for stromatolites (Fairchild, 1991; Riding, 2000). Limestones were lithified, as demonstrated by broken crusts and dispersed and stacked intraclasts, for example along foresets, as expected for significant tractional flows in shallow-water. The later disruption and discontinuity of the limestone units indicates highly variable flow conditions, whereas the locally highly regular microbial lamination, including clastic layers, indicates periodically fluctuating flows.

Facies 2S resembles tidal sandflat deposits, consistent with the occurrence of well-preserved radiaxial cements with relatively high $\delta^{18}$O compositions (Fairchild & Spiro, 1987). However, there is an absence of herringbone cross-stratification and reactivation surfaces which commonly occur in such facies (Fairchild, 1980; Fairchild & Herrington, 1989). There is a clear contrast with the more regular macrostructures of marine stromatolites elsewhere in the basin (Fairchild & Herrington, 1989; Knoll & Swett, 1990; Halverson et al., 2004) and Neoproterozoic deposits more generally (Grotzinger & Knoll, 1999). This may be attributable to a more hostile environment, with highly variable rates of sedimentation. Furthermore, unlike the Facies 2S stromatolites, Neoproterozoic peritidal deposits are invariably dolomitized (Knoll & Swett, 1990), probably a feature of high Mg/Ca in seawater (Hood & Wallace, 2012).

The present authors favour a freshwater, fluvial context for this facies association. It is recognized that radiaxial fabrics are not diagnostic of marine waters, but also occur in speleothems (Neuser &
A non-marine environment is consistent with the relatively low Sr content of the calcite (Fairchild & Baker, 2012). Hence, the radiaxial calcite is interpreted here as the pristine original low-Mg calcite phase. Micrite and microspar fabrics have similar chemistries and are also considered to reflect depositional conditions. Following the same arguments made for stable isotopes, the implication is that the Mn content of FA2 calcites is also primary and reflects low contemporary atmospheric PO2 (cf. Hood & Wallace, 2014), but not anoxic conditions under which sulphate reduction would have occurred, disturbing the Δ17O systematics and producing sulphides (Bao et al., 2009).

Importantly, the Mg composition of Facies 2S limestone is similar to modern speleothem deposits in a cool Scottish cave depositing from waters with Mg/Ca controlled by dolomite dissolution (Fairchild et al., 2001). The lamina thickness of the stromatolites is very similar to those of modern fluvial microbial tufas which are similarly complex deposits containing both biologically mediated and inorganic precipitates (Andrews & Brasier, 2005; Andrews, 2006). Interestingly, the lamination of these modern deposits reflects a strong annual variation in discharge; Facies 2S likewise possesses physical sedimentological characteristics consistent with those of ephemeral streams. In this interpretation, the stable isotope compositions, which are similar for radiaxial and microsparry calcites, can also be interpreted as primary, in which case the isotopic covariation (Fig. 6B) reflects an evolutionary trend towards more evaporated equilibrated solutions (Talbot, 1990), rather than variations associated with recrystallization. Modern Antarctic streams lack the calcite mineralization, but microbial mats are well-developed and are adapted to ephemeral flow conditions, readily reactivating even after being dry for many years (McKnight et al., 2007). The fluvial interpretation will be developed later in the light of the relationship of FA2 to other facies associations.

Facies Association 3 (Facies 3D and 3S)

Description

Facies 3D is marked by discrete zones of pronounced dolomite cementation within a sandstone or siltstone, in some cases pervasive. Where dolomite is most abundant, detritus floats in a displacive mass of dolomite crystals (Fig. 10B, D, E and F), but other dolomite-cemented silty sands are still clast-supported (Fig. 10C). Locally, distinct dolomite-cemented nodules are visible (Fig. 10A) or a structureless dolomite bed occurs with a low content of floating silt and sand. The most characteristic structures are millimetre-scale nodular dolomicrite structures within massive dolomite-cemented layers and associated with calcite-filled fractures. These phenomena are found at one horizon in member W3 (Fig. 10D), as well as in

© 2015 The Authors. Sedimentology © 2015 International Association of Sedimentologists, Sedimentology, 63, 443–497
several locations in member W2 (for example, Fig. 10F). A rarer phenomenon is the presence of equant centimetre-scale cauliflower-shaped pseudomorphs, filled by ferroan saddle dolomite cement (Fig. 11A) occurring at the top of a conglomerate-based fining-upward cycle (Fig. 8G). Since saddle dolomite is a burial phase (Radke & Mathis, 1980), the pseudomorphs must have been occupied with soluble crystals that dissolved during burial prior to cementation.

Facies 3S refers to dolomitic laminites, with broad centimetre-scale domed macrostructure, with an aspect ratio of 10:1; they are found uniquely in a single complex bed, in association with Facies 3D, and overlying Facies 2S (at 70 m, Dracoisen, Fig. 4). It has been studied on the ‘Multikolorfjellet’ cliffs and the ‘Tophatten’ nunatak 1 km to the north. The bed is around a metre in thickness, and has an internally variable structure. Most commonly, the base of the bed shows minor erosion of underlying diamicrite and begins with crudely laminated, very fine to medium-grained green sandstone, locally with millimetre-scale limestone layers that are partly disrupted into intraclasts (Facies 2S). In places, the limestone passes upward into intensively dolomite-cemented sand in which the rock fabric appears to have expanded. In this sand dolomite corrodes quartz detritus and there are cavities lined with dolomicrospar and occluded by calcite. At the ‘Tophatten’ locality, a chaotic breccia unit a few decimetres thick is locally found at the base of the bed instead of sandstone. Everywhere, the top of the bed is marked by 10 to 20 cm of dololaminites with a complex microstructure, which alternate on a centimetre-scale with displacively cemented sands (Fig. 10E). The laminae are variably composed of dolomicrite or dolomicrospar and contain common fenestrae (Fig. 9E and H), while weathered surfaces reveal a finely textured microtopography (Fig. 10G). Locally, slightly lower in the bed, limestone laminites (FA5) form a 10 cm horizon overlying a 20 to 30 cm chaotic carbonate breccia (Fig. 10I) and gradually become disrupted downward.

Dolomite from FA3 is characteristically bright under CL (Fig. 11B to D). In Facies 3S, dolomicrospar clots are uniformly bright, while adjacent dolomicrospar displays duller growth filling small fenestrae, and larger fenestrae are filled by dolospar with more variable properties (Fig. 11B). Manganese (3000 to 4000 ppm), Fe (10 000 to 15 000 ppm), Na (2000 ppm) and Sr (250 to 350 ppm) concentrations are all unusually high (Bao et al., 2009), and unpublished electron microscope images and microanalyses from the present authors also show enrichments in many transition metals and rare earths, as well as a consistent chemical zonation within crystals of dolomicrite mosaics. In Facies 3D, a difference in mean CL brightness, and hence timing of growth, is observed between some nodules and surrounding matrix (Fig. 11D), while zonation within individual crystals growing between siliciclastic sand grains is observed locally (Fig. 11C). Sulphate is enriched (4000 ppm); there is no Δ17O anomaly but sulphate δ18O is exceptionally high (Bao et al., 2009; Benn et al., 2015).

Carbon and oxygen isotope values are correlated in Facies 3D (Fig. 6), but Fig. 12 illustrates that the two analyses from member W3 lie about 1‰ higher in δ13C than expected from this trend. Facies 3D has a range of δ18O from −1.9 to +11.4‰, but the mean value is biased upward by multiple analyses from a single sample which passes up into Facies 3S with even higher values (Fig. 12). Facies 3S is notable for possessing possibly the heaviest oxygen isotope values of carbonate rocks so far recorded in the geological record (Bao et al., 2009), with values up to +14.7‰ (VPDB; Fig. 12). A micromill traverse (Fig. 10H and J) demonstrates that these extreme high values are maintained on the millimetre-scale, but that over petrographic boundaries, δ18O values can vary by as much as 6‰.

Interpretation
For Facies 3D, the dolomicritic, syndepositional, passive to displacive growth with nodular structure and cracks is characteristic of calcrites in which precipitation is driven by evaporative concentration at or above a water table. Although rare, the spar-filled pseudomorphs (Fig. 11A), interpreted to have originated as anhydrite (Fairchild et al., 1989), attest to evaporative conditions. The displacive growth, nodules and cracks identify these carbonates as alpha calcrites (Wright, 1990), which in Phanerozoic examples tend to occur on non-carbonate substrates and in more arid conditions than the more common beta calcrites that are influenced by higher plants (Wright & Tucker, 2009). The strongly positive δ18O values and covariation with carbon isotopes require evaporation (Fairchild et al., 1989), which at the higher end of the spectrum necessitates an extremely arid environment. Dolocretes are less com-
mon than calcareous calcretes and tend to be better developed when originating from groundwater than when pedogenic, as in Triassic strata of the Paris Basin (Spötl & Wright, 1992). In this example, pedogenic and groundwater dolocretes had a similar range of stable isotope compositions to each other, but their covariance slope (1:1) was steeper than in FA3. Overall, the absence of any signal of light carbon from oxidation of organic matter in FA3 is consistent with the extremely low organic carbon contents of the rocks. The Wilsonbreen Formation dolocretes are interpreted as pedogenic, primarily because the extremely high δ18O values would require ground surface conditions for such extremely effective evaporation to occur. As will be discussed later, this interpretation is also consistent with the vertical facies relationships.

The differentiated microstructures in Facies 3S are again typical of microbialites, as are the distinctive surface textures (Fig. 10G; Callow et al., 2011). Such laminates are found in association with soils and intermittently flooded subaerial surfaces (Alonso-Zarza, 2003), although younger examples include root mats from higher plants that are clearly inapplicable here. Klappa (1979) ascribed centimetre-scale laminated deposits of ‘hard pan’ on calcitized limestone substrates as originating from the activities of lichen which colonize, bore into and form accretionary deposits on surfaces. The lichen-formed deposits exhibit features such as fenestrae, sediment incorporation and variable crystal size which are consistent with the Wilsonbreen Formation example. However, no evidence of alteration of underlying cemented material has been found, and the Wilsonbreen Formation microbial laminae are more distinct and are noticeably domed, in contrast with laminar calcretes. In fact, the microbial layering is indicative of active upward accretion, rather than slow pedogenic alteration. Accretion occurred through both growth of carbonate-mineralized microbial mats and deposition of sand laminae. A shallow depression on a floodplain/playa margin is an apposite environment. A combination of a high water table from which evaporation could occur and very shallow-water inundation followed by drying out and sediment addition, perhaps by aeolian action, is indicated. At Dracoisen (Fig. 9D), the gradational relationship between laminated carbonate and underlying chaotic breccia is a classic characteristic of evaporite dissolution breccias. The calcite-cemented nature of the breccia is consistent with removal of one or more horizons of calcium sulphate evaporites either during deposition of the bed or soon afterwards following resumption of glacial conditions. Brasier (2011) presented a similar Mesoproterozoic example from Ontario in which stromatolites, associated with collapse breccias and calcretes, are inferred to form at a playa lake margin. Likewise, the modern McMurdo Dry Valleys contain a record of many shallow saline lakes and salt pans (Wilson, 1981).

Dolomite is known to precipitate as a primary phase or by replacement of a CaCO3 precursor in a range of surface environments (Warren, 180 and 13C.

Fig. 10. Facies Association 3 (Dolomitic floodplain). Facies 3D is shown in (A) to (D), Facies 3S in the other panels, and both facies in (E). All of the Facies 3S images come from W2, Dracoisen, 70 m. (A) Nodular dolocrete with calcite-lined vugs in siltstone with scale in millimetres (W2, East Andromedafjellet, 35 m). (B) Stained thin section in plane polarized light showing matrix-supported fabric of dolomite cementation of sandy siltstone. Dolomicrospar lines a fenestra which is occluded by calcite. W2, Dracoisen, 70 m. (C) Thin section in plane polarized light. Grain-supported dolomicrite cement of silty sandstone. The dolomite has a δ18O composition of +2.7‰ and has a uniform texture in contrast to clastic dolomite of Fig. 5D. W2, South Klofjellet, 57 m. (D) Displace dolomite cement supporting silt and sand grains. Well-developed structure of dark nodules which show different CL characteristics from surrounding dolomite from which they are separated by curved cracks. W3, South Ormen, 78 m. (E) Stained thin section of interlaminated dolomite-cemented sand and microbial laminae with fenestrae, some occluded by ferroan dolomite (turquoise arrow) or ferroan calcite (purple arrow). (F) Stained thin section illustrating similar fabric to (D), but with calcite cementation of cracks and larger pores (W2, Dracoisen, 83 m) (G) Field photograph of textured bedding surface of dololamine identified as microbial mat texture (W2, Dracoisen, 70 m). (H) Polished rock chip of microbial dololaminites with arrow marking position of 5-2 mm micromill traverse [shown in (J) below]. (I) Microbial laminates draping downward into underlying laminate whose brecciation is attributed to evaporite dissolution collapse. Outlined ruler is 20 cm long. (J) Stable isotope profile (in ‰, with respect to V-PDB) of microbial dololaminites along line illustrated in (H) The isotopes covary over a magnitude of 6‰ for δ18O and 1‰ for δ13C.
2000), although the initial crystals (protodolomite) may lack well-developed ordering reflections, which increase during ageing (Gregg et al., 1992). The petrographic characteristics of FA3 dolomicrite are consistent with very early diagenetic replacement of a precursor carbonate or of primary growth of (proto)dolomite; the latter is clearly the case for zoned dolomicrospar cavity-linings (cf. Hood & Wallace, 2012). The presence of euhedral crystals within displacive fabrics (Fig. 11C) is distinctive. Although Tandon & Friend (1989) interpreted euhedral growth zones in displacive calcite in calcrites as evidence of recrystallization, it is more logically interpreted as a primary growth fabric, as argued by Spötl & Wright (1992) in a dolocrete example.

The extremely high δ^{18}O values rule out postdepositional modification. Interpretation of the values as reflective of the depositional environment is also consistent with the trace element chemistry and preserved crystal growth zones. The high Mn content and absence of pyrite implies low pO_2, but not anoxia, although the sulphate oxygen isotope systematics are indicative of more redox variability than in Facies 2S.
Specifically, bacterially mediated electron shuttling by Mn-species can catalyse repeated transitions between sulphate and sulphite, which would erase any $\Delta^{17}$O anomaly and lead to high $\delta^{18}$O in sulphate (Bao et al., 2009). Such processes could trigger dolomite nucleation given the evidence from other field and experimental studies on the catalytic role of sulphate reduction (Vasconcelos et al., 2005; Zhang et al., 2012). The inferred redox variations may be related to a supply of brine primarily from within the sediment, contrasting with the surface waters from which Facies 2S precipitated. The occurrence of the highest $\delta^{18}$O values in laminated dolomites of Facies 3S is consistent with their formation by very near-surface evaporation, whereas abrupt variations in $\delta^{18}$O (Fig. 10J) imply occasional inundations by less evolved waters. In summary, FA3 provides examples of facies that stretch the boundaries of earth surface phenomena and indicate deposition in unusually arid terrestrial environments.

Facies Association 4 (Facies 4I, 4R and 4S)

Description
Facies 4R is the most common facies in this association and consists of rhythmic alternations of carbonate and sorted terrigenous sediment, which occur in association with structures implying shallow-water to intermittently emergent conditions, such as wave-ripple lamination and desiccation structures. The fine carbonate layers are usually dolomitic, or mixed dolomitic–calcitic, but include some limestone (Figs 7A and 12). The coarser sediment layers are universally composed of coarse silt to fine sand with evidence of tractional sorting, which distinguishes this facies association from FA5. Wherever laminae are sufficiently thick, undulatory cross-lamination is displayed (Fig. 13B) which can be confidently identified as wave-generated. Locally, symmetrical ripples are preserved in cross-section (Fig. 13A) or on bedding planes (Fig. 13C). Dry-
This facies association display a range of tions (Fig. 14A and B). The limestone laminae in ter is authigenic, as confirmed by CL observa-
dolomite) into dolomicrite, implying that the lat-
in isotopes from the sandy layers (with detrital

The isotope traverse of Fig. 13J reveals a shift in isotopes from the sandy layers (with detrital dolomite) into dolomicrite, implying that the latter is authigenic, as confirmed by CL observations (Fig. 14A and B). The limestone laminae in this facies association display a range of $\delta^{18}O$ values from $-11.9$ to $-3.2\%o$ with a mean of $-8.1\%o$, whereas dolomite layers range from $-5.3$ to $+1.4\%o$ with a mean of $-1.9\%o$ (Fig. 6B). The difference of $6\%o$ in mean value, compared with inferred and observed differences of 2.6 to 3.0%o for calcite and (proto)dolomite precipitating from equivalent fluids (Land, 1980; Vasconcelos et al., 2005) implies that the dolomites precipitated, on average, from waters with higher oxygen isotope values. The dolomites display covariance between $\delta^{13}C$ and $\delta^{18}O$ (Fig. 6B). Trace element data will be presented elsewhere, but FA4 and FA5 dolorhythmites also show a covariation of Sr (from 100 to 200 ppm) with $\delta^{18}O$ and somewhat higher Sr values in calcites and, like other Wilsonbreen precipitated carbonates, they are Mn-rich (>1000 ppm).

Facies 4I occurs typically as discrete beds, normally 10 to 20 cm thick, of sharp based to erosionaly based intraclastic sandstone with wave-generated lamination. The sand matrix is moderately sorted coarse silt to medium-grained sand and intraclasts are sometimes confined to the lower half of the bed. Several successive beds are shown in Fig. 13H in a section transitional upward from FA5, and an example of this facies in thin section is illustrated in Fig. 13G. Two occurrences of ooids (Fig. 13E) have been found. At North Klofjellet, high in a generally poorly exposed W2 section, is a 1 m bed of indistinctly cross-laminated sands alternating with centimetre-scale desiccated limestone beds containing scattered sand grains. This section is the lateral equivalent of fluvial facies (FA2) 1 km away at South Klofjellet. Ooids are found near the top of the unit, but make up less than 5% of the sand fraction. A range of cortices, from superficial coatings through to fully developed ooids with no visible core, is developed. Internal fabrics are micritic and microsparitic with a crude concentric structure. The mean oxygen isotope value of the limestone (>90 wt. % CaCO$_3$) is $-7.6\%o$. The second occurrence of ooids is as a small proportion of the total grains within thin (0.1 m) cross-laminated green sandstone underlying FA5 sediments in member W3 at Ormen (Table 3).

Facies 4S is represented by distinct sandstone beds in the Ditlovtoppen and Dracoisen sections.

![Fig. 13. Facies Association 4 (Calcareous Lake Margin). Images (A), (B), (D) and (H) to (J) are Facies 4R; (C), (E) and (G) are Facies 4I and (F) is Facies 4S. Well-sorted quartzose sandstone with very well-rounded grains and low-angle lamination marked by subordinate interstitial dolomite. W2, Ditlovtoppen, 114.2 m. (G) Stained thin section in transmitted light. Sandstone with conspicuous stromatolitic rhythmite limestone intraclasts. W2, Backlundtoppen-Kvitfjellet ridge, 76.5 m (Fig. S6). (H) Two-metre high section at of Ditlovtoppen (108.5 to 110.5 m on supplementary Fig. 1) showing poorly stratified sandstone bed (Facies 4S) overlying Facies 4R with several discrete graded intraclastic sandstone beds (Facies 4I). (I) Polished slab of dolomitic rhythmites with desiccation cracks (C). The 3-2 mm long micromill isotope traverse of (J) is indicated. W2, South Ormen, 31.3 m. (J) Isotope results from the micromill traverse with lighter isotope values corresponding to detrital dolomite matrix and the heaviest values (at right) indicative of precipitated dolomite composition.](https://doi.org/10.1002/sed.20741)
These sandstones are highly uniform, consisting of well-sorted fine-grained to medium-grained sandstone, with very well-rounded grains. Bedding structures are confined to an indistinct, discontinuous parallel stratification. At Ditlovtoppen, this facies presents as a tabular 3 m thick bed spanning the 200 m width of the outcrop. Its lower few decimetres are locally thinly laminated sand and dolomite, changing laterally to uniform sandstone. Two thin beds of dolomite with floating grains are also found at the top of the unit. Grains range from very fine to coarse-grained, but most of the rock volume is composed of medium to coarse sand grains (Fig. 13F). The only sedimentary structure consistently displayed is an indistinct centimetre-scale horizontal lamination with slight variations in grain size, or locally with millimetre-scale laminae with silty dolomitic matrix. Locally the laminae are deformed into cusps, suggestive of upward fluid escape. Oxygen isotopes in several samples are slightly heavier than expected for detrital matrix, consistent with addition of precipitated dolomite. This bed transitions downward (Fig. 10H) to Facies 4R in which millimetre to centimetre-scale sand laminae between rhythmic carbonates exhibit cross-lamination and wave-ripple morphology. Within 20 to 30 cm of the boundary, thin intraclastic flake breccias (Facies 4I) and desiccation structures occur.

**Interpretation**

Facies 4R and 4I display evidence of sorting and reworking of the sediments by wave action. This indicates deposition in a water body that was unfrozen at the time of deposition of the coarser layers, which represent distinct time periods with more pronounced wave action. The sharp-based intraclastic beds (Facies 4I) appear to represent distinct storm events in which considerable disruption and transportation of cemented carbonate layers occurred, although at least in some cases these layers were already disrupted by desiccation.

The grains and structures in Facies 4R and 4I are consistent with either a marine or a lacustrine origin, although no demonstrable tide-related phenomena are documented (cf. Fairchild & Herrington, 1989). A quantitative description of wave climate (Allen, 1984) based on these structures is not possible, but no wave phenomena were seen requiring oceanic conditions. Although ooids are best known from marine environments and thick oolitic units were used as a criterion for warm climates in the Neo-proterozoic context by Fairchild (1993), ooids have been described from Quaternary sediments reworked into Antarctic moraines (Rao et al., 1998) and also occur widely in various modern alkaline or hypersaline lakes. Lacustrine ooids form in water depths of 1 to 5 m, with the best development in shallowest water. The Wilsonbreen Formation examples do not resemble hypersaline aragonite ooids with radial structure (e.g. Halley, 1977), consistent with their oxygen isotope composition unenriched in $^{18}$O. Ooids in smaller modern lakes tend to be superficial with relatively irregular outlines, whereas fully developed ooids are found on the shores of the large Lake Tanganyika in Burundi (Cohen & Thouin, 1987) corresponding to stronger wave action.

Chemical arguments also favour a lacustrine origin for the carbonates; they probably arose as
some combination of water-column precipitates or within the sediment, for example as microbially influenced precipitates. Dolomite could be primary or, given the CL evidence, be a very early diagenetic replacement of CaCO₃, although not one with high Sr content. Given the consistent Mn-enrichment, it is improbable that burial diagenetic recrystallization took place, making it more straightforward to interpret the stable isotope values as primary. The wide range of δ¹⁸O compositions is uncharacteristic of marine waters. For dolomites, the wide range of values cannot be explained by the relatively small changes (1 to 2‰) that might be expected to accompany increased ordering from an initial protodolomite to an ordered dolomite (Gregg et al., 1992; Kaczmarek & Sibley, 2014). However, the formation of dolomite from more ¹⁸O-rich, evaporated waters, is consistent with the standard paragenetic model in playa lakes (Dutkiewicz et al., 2000), although changes in source water composition as well as evaporation probably occurred.

The well-rounded sand grains found in Facies 4S are consistent with aeolian transport, as in the McMurdo Dry Valleys of Antarctica (Fig. 3C; Calkin & Rutford, 1974; Hambrey & Fitzsimons, 2010). However, grains with a long history of aeolian transport can be finally deposited in aeolian, fluvial or lacustrine settings. The good sorting, particularly of coarse laminae, instead point to tractional flows, but lack of cross-stratification rules out aeolian or subaqueous dunes. Hendy et al. (2000) developed the ice-conveyor model to account for sandy deposits on the floors of certain ice-covered Antarctic lakes with floating glacier-ice margins. In this model, wind-blown sand melts its way through the ice in contrast to gravel which remains on the surface where it is transported by ice flow to the distal lake margins. The indistinct parallel stratification observed in this facies would develop in this context, but two features of the modern systems are not observed at Ditlovtoppen: mounded bedding and upward gradation into coarse gravel (Hall et al., 2006). The Ditlovtoppen bed is tabular, whereas in the modern lakes, sand transmission to the ice is focused, leading to mounds and ridges on the lake floor.

A plausible alternative for Facies 4I is an inter-dune setting where wind ripple migration would be expected (Lancaster & Teller, 1988). Ripple migration would give rise to translatent sub-horizontal laminae, representing set boundaries, without internal ripple cross-lamination being preserved (Mountney & Thompson, 2002). A water table that was at least seasonally high is required to account for dewatering structures and the precipitation of dolomite (incipient dolocrete). In such modern environments, seasonal flooding by surface water or emergent groundwater might occur, accounting for occasional dolomericite laminae. The horizontal stratification is inconsistent with dune deposition, but is as expected on a sandflat or playa with a high water table, which fits with the transition to Facies 4R and 4I observed in Fig. 13H.

Overall FA4 represents shallow-water and exposed sediments associated with a wave-dominated shoreline and is susceptible to wind-rewarking. The balance of physical and chemical evidence favours a lacustrine coast setting.

**Facies Association 5 (Facies 5D and 5R)**

**Description**

This facies association is dominated by rhythmic alternations of carbonates and poorly sorted clastic sediment (Facies 5R). Locally, this facies grades into brecciated rhythms which are distinguished as Facies 5D. Facies Association 5 is only a minor constituent of most of the W2 sections, although prominent in the South Klofjellet and BAC sections (Figs S5 and S6). However, it is the dominant carbonate-bearing facies association in member W3 where it alternates with ice-rafted diamicrites of FA6.

Figure 15 illustrates variants of Facies 5R found in member W2. Figure 15A exhibits highly regular millimetre-scale alternations of limestone and wacke. The clastic sediment includes many microscopic diamicrite pellets (arrowed) that are a normal feature found in this facies, whereas the small pseudomorphs crossing lamina boundaries are found more locally. Pebble-sized fragments in clastic layers (Fig. 15C and D) commonly display a dropstone texture associated with disruption of limestone laminae. An indicator of instability is shown by small-scale sedimentary growth faulting (Fig. 15C). Folds (Fig. 15E) demonstrate both some plasticity and fracturing of limestone, indicating partial cementation and synsedimentary deformation. Above these folds, the sediments are visibly disrupted and transitional to Facies 5D. The thickest example of Facies 5D observed was a 0.4 m thick bed at Ditlovtoppen, containing both intraclastic and terrigenous sediment, and which disappears laterally within 100 m. This bed clearly was derived by localized resedimentation of Facies 5R.
In member W3, Facies 5R is present as isolated beds up to 1 m thick exhibiting similar alternations of carbonate laminae and wacke/diamictite as in member W2 (Fig. 16). Figure 16A illustrates the base of one such bed with clear alternations of thick diamictite laminae and carbonate passing upward into more carbonate-dominated facies with only thin clastic laminae. The dominance of precipitated carbonate in this facies is shown in Fig. 16C, D and E, the latter being the sole example of precipitated carbonate in member W1. Disturbance by soft-sediment folding is nearly universal and the same combination of ductile and brittle behaviour of carbonate layers is shown (Fig. 16D and E) as in member W2. Figure 16B illustrates the development of a resedimented bed (Facies 5D) dominated by intraclasts, but with some poorly sorted sediment material, over a horizon with soft-sediment folds.

It is common for carbonate layers in Facies 5R to show irregular lamination or domal structures. Layers may be domed (Figs 15C and 16C) and up to centimetre-scale (Fig. 15F). Topography can be inherited from underlying layers (Figs 15F and 16C), and sometimes the base as well as the top of the layer is domed (Fig. 15C). Figure 15B displays both of these features in layers underlain by complex cement crusts with some remaining porosity. The crusts show neither botryoidal nor euhedral morphology and are composed of polycrystalline calcite mosaics in which each calcite shows the same zonation in CL. Some beds display only minor clastic debris (Fig. 15F) and there are even some more pure limestones with complex microstructures.

Petrographically, carbonate laminae can be regularly (rhythmically) developed, millimetre-scale in thickness. Laminae are often heterogeneous, and may be dolomitic, calcitic (Fig. 17A, B, D and F) or mixed mineralogy in composition (Fig. 17C). Where heterogeneous, laminae may show an increase in crystal size upward (Fig. 17A) or clotted textures of micrite within microspar. Under CL, both calcite and dolomite present coherent replacive fabrics (for example, Fig. 17F), in which crystals with identical zones grow throughout the fabric and enlarge into fenestrae. Rare examples of micritic rods around 10 to 20 μm in diameter, with minor associated pyrite, are reminiscent of calcified sheaths such as those found in the pre-Cryogenian Draken Formation in the study area (cf. Knoll et al., 1993), but are not as distinct. Millimetre-scale convexities on the upper bed surface are thrombolitic in texture (Riding, 2000) with irregular fenestrae (Fig. 17B). Clastic laminae tend to smooth the microtopography (Fig. 17A), whereas individual sand grains, dropstones or diamictite pellets can occur anywhere within the carbonate fabrics (Fig. 17D).

Trace element compositions of carbonate are similar to FA4. The limestone laminae in this facies association display a range of δ18O values from −5.6 to −12.8‰, with a mean of −9.2‰, and the δ13C values also display a large range from −2 to +3.5‰. Although the full range in δ13C is shown by member W2, values in member W3 tend to be lower (Fig. 12). Facies Association 5 dolomite δ18O ranges from −10.3 to +3.7‰, with a mean of −3.2‰ (Fig. 6B) and covaries with δ13C.

Common examples of crystal pseudomorphs occur in FA5, usually as subhedral to euhedral crystals, variably joined into confluent masses embedded within or apparently cutting across lamination (Fig. 18E, F and G). In some cases, trains of crystals are aligned along or concentrated within particular laminae. Size of indivi-
Continental glacial carbonates
dual crystals is similar within samples and ranges from 0 to 0.2 mm (Fig. 18F) to 1 to 3 mm (Figs 18B and 19A), the most common size being 0.5 to 1.0 mm (Fig. 18E and G). The range of cross-sections is dominated by four-sided or six-sided figures of crystals with equant to columnar habit. Pseudomorphs are equally likely to be developed in rhythms with prominent centimetre-scale pebbles. W3, South Klofjellet, 120 m. (D) Thin section in transmitted light of partly brecciated rhythmite with laminae up to centimetre-scale with interstitial ice-rafted sediment. Equant white areas a few millimetres across are mineral pseudomorphs. W3, East Andromedafjellet, 63 m. (E) Slump-folded 1 to 3 mm limestone rhythmite layers with interstitial green ice-rafted sediment. Scale is in centimetres. This is the only precipitated carbonate horizon in W1 (South Ormen, 3.5 m).

Although the within-sediment mode of occurrence is found in both members W2 and W3, the most spectacular, upward-growing crystals have only been seen at two levels in the South Klofjellet section of W3. A polished hand specimen (Fig. 19A) displays three distinct crystal horizons of which the upper two are shown in the photomicrograph of Fig. 18B. The crystals evidently grew freely upward and their terminations are draped by overlying sediment layers indicating
Fig. 17. Crystal fabrics in FA5. (A) Transmitted light. Millimetre-scale microbial calcite laminites separated by thinner ice-rafted laminae and locally containing till pellets (P). Calcite laminites display peloidal clots and local fenestrae and have variably bulbous tops. W2, Reinsryggen, 79·8 m. (B) Transmitted light. Similar horizon to (C) displaying clastic lamina overlain by clotted and fenestral microbial lamina with bulbous top. W2, East Andromedafjellet, 13·5 m. (C) Stained thin section, transmitted light. Dolomitic microbial laminites containing dolomicrite and dolomicrospar laminae and floating detritus (white). Conspicuous fenestrae are filled by pink-stained calcite. W2, South Ormen, 31·4 m. (D) Transmitted light. W2, Reinsryggen, 79·8 m, microbial fabrics. Faintly clotted (peloidal) micrite (examples arrowed) and microspar laminae with intervening calcite-filled fenestra. Dark patches are micro-till pellets (some are labelled ‘P’), now partly silicified. (E) Transmitted light, stained thin section. Enlargement of the ikaite pseudomorphs of Fig. 18B showing relic crystal outlines in dark micrite and replacive calcite (micro-)spar mosaic of zoned euhedral non-ferroan calcite overgrowth by ferroan calcite. W3, South Klofjellet, 116·5 m. (F) Paired transmitted light (left) and CL (right) images. Fenestral microbial fabric similar to (D) displaying consistent crystal zonation: brighter to duller in micritic matrix and sharper zones within fenestral cements. Fabric is consistent either with primary calcite growth within extracellular polymeric substance or replacement of ikaite, followed by cementation of fenestrae. W2, Reinsryggen, 80·6 m.

Note the small pink pebble to the left in the diamictite layer overlying the top crystal layer. Crystals grew upward at three horizons and were draped by overlying sediments before being replaced by calcite as illustrated in Figs 18D and 20A. W3, South Klofjellet, 116-5 m. (B) Examples of ‘thinolite’ crystals from Dana (1884), interpreted as ikaite pseudomorphs by Shearman et al. (1989). Scale not given in the original, but crystals are typically centimetre to decimetre-scale. (C) Profiles of ikaite crystals recovered from Arctic sea ice by partial melting (Nomura et al., 2013). (D) and (E) ikaite pseudomorphs from a Patagonian lake (Oehlerich et al., 2013). (D) Illustrates crystals with equant habit and stepped faces as seen by scanning electron microscopy. (E) Illustrates pseudomorphs attached to moss filaments.
that they formed at the sediment–water interface; they are variably drayed by carbonate (Fig. 18B) or poorly sorted sediment (wacke or diamictite). In the latter case, crystal faces are variably corroded at the contact (Fig. 18B and D). Measurement of the internal crystal angles (equal to 180° minus the apparent interfacial angle) in cut sections of this sample (n = 75) yielded two modes centred around 40 to 50° and 90 to 110° (Fig. 18C). Inspection of the crystal pseudomorphs which grew within sediment (Fig. 18E and G) is consistent with these results.

The pseudomorphs are typically preserved in the same mineral as the host carbonate, i.e. as dolomite or calcite. In some cases, the infilling phase is wholly cementing (Fig. 18E), whereas in others the variable internal fabrics point to a dominantly replacive origin (Fig. 18G). Such an origin is most evident for the upward-growing crystals where each is pseudomorphed in a mosaic of 20 to 100 μm calcite crystals, which in stained thin section show a non-ferroan core and a ferroan periphery (Figs 17E and 18D).

Interpretation
The lack of size-sorting in FA5 sediments indicates that they were laid down in a water body lacking significant current activity, but on unstable slopes as suggested by the soft-sediment folds, interpreted as slump structures. All transitions occur from disturbed and slump-folded Facies 5R to resedimented diamictites (Facies 5D, interpreted as debris flows) composed largely of Facies 5F blocks with some exotic clasts. The clastic sediment in Facies 5R is clearly glacially derived because it is invariably very poorly sorted, and contains diamictite pellets probably derived by ice-rafting (till pellets) and local ice-rafted clasts (dropstones). Gravel is present in thicker laminae. Also FA5 transitions vertically into stratified diamictites interpreted by Fleming et al. (2016) as representing more continous deposition from floating ice. In contrast, no distinct fine-grained sediment-gravity flows were observed, implying lack of proximity to fluvial input to the water body. The carbonate laminae commonly display evidence (thrombolitic domal growth morphology and complex microstructures) of a microbial origin (Fairchild, 1991; Riding, 2000), including much evidence for in situ carbonate precipitation, coupled with incorporation of some siliciclastic sediment. A combination of photosynthesis and favourable nucleation of carbonate within extracellular polymeric substance and dead cellular material present in microbial mats may have promoted carbonate precipitation (Riding, 2000; Bosak & Newman, 2003). However, in some cases, microbial structures are not apparent and carbonate laminae could be derived from settling of water-column precipitates.

The highly regular nature of the millimetre-scale carbonate–siliciclastic couplets, particularly in the thickness of the carbonate layers, is striking (Figs 15 and 16), and there are many modern and late Quaternary lacustrine analogues in which such couplets are annual, i.e. varves. Although there is no barrier to such sediments forming under marine conditions, photosynthesis raises carbonate saturation faster in low ionic strength waters than in seawater (Fairchild, 1991; Aloisi, 2008) and no modern marine analogues have been described. The dominant process creating carbonates in Alpine lakes is water-column photosynthesis from algal blooms (Kelts & Hsü, 1978) and this mechanism has guided many interpretations of late Quaternary varves, allowing the succession of events through the year to be inferred (e.g. Neugebauer et al., 2012). However, lakes vary greatly in their hydrology, internal structure, salinity and carbonate saturation state, leading to different patterns of carbonate production. For example carbonate mineral production may continue through to the autumn (Shanahan et al., 2008), or may partly depend on timing of input of ions from riverine input (Stockhecke et al., 2012). In some cases, winter freezing conditions may control carbonate input (Kalugin et al., 2013). Variations in redox conditions over time influence the preservation of varves in modern lakes, and in the case of the Gotland deep in the brackish Baltic Sea episodic oxygenation episodes may trigger a chain of events leading to characteristic Mn-carbonate layers superimposed on the annual pattern (Virtasolo et al., 2011). The absence of burrowing organisms in Cryogenian times led to continuous preservation of varve structure, but the Mn-chemistry of these carbonates is quite consistent (Fairchild et al., 1989; Bao et al., 2009) implying subdued redox fluctuations in the water body.

The crystal pseudomorphs also present important environmental evidence. The facies occurrence of these pseudomorphs argues against an evaporative origin. Although 18O-enriched dolomite samples indicate some evaporation, the oxygen isotope composition of most limestone and dolomites with pseudomorphs is typical for FA5 and lacks evidence for increased salinity,
implying that the primary crystals were carbonates. The very regular mode of replacement by calcite with internal crystal-growth zonation (Fig. 17E) indicates that the precursor was more soluble than calcite, but still capable of forming euhedra, and hence was crystalline rather than amorphous. Vaterite and monohydrocalcite can be ruled out because they invariably form spherulites or microcrystalline precipitates (Dahl & Buchardt, 2006; Pollock et al., 2006; Rodriguez-Blanco et al., 2014). Although aragonite typically forms mosaics of microcrystalline orthorhombic fibres, it is capable of forming radiating pseudo-hexagonal twinned ‘ray’ crystals of similar size to those seen in the present study (Fairchild et al., 1990; Riccioni et al., 1996). However, where six-sided cross-sections are seen in the Wilsonbreen Formation (Fig. 16E), they are often elongated rather than equant, and the most elongated crystals in cross-section show a pair of terminating faces, not a basal pinacoid characteristic of aragonite. Strontium content of Wilsonbreen rhythmites is also low, whereas it is typically high in formerly aragonitic limestones (e.g. Fairchild et al., 1990).

Ikaite is a high-pressure phase, metastable at Earth surface conditions, but becomes relatively more stable at cold temperatures (Kawano et al., 2009), and nearly always forms naturally at cool temperatures (−1.9 to +7°C, Huggett et al., 2005), on the sediment surface in spring-fed alkaline lakes and fjords and within marine sediment (Buchardt et al., 2001). It readily disintegrates to form calcite unless the solution contains an inhibitor for calcite precipitation. Bischoff et al. (1993) found that phosphate was most effective in this respect and indeed significant phosphate levels are typical of modern ikaite occurrences (Huggett et al., 2005; Selleck et al., 2007; Zhou et al., 2015). Ikaite is probably under-diagnosed as a primary phase (Shearman & Smith, 1985; Bischoff et al., 1993; Buchardt et al., 2001) as borne out by new discoveries such as within sea ice (Fig. 19C, Nomura et al., 2013) and as millimetre-scale crystals in cold lakes (Fig. 19D and E; from the Patagonian Argentinian Laguna Potrok Aike, Oehlerich et al., 2013).

Ikaite is a monoclinic mineral that varies considerably in habit, from equant (Sekkal & Zaoui, 2013) to elongate prismatic (Buchardt et al., 2001; Last et al., 2013) and the dominant crystallographic forms vary greatly, and may be stepped or curved (Shearman & Smith, 1985), which make its positive identification from morphology difficult. Most current knowledge comes from pseudomorphs, including the ‘bipyramidal’ aggregates of crystals known as glendonites (David et al., 1995; Fig. 18A), first found in shales associated with Permian glacial deposits and other cool-water environments and the ‘thinolites’ of Quaternary lakes of the western Great Basin, USA. The latter were detailed by Dana (1884) (Fig. 19B) and interpreted as ikaite pseudomorphs by Shearman & Smith (1985) and Shearman et al. (1989). Swainson & Hammond (2001) reinforced this identification following determination of refined lattice cell parameters of a = 8.8, b = 8.3 and c = 11.0 Å with angle β between ’a’ and ’c’ of 110°.

The pseudomorphs of the Wilsonbreen Formation are interpreted to represent a combination of forms. Prism and pinacoid forms meet at internal angles of 90° and 110° when cut at a high angle to the faces. This would account for the higher mode in the crystal angle distribution (Fig. 18C) and the common ‘rhomb’ shapes in section, similar to the crystals in Fig. 19C. Secondly the 30 to 60° mode is interpreted to represent the junctions between prismatic faces, such as those seen to terminate crystals in Figs 18A, 19B and E. It is notable that ikaite is only one-third as dense as calcite and so pseudomorphs in calcite would be expected to be initially highly porous even if the CaCO₃ was precipitated locally. This property is consistent with the styles of preservation observed (Fig. 16); Figs 17E and 18D compare well with examples in Larsen (1994), Huggett et al. (2005), Selleck et al. (2007) and Frank et al. (2008). An important corollary is that the replacive calcite mosaics more generally observed in FA5 (and FA4) limestones (Figs 15B and 17F) are also probably after ikaite.

Identification of presumably syngenetic ikaite replacement, and preservation of the crystal-growth zones in CL, supports the preservation of primary isotopic chemistry in FA5 (and FA4) carbonates. In the Wilsonbreen Formation as a whole, discussed above for FA2 and FA4, burial diagenetic calcite lacks Mn-enrichment and has δ¹⁸O of < −10‰. In FA5, the alternation with ice-rafted sediment implies temperatures consistently close to freezing. Hence, given the low δ¹⁸O signatures, the water body must have been fresh. Application of experimentally determined fractionation factors (Kim & O’Neil, 1997) extrapolated to 0°C, indicates that water compositions on the VSMOW (Vienna Standard Mean Ocean Water) scale are ca 2−7‰ higher than cal-

© 2015 The Authors. Sedimentology © 2015 International Association of Sedimentologists, Sedimentology, 63, 443–497
cite compositions on the VPDB scale, i.e. −8.3 to −15.5‰, and probably reflect mixing of different water sources. Dolomite facies have values on average 6‰ higher, implying formation from waters with higher salinity and higher mean Mg/Ca (Müller et al., 1972).

Many modern analogues for calcareous microbial laminae in cold lakes exist, including such extreme environments today as the ice-covered lakes of the McMurdo Dry Valleys of Antarctica (Parker et al., 1981) and reducing solution hollows beneath the Great Lakes (Voorhuis et al., 2012). One curious phenomenon is that of the thick cement crusts filling internal cavities found in both FA5 and FA2. A possible origin for these is the phenomenon observed in certain Antarctic lakes of the localized lifting of mats by gas generation (Parker et al., 1981). Early cementation of the mat would allow a more gradual fill of the resulting fenestrae as found in modern Antarctic lakes (Wharton et al., 1982).

In respect of seasonality, many well-studied modern lakes show a turnover associated with cooling in winter and may have a frozen surface during that season. In this case, winter sedimentation is typically dominated by clay and organic matter (e.g. Lauterbach et al., 2011; Kalugin et al., 2013), but both of these components are scarce in the Wilsonbreen Formation. In Antarctica, carbonate precipitation is linked to peak water column or microbial mat photosynthesis in late spring to early summer (e.g. Wharton et al., 1982; Lawrence & Hendy, 1985), limited also by nutrient availability. Higher sediment input would be expected in the late summer to autumn when ice cover was at a minimum.

Work on Antarctic stromatolites offers further clues as to the relationship between different microbial fabrics in the Wilsonbreen Formation. The first major mat-former to be identified (Phormidium frigidum Fritsch) is known to be pre-adapted to cold environments and low light conditions (Parker et al., 1981), and tolerates conditions from fresh to saline and anoxic to oxygen-saturated. Simmons et al. (1993) showed that this species is found not only in lakes, but also in glacial meltstreams, soils and cryoconite holes on ablated glacier surfaces, spanning the range of environments in which microbial deposits formed in the Wilsonbreen Formation. Voorhuis et al. (2012) found that a species of Phormidium also dominated the mat community at low oxygen levels in a 23 m deep Great Lakes sinkhole and demonstrated that species of this genus adapted to tolerate or even utilize sulphide for anoxygenic photosynthesis. It is therefore probable that the Wilsonbreen Formation microbial communities were of low diversity, as expected for extremophiles, with specialized cyanobacterial species dominating the biota.

**Vertical and lateral facies relationships**

Vertical facies transitions can be used to establish whether sedimentary successions have the Markov property of being randomly stacked or whether they have predictably cyclic properties (Powers & Easterling, 1982). A transition matrix derived from all of the logged W2 sections (Fig. S7) demonstrates that there are vertical transitions between all of the facies associations, except FA1/FA7, which are only found bounding W2 and not within it. This pattern indicates a stochastic element to the facies accumulation, but there are clearly also preferred transitions. Although data are insufficient for formal statistical analysis, the relative number of transitions is a useful guide since total occurrences of each facies association are similar (Fig. 20). Two sets of the most common transitions concur with the interpretations made earlier. Firstly, fluvial channels (FA2) most commonly pass upward into floodplain sediments (FA3) and vice versa. Such a close relationship would not be expected if FA2 was marine. Secondly, calcareous lake sediments (FA5) pass into FA6 (glacilacustrine) and vice versa (and this is also the dominant pattern in member W3). This relationship emphasizes the transitional nature of change between major amounts of floating ice and reduction in ice sufficient to permit carbonate accumulation in microbial mats. Other transitions, such as those between ice-rafted sedimentation (FA6) and floodplain and lake-marginal sediments (FA3 and FA4), would require more sudden changes in lake level.

Regarding lateral relationships, overall, the Northeast Greenland – north-east Svalbard Neoproterozoic sedimentary basin is envisaged as elongate, with basement exposed in the far south-west of the Greenland sections and an overall NNE–SSW orientation (Fairchild & Hambrey, 1995). Palaeocurrent data from Wilsonbreen Formation subglacial diamictites and associated grounded ice phenomena demonstrate glacier movement flow axially (to the NNE, Fleming et al., 2016).
ment is consistent with the orientation of a thick grounding line fan in the Draocisen section (Fig. 1 and Fleming et al., 2016). Within member W2, however, the facies mosaics do not illustrate this overall pattern so clearly. Figure 21 illustrates the cumulative thickness of each of the facies associations and demonstrates that there is no simple north–south spatial trend in facies within W2, except perhaps for the high incidence of fluvial facies (FA2) in the southernmost section. Such a complex facies mosaic implies that water and sediment are derived from multiple sources.

**SIGNIFICANCE OF THE WILSBONBREEN FORMATION**

Consistency of environmental conditions and climate

This section assesses whether the Wilsonbreen Formation environments can be considered as a coherent whole and hence be interpreted via modern analogues as a single climatic setting. The sedimentological evidence clearly points to syn-glacial carbonate deposition in FA5: ice-rafted sediment and ikaite formation. Facies 4R and 4I show similar types of carbonate accumulation, and localized dropstone deposition, but also evidence of reworking by waves in shallow-water. Facies Association 3 evinces a hyperarid terrestrial environment that nevertheless borders accumulation of microbial tufas in streams with regularly fluctuating discharge (Facies 2S). Facies 4S evokes a landscape with significant aeolian sediment transport. All of these facies are consistent with a cold, arid terrestrial environment. It is notable also in the South Ormen section of member W3 that a dolocreted sandstone bed (FA3, Table 2) lies within a thick diamicrite of FA6 (Table 2), indicating that the climatic aridity persisted, despite the dominance of deeper lakes with extensive ice-raifting within W3. All of these facies have little resemblance to standard Neoproterozoic facies found between glaciations (Fairchild, 1993).

Other important evidence is provided by the sulphate isotope systematics (Bao et al., 2009; Benn et al., 2015), demonstrating that throughout deposition of all the carbonate facies in W2 and W3, atmospheric PCO2 was very high, in spite of glacial conditions. This paradox is explained by climate simulations of a Snowball Earth, that is, a planet that is experiencing extreme glaciation caused by runaway ice-albedo feedbacks and linked to CO2-hysteresis. Modelling clearly demonstrates that glaciation must be initiated at low PCO2 (0-1 to 1-0 mbar, Pierrehumbert et al., 2011) but can only be terminated at high PCO2 (>20 to 100 mbar, Benn et al., 2015). Modelling of continental environments with the Wilsonbreen case in mind demonstrates that at sufficiently high PCO2, precession forces glacial advances in one hemisphere while retreats occur in the other hemisphere (Benn et al., 2015). The climate remains uniformly cold, changing primarily in terms of the accumulation of snow and ablation...
of snow and ice. Because continental ice volume changes little, eustatic sea-level change would not be expected, but a large sea-level rise would occur at the end of Snowball Earth glaciation. Once warm, ice-free conditions were re-established, glacial conditions could not return without a necessarily slow (multi-million year) fall in PCO₂ (Le Hir et al., 2009). Consequently, fluctuations between non-marine and marine conditions in the Wilsonbreen Formation are not anticipated unless there were local isostatic effects (and basin subsidence effects) strong enough to overcome the consequences of a fall in sea-level of several hundred metres (Creveling & Mitrovica, 2014). A distinct marine transgression is clearly reflected in the basal part of the overlying Dracoisen Formation with a locally conglomeratic base passing up into storm-dominated sediments and then offshore shales (Fairchild & Hambrey, 1984; Halverson et al., 2004). The absence of such facies or other evidences of marine conditions in the Wilsonbreen Formation indicates that during its deposition isostatic depression by neighbouring ice sheets was much smaller than eustatic sea-level fall due to build-up of ice (Benn et al., 2015). In summary, the Wilsonbreen facies consistently reflect a mosaic of arid terrestrial environments subjected to glacial advances and, hence, in principle can be calibrated against modern analogues as a single climatic-environmental system.

Interpretation of stable isotopes and their covariation

The interpretation of stable isotopes is simplified by several factors following from the above: (i) the same overall environment and climatic setting is represented throughout the period of carbonate deposition in the Wilsonbreen Formation; (ii) stable minerals were formed either as primary precipitates or by early diagenetic replacement of other carbonates; and (iii) the possible impact of variation in depositional temperature, or minor post-depositional exchange, are small compared with the very wide range of δ¹⁸O values. Hence, the stable isotope data can be taken as direct indicators of depositional conditions and the variation in δ¹⁸O in carbonates interpreted to reflect that of the depositional waters (Fig. 22). The δ¹³C signature is linked to acquisition of carbon from bedrock and oxidation of organic sources and variable equilibration with atmospheric carbon dioxide, whereas variability in δ¹⁸O is interpreted as due to differ-

ing snow and ice compositions and mixing of resultant meltwaters, coupled with evaporation. The interpretation herein (Fig. 22) is aided by observation of modern processes in the McMurdo Dry Valleys and other cold settings.

A potential organic source in the Dry Valleys is the periodic flushing of cryoconite holes on the glacier surface, which provide nutrients for ephemeral streams and lake basins (Bagshaw et al., 2013). Addition of respired carbon from this source can be seen in the chemistry of some streams with δ¹³C values as light as −9.4‰ (Lyons et al., 2013). Most Dry Valley stream values are −3 to +2‰, possibly reflecting carbon contribution from a carbonate source rock (cf. Leng & Marshall, 2004) and ranging up to +5‰, which Lyons et al. (2013) attributed qualitatively to progressive equilibration with atmospheric CO₂. Chemical equilibration between atmospheric CO₂ and an Alpine meltwater was shown to be attained within a few hundred metres of flow (Fairchild et al., 1999), although this situation falls short of isotopic equilibration, requiring more extensive exchange until the large gaseous source of carbon dominates (Fairchild & Baker, 2012, chapter 5). In Dry Valley lakes, more efficient processes for modifying δ¹³C are found: vertical trends caused by water-column photosynthesis at shallow depths (leading to positive values of δ¹³C), organic matter oxidation (causing a decrease in δ¹³C with depth) and local methanogenesis (releasing CO₂ with complementary high δ¹³C values at depth) have been described (Lawrence & Hendy, 1985; Neumann et al., 2004). Cold lakes in other settings can sometimes develop very low δ¹³C values through release of methane from solid hydrates (Propenko & Williams, 2005).

Gooseff et al. (2006) summarized data on δ¹⁸O variation for glacier ice, snow, streams and lakes in the Dry Valleys, although interpretation was complicated by strong inter-annual variations. In Taylor Valley the mean composition of glacier ice in each sub-basin feeding a specific lake varied from −21 to −33‰ and some samples were as light as −45‰. Stream samples varied from −42 to −22‰ and lay close to the meteoric-water line up to −32‰, but diverged from it at higher values, reflecting the consequences of evaporation in streams longer than 2 km. In addition to simple surface evaporation, mixing with isotopically heavy shallow subsurface (hyporheic) water was also a factor, indicative of the effectiveness of evaporation of subsurface water at a shallow-water table. Further isotope
fractionation occurs where water resides longer in saline lakes. Matsubaya et al. (1979) measured and modelled the δ18O-enrichments in the most saline ponds in the Dry Valley area and found up to 20%o higher values in the unfrozen Don Juan Pond and the east lobe of Lake Bonney compared with the source. Likewise, Nakai et al. (1975) documented a 23%o variation in δ18O composition of calcites with the highest values representing evaporative deposits on land surfaces. Such pronounced 18O-enrichments along streamcourses, and the ca 20%o total variation, are only permitted because of the meteorological factors leading to persistently low relative humidities of 50 to 60%.

For the ancient carbonates, it is useful to consider the presence or absence of covariance of δ18O and δ13C (Figs 7 and 22). Talbot (1990) compiled data from a variety of modern and ancient lakes and found that a lack of isotopic covariation is typical of open lakes in which controlling factors for the variation in the two isotopes are decoupled. This is typical of the limestones of FA4 and FA5 (Figs 7B and 23). Conversely, covarying trends in lacustrine carbonates (as in FA4 and FA5 dolomites) were identified as a characteristic feature of closed lakes and reflected a combination of evaporation to cause an increase in δ18O, and residence time, permitting equilibration with atmospheric CO2 as a first-order control on ultimate δ13C values. Although δ13C and δ18O data on Antarctic streams (Gooseff et al., 2006; Lyons et al., 2013) were obtained separately and so cross-plots are

not available, these environments too can be anticipated to display covariation. The slopes of covariation in the Talbot (1990) data were found to be quite varied, with lower slopes interpreted as reflecting broad, shallow lakes in which evaporation would play a more prominent role. The data were primarily from limestone and water-column precipitates, although examples were shown where benthic carbonate and dolomites fitted the trends. Apart from attaining high absolute values for $\delta^{18}O$ in FA3, the Wilsonbreen Formation carbonates show covarying slopes and ranges within those presented by Talbot (1990), providing a confirmation that the evaporation–equilibration explanation for data trends is reasonable.

Now the $\delta^{13}C$ values are interpreted: both where covariations are absent and at the starting points for covariation. The initial carbon isotope composition of a glacial meltstream may not reflect any atmospheric influence because many meltwaters derive from ice with low air content and have PCO$_2$ values well below atmospheric (Fairchild et al., 1994). The mean $\delta^{13}C$ of detrital dolomite in the Wilsonbreen Formation is $+2.4_{\text{iso}}$ (Fig. 6A), but with significant local variations ($\pm 1.3_{\text{iso}}$) and additional uncertainty because limestone appears to have preferentially dissolved from the matrix. A combination of moderately positive $\delta^{13}C$ from detritus and negative $\delta^{13}C$ values of organic carbon could have fixed the starting $\delta^{13}C$ value of around $+1_{\text{iso}}$ for the FA2 fluvial facies covarying trend. The higher starting point for FA3 reflects the more evolved nature of these floodplain surface fluids, which consistently formed dolomite. In contrast, the trend for FA4 and FA5 lacustrine dolomites starts at lower values of 0 to $+1_{\text{iso}}$ within the range of limestones. Carbon isotope signatures $<-1_{\text{iso}}$, that is lower than those in fluvial facies, presumably reflects addition of carbon from an organic source, but overall variations are not large enough to suggest a role for methanogenesis. In the open sections characterized by lack of isotope covariation (FA4 and FA5 calcite), the higher $\delta^{13}C$ values could reflect either the effects of photosynthesis or greater CO$_2$-equilibration, without evaporation. The most extreme high $\delta^{13}C$–low $\delta^{18}O$ limestones in FA4 are from member W3 (Fig. 12); these are intraclastic breccias implying possible exposure, which would have aided atmospheric equilibration. No difference is noted between obviously microbial and other limestones, a common pattern in the Neoproterozoic (Fairchild, 1991). Low $\delta^{13}C$ values occur in each studied section and are almost always stratigraphically close to values that are much higher, possibly indicative of changing lake levels. The FA5 sediments from W3 all have relatively low $\delta^{13}C$ values which might reflect a relatively deep water setting, consistent with the dominance of ice-rafted sedimentation in this member in the southern sections and the universal disruption of FA5 sediments by slumping.

Now the theoretical $\delta^{13}C$ end-point resulting from equilibration is considered. Carbonate precipitated from a solution in isotopic equilibrium with atmospheric CO$_2$ is expected to display $\delta^{13}C$ values heavier than the atmosphere by 10–40$_{\text{iso}}$ at 0°C (falling to 9–1$_{\text{iso}}$ at 20°C), as calibrated by the experimental work of Mook et al. (1974). The long-term (>10$^5$ year) $\delta^{13}C$ composition of the atmosphere should show variation largely in parallel with ocean water with which it tends to equilibrate, and ocean water in turn has a composition constrained by the proportional burial of isotopically light organic carbon. As a result, short-term variations can be expected because of flux variabilities, as demonstrated by direct measurement of past (pre-industrial Holocene) atmospheres from ice cores showing a range from $-6.3$ to $-6.6_{\text{iso}}$ (Elsig et al., 2009). A further mass balance constraint is the bulk Earth mean composition of carbon (Berner, 2004). The latter can be estimated from mantle and meteorite samples as around $-7_{\text{iso}}$, but volcanic gases are typically somewhat heavier (Javoy et al., 1986). An atmosphere with a composition around $-6_{\text{iso}}$ would be in equilibrium at zero degrees with carbonates around $+4.4_{\text{iso}}$.

The carbon dioxide level in the Snowball Earth atmosphere should have progressively risen because of sustained input from volcanic sources and limited removal, mainly by dissolution in the ocean wherever gaps in the ice cover occurred (Le Hir et al., 2008). The limited opportunities for back-exchange from the oceans imply that the atmosphere should have provided a good sample of the carbon isotope composition of volcanic emissions. For the W2 data, each of the facies association fields (Figs 12 and 22) tops out at around 3.5 to 4.5$_{\text{iso}}$ which is close to the expected values for equilibration with the atmosphere dominated by volcanic emissions as discussed above. Member W3 dolocretes have $\delta^{13}C$ values $1_{\text{iso}}$ higher than considered so far (Fig. 12), but this difference is difficult to interpret without an overall data trend. One possibility is that there is a local contribution by freezing, which Lyons et al. (2013) invoked to
explain $\delta^{13}C$ values in the range $+5$ to $+12\%_o$ on carbonate-encrusted rocks on the land surface of Dry Valley.

Equilibration would have been aided by evaporation, the extent of which can be deduced from $\delta^{18}O$ data. In FA2 limestones, the range of $\delta^{18}O$ is rather less than observed in the Dry Valley streams; both evaporation and variation in source water composition may be responsible for the variation in these compositions. Similar remarks apply to the dolomites of FA4 and FA5, although largely open lacustrine environments such as these are not found in the Dry Valleys. However, evaporation is clearly a powerful agent for FA3 and the slope of isotope covariation is lower, consistent with a surficial origin leading to more efficient evaporation (Talbot, 1990). Allowing for a 3% offset between dolomite and calcite (Lad, 1980), the evaporative trend (Figs 7B and 12) extends beyond the composition of fluvial limestones by a further 11% for dolocretes (Facies 3D) and 15% for stromatolitic laminites (Facies 3S). Evaporation of coastal sea-water, under typical high humidity conditions would cause an increase in $\delta^{18}O$ of at most 6%o, whereas a 17% increase from a $-10\%_o$ starting point was observed in a freshwater Texan pond under conditions of less than 50% humidity (Lloyd, 1966). The extreme enrichments in FA3 stromatolitic crusts require similarly low humidities to this example and the Dry Valleys, and could only be possible for facies developed at the land surface.

The FA4 and FA5 lacustrine calcites have lower $\delta^{18}O$ compositions than those of FA2 fluvial limestones. By analogy with modern environments, this probably reflects a local, low-altitude source of water for FA2, whereas the variability in $\delta^{18}O$ within FA4 and FA5 could reflect varying meltwater sources, including large glaciers with low $\delta^{18}O$. The range of $\delta^{18}O$ is actually rather less in FA2 than in the Dry Valley streams and, given that the values are typically heavier than for the lakes, a relatively local, low-altitude source for meltwater is implied. For the Carbonate Lake Margin FA4, the $\delta^{18}O$ values are similar to Carbonate Lake FA5 and there is a lack of isotopic covariation with both sets of data. This would imply an open lake (Talbot, 1990), but care is needed with such an interpretation because the data represent several different lakes that formed successively. As derived earlier, the range of $\delta^{18}O_{\text{water}}$ values implied from calcite precipitation at 0°C is around $-8.5$ to $-15.5\%_o$ on the VSMOW scale. This range might be explained by variable mixing of local snow, local glacier ice and melt from larger or higher glaciers, by analogy with the Dry Valley region.

The ultimate driver for Rayleigh fractionation in the atmosphere, which leads to $^{18}O$-depleted values in atmospheric precipitation, is partial condensation and removal of vapour as a result of a fall in temperature of the air mass. Inferred Wilsonbreen meltwater $\delta^{18}O$ values higher than those in the modern Dry Valleys implies a lesser degree of fractionation, as originally noted by Fairchild et al. (1989). A comparable modern glacial area for the Wilsonbreen in terms of $\delta^{18}O$ is the Vatnajökull ice cap of Iceland below which Robinson et al. (2009) found a representative icemelt and snowmelt composition of $-12\%_o$. Note that indirect evidence for more isotopically light Neoproterozoic meltwater has been found in two records from South China (Zhao & Zheng, 2010; Peng et al., 2013), although these do not necessarily relate to a panglacial and in the former case is a younger, Ediacaran glaciation. A more pertinent record is that of Kennedy et al. (2008) in calcite-cemented Marinoan tidal siltstones of South Australia where calcite as light as $-25\%_o$ was analysed, and interpreted to reflect input of meltwater from highly fractionated low-latitude ice sheets, although there may be other possible interpretations of these data bearing in mind the possible decomposition of clathrates at this site. In summary, the distinctively heavy isotopic signature of Wilsonbreen meltwater may be a characteristic feature of low-latitude glaciation which should prompt future studies by an isotope-enabled general circulation model.

**Similarities and differences with the McMurdo Dry Valleys**

The Wilsonbreen Formation represents a small part of a largely marine depositional basin-fill many kilometres thick, deposited over 300 Myr. The outcrop belt is orientated NNE–SSW, and the original basin may have been an intracratonic rift with a similar trend (Cawood et al., 2007) leading to the tabular nature of the Formation from north to south. The Dry Valleys region occupies a hinge between the uplifting Transantarctic Mountains and the rift-related subsidence of McMurdo Sound and Ross Sea (Etienne et al., 2007). Hence, both the ancient and modern basins have the capacity for long-term sediment accumulation, but in the short-term, rates of erosion and deposition will be
highly dependent on local geomorphic changes. Local topographic controls for the Wilsonbreen Formation, for example from lateral basin margins, are unknown.

The long-term record of the McMurdo Dry Valleys shows a progression from temperate ice in the early Cenozoic through to the cold, arid conditions that have held since the Pliocene (McKelvey, 1979; Barrett & Hambrey, 1992), associated with cold-based local glaciers. The Dry Valleys have been subject to out of phase advances of Taylor Glacier, an outlet glacier from the East Antarctic Ice Sheet (EAIS) and encroachment of the West Antarctic Ice Sheet from the Ross Sea. In contrast, it appears that the Wilsonbreen Formation was remote from any marine influence because of the extreme eustatic sea-level fall in the late Cryogenian. The subglacial phenomena (FA1) clearly require warm-based glaciers, as does the deposition of the thick waterlain diamictites of FA6 (Fleming et al., 2016). The complex facies interstratifications, even in members W1 and W3, imply a greater dynamism of Wilsonbreen Formation environments than those experienced in the recent history of the Dry Valleys. Nevertheless, in both cases, ice-damming is required to permit deep lakes to form, later to be replaced by exposed conditions. Such externally imposed changes in lake level or glacial advances and retreats would be superimposed on any intrinsic tendency for facies migration and are the most probable reason for the myriad vertical facies transitions and complex lateral geometries in the Wilsonbreen Formation. As argued above, the shifts in depositional style between members W1, W2 and W3 are probably a primary function of mean lake level rather than representing a fundamental change in climate or regional palaeogeography.

The high palaeolatitudes of the Dry Valleys ensures a high seasonality of temperature such that meltwater production is limited to a couple of months in summer. The Wilsonbreen Formation is thought to have lain in the sub-tropics (Li et al., 2013) where seasonality today primarily relates to moisture balance. This also applies in the late stages of a Snowball Earth, since general circulation modelling indicates that alternating seasons in which precipitation exceeds ablation in the summer and vice versa in the winter would have been a strong feature of the climate in latitudes 20 to 30° from the equator (Benn et al., 2015). The Snowball climate also has greatly enhanced diurnal and annual temperature variability at a given latitude compared with that of today (Pierrehumbert, 2005) because temperature responds directly to insolation, with less effective smoothing than today by lateral latent heat transport by moisture. The implications remain to be fully explored, but Benn et al. (2015) presented an indicative plot (fig. S15) demonstrating that, in the month of April, although mean temperatures remain below zero, lowland areas in the tropics and sub-tropics should experience a significant number of positive degree days when melting can occur. The overall effect is that open water in Wilsonbreen lakes was clearly extensive, at least seasonally.

This difference implies that there is no necessity for a permanent ice cover in Wilsonbreen Formation lakes and indeed the open water structures of FA4, and the extensive ice-rafting in FA5 and FA6 clearly shows this to be lacking. Hence, the mean annual temperature of the Wilsonbreen environment was presumably higher than the ca –20°C of the Dry Valleys. Nevertheless, a remarkable similarity is found in the range of oxygen isotope values. The initial isotope values of meltwater in Wilsonbreen times were more typical of modern sub-Arctic rather than polar regions, but this is argued to be caused by the peculiar conditions of Rayleigh fractionation in a warm atmosphere above ice sheets. The wide range caused by evaporation is comparable, caused by extreme evaporation driven by unusually low humidity.

Another latitude-related factor is the relative sensitivity to climatic change related to orbital forcing. While the Dry Valley region is susceptible to facies changes related to subtle environmental changes on inter-annual to millennial timescales (Hendy, 1980). The slowly depositing Elbobreen Formation, which underlies the Wilsonbreen Formation, shows the influence of orbital forcing in the development of 200 regular cycles in offshore marine sediments. In the Wilsonbreen Formation, Fig. 1 illustrates about ten intervals of cessation of glacial deposition, with uncertainties because of the thin and lensing (possibly eroded) intervals in W3 in particular. Accumulation rates of annually laminated carbonate facies, both fluvially (FA2) and in lakes (FA4/FA5) is of the order of 1 mm/year: hence such retreat phases represent minimum periods of 103 to 104 years since periods of non-deposition, due to lack of local accommodation space.
or sediment supply, are probable. Such timescales are approaching the present-day Milankovitch scale of climatic fluctuation, an observation which stimulated the modelling of precessional cycles in Benn et al. (2015). The effect of such cycles is to cause mirrored interhemispheric differences in ablation and accumulation linked to aridity/humidity, rather than significant temperature change, which is analogous to the modern Antarctic environment except that forcing on precessional timescales is a feature of low-latitude systems. Given that ca 20 kyr precession is greatly enhanced during higher eccentricity (on the 100 kyr timescale), the suggested interpretation of members W2 and W3 here is that they represent one or two eccentricity cycles, within each of which several precession-related fluctuations are recorded. Although this interpretation is plausible rather than demonstrable, the two basin-wide advances and retreats of terrestrial ice in the centre of the Wilsonbreen Formation (Fig. 1) provide strong evidence for major, orbitally forced facies change.

A final point of comparison is the carbonate mineralogy. Modern Antarctica has very little carbonate bedrock, but alkalinity is generated both by carbonate and silicate weathering, permitting carbonate precipitation, particularly in lakes, controlled by seasonal photosynthesis. By contrast, the Wilsonbreen Formation reflects the erosion of carbonate-rich catchments and calcite precipitation is recognized also in streams. Although limestone makes up 20% of the gravel fraction, dolomite is the only carbonate in the fine fraction of detritus because of preferential calcite dissolution, implying that unmodified molar Mg/Ca ratios will on average be less than one, although they will increase as calcite is reprecipitated within the basin. Data from streams and most lakes in the Dry Valleys also have Mg/Ca less than one, although extensive CaCO₃ precipitation in Lake Fryxell leads to enhanced Mg/Ca (Green et al., 1988) and presumably such waters were responsible for precipitation of aragonite in many late Quaternary lakes (Hendy, 1979). Rather than aragonite, ikaite is recognized as a precursor to calcite in the Wilsonbreen case. As noted earlier, modern examples of ikaite formation are associated with high aqueous phosphate, which inhibits calcite precipitation, and yet modern Antarctic lakes are oligotrophic. However, phosphate fluxes should be enhanced by glacial erosion in most cases and Planavsky et al. (2010) argued for a glacially induced nutrient surplus following Neoproterozoic ice ages. However, Burton (1993) stressed that there are a wide range of aqueous inhibitors for calcite precipitation. A circum-neutral pH would be expected in Wilsonbreen waters because of high atmospheric PCO₂, which has the effect of increasing the ratio of HPO₄²⁻ to PO₄³⁻ thus strengthening the phosphate-inhibition effect on calcite. The effect is also accentuated by high sulphate (Burton, 1993) which is exceptionally high in Wilsonbreen carbonates (Bao et al., 2009). Modern dolomite has not yet been recognized in Antarctica, yet it is common in the Wilsonbreen facies, apparently aided by factors such as evaporation and fluctuating redox, and possibly also the widespread occurrence of dolomitic rock flour as nuclei.

**CONCLUSIONS**

1. Carbonate in the Wilsonbreen Formation confirms the non-marine environment of deposition in a glaciated basin supplied with debris from erosion of platform carbonates. The consistently dolomitic nature of the detrital matrix of Wilsonbreen Formation sediments contrasts with the common presence of limestone in coarser debris and demonstrates the preferential dissolution of calcite over dolomite. Carbonate-rich meltwaters were thus able to precipitate CaCO₃ once supersaturation was achieved by processes such as photosynthesis or evaporation.

2. Evidence from physical sedimentary structures allows four facies associations to be distinguished in which carbonate was precipitated, distinct from three facies associations dominated by glacial and periglacial processes. The Fluvial Channel Facies Association (Facies Association 2; FA2) commonly contains microbial limestone laminae with millimetre-scale lamination and notable syn-depositional radiaxial calcite cements; these compare physically with modern microbial mats in ephemeral Antarctic streams. The Dolomitic Floodplain Facies Association (Facies Association 3; FA3) consists of soil zone/playa surficial dolocretes and dolomiticstromatolites in which dolomite was probably a primary precipitate. The Carbonate Lake Margin Facies Association (Facies Association 4; FA4) typically displays micritic and locally microbial laminae interlaminated with wave-sorted silts and sands with local development of intraclastic breccias. Finally, the Carbonate Lake Facies Association (Facies Association 5; FA5) displays millimetre-scale (varved) alternations of micritic carbonate or laminated microbial carbonate (including
microsparitic and fenestral laminae) with poorly sorted sediment containing recognizable icerafted debris. Locally in member W2, and pervasively in member W3, partly lithified sediments were disturbed by slump folding and locally transformed to carbonate-rich debris flows.

3 In both FA4 and FA5, there are textural indicators of mineralogical replacements. Dolomite can be seen to replace a CaCO₃ precursor. Although some calcite is likely to be primary, calcite pseudomorphs after ikaite (CaCO₃·6H₂O) are common. The ikaite formed individual crystals within the sediment, formed crusts which grew centripetally into pores, and locally grew upward at the sediment–water interface. This paragenesis is now becoming better known in modern cold lakes.

4 Stable isotope data demonstrate that carbonates in the different facies associations form distinct fields that are all interpreted as consistent with primary depositional conditions. Limestones in FA4 and FA5 lack δ¹³C–δ¹⁸O covariation and were primarily influenced by mixing of meltwater sources, the variable addition of light carbon from organic decomposition, and some re-equilibration with the atmosphere. Other sub-sets demonstrate covariation, interpreted as a combination of evaporation and equilibration with the atmosphere. This allows the δ¹³C composition of CO₂ released from volcanism during the glaciation to be constrained to −6 to −7‰. Direct evidence of primary fluid compositions is unavailable because of secondary fluid migration into inclusions, despite the presence of primary trace element growth zones. Nevertheless, the very wide range of δ¹⁸O values must be primarily related to changes in water composition, given the consistently cool depositional conditions. The exceptionally high δ¹⁸O signatures of FA3 dolomites, up to +14.7‰ (VPDB), attest to the hyperaridity of the environments. Conversely, the inferred δ¹⁸O compositions of the input meltwaters (−8 to −15‰, VSMOW) are more comparable to modern Iceland than to present-day polar regions, which is likely to reflect relatively limited Rayleigh fractionation in the atmosphere, because of its relative warmth, linked to enhanced absorption of infra-red radiation from high CO₂ levels.

5 Although preferred vertical facies transitions occur, there is no development overall of multifacies cyclicity. The strong isotopic covariations associated with closed lakes and streams, and rhythmic carbonate laminae are strong motifs of non-marine facies. In these environments, the landscape was repeatedly transformed by damming and draining of lakes as the glaciers advanced and retreated. In turn, these are likely to have represented amplified geomorphic responses to subtle climatic shifts in a persistently hyper-arid setting, for which the McMurdo Dry Valleys provide a rich modern analogue. Although Wilsonbreen lakes were not perennially ice-covered, as in the modern environment, many points of similarity between the modern Antarctic and the ancient environments have been drawn in this study, specifically including the rates and styles of sediment deposition, biogeochemistry and extreme ¹⁸O-enrichment related to the hyperarid climate.

6 The carbonates of the Wilsonbreen Formation are distinctive and include unique facies and record-breaking isotope compositions. They represent, along with interbedded diamictites, the complex environmental response to changing rates of accumulation and ablation of snow and ice, likely to have been forced by a series of precessional cycles late in the evolution of a Snowball Earth.

ACKNOWLEDGEMENTS

The fieldwork and subsequent analyses were funded by Natural Environment Research Council grant GR3/NE/H004963/1 within project GAINS (Glacial Activity In Neoproterozoic Svalbard). We are grateful to the Norwegian authorities in Svalbard and the logistical department of the University in Svalbard in facilitating our fieldwork, and other members of the GAINS team for their collegiality and scientific zest. The senior author records his personal appreciation to Paul Hoffman for his inspiration and support for this project at a critical stage, to Martin Kennedy for his friendship and rigorously critical feedback on Neoproterozoic data and ideas, and to Tony Spencer for his insight and careful editorial comments on a draft. Journal referees, including Alex Brasier and Kristin Bergmann, gave invaluable advice leading to significant improvements in the paper.

Supplementary Information

Additional supplementary information may be found with the online version of this article:
Figure S1. Profile of Member W2 at Ditlovtoppen (DIT). See Fig. 4 for key. 
Figure S2. Profile of Member W2 at S Ormen (ORM). See Fig. 4 for key. 
Figure S3. Profile of Member W2 at E Andromedafjellet (AND). See Fig. 4 for key. 
Figure S4. Profile of Member W2 at Reinsryggen (REIN). See Fig. 4 for key. Dolomite analyses at 83 m are of dolocrete clasts in diamicrite. 
Figure S5. Profile of Member W2 at S Klofjellet (KLO). See Fig. 4 for key. 
Figure S6. Profile of Member W2 at the Backlundtoppen-Kvitfjellet ridge (BAC). See Fig. 4 for key. The upper part of W2 lacks precipitated carbonate, but is correlated with other W2 sections as shown in Fig. 1 by the presence of shallow lake sediments with wave ripple lamination, inferred to be shallow lake deposits, in the 105 to 110 m interval. 
Figure S7. Transition matrix which summarizes the vertical transitions in member W2 from one facies association with another. The upper part of W2 at sections BAC includes non-calcareous shallow lake deposits that are not included in these data. 
Figure S8. Results of stable isotope analysis of fluid inclusions from W2 carbonates. A. Cross-plot of hydrogen versus oxygen isotopes illustrating that fluid inclusions do not lie along a meteoric water line. B. Cross-plot of δ^{18}O in water versus δ^{18}O in the carbonate phase to illustrate that most samples have water that is too heavy to have precipitated the carbonate at earth surface temperatures. Dolomite values have been adjusted by −3‰ for comparison with calcite. Equilibrium precipitation lines are calculated from the experimental data of Kim and O’Neil (1997) for calcite. C. Cross-plot of the volume yield of inclusion water per mass of carbonate versus the δ^{18}O composition of the fluid inclusions. There is no relationship. See text for discussion. 
Data S1. Fluid inclusion stable isotope analysis. 
Table S1. Excel file containing all numerical data in stratigraphic order and originals for stratigraphic data plots.
