Abstract The transition to turbulence in flows where the laminar profile is linearly stable requires perturbations of finite amplitude. “Optimal” perturbations are distinguished as extrema of certain functionals, and different functionals give different optima. We here discuss the phase space structure of a 2-d simplified model of the transition to turbulence and discuss optimal perturbations with respect to three criteria: energy of the initial condition, energy dissipation of the initial condition and amplitude of noise in a stochastic transition. We find that the states that trigger the transition are different in the three cases, but show the same scaling with Reynolds number.

Keywords: Transition to turbulence, shear flows, noise driven, optimal initial conditions

INTRODUCTION

In parallel shear flows like pipe flow, plane Couette flow or Poiseuille flow and in boundary layers like the asymptotic suction boundary layer or the Blasius profile, turbulence appears when the laminar profile is linearly stable against perturbations \cite{1}. Accordingly, finite amplitude perturbations are required to trigger turbulence, a scenario referred to as by-pass transition \cite{2}. Many studies in the above flows have shown that the transition to turbulence is associated with the presence of 3-d exact attractors or saddles are formed \cite{5,6}. Initial conditions can only trigger turbulence when they reach into that interior region, i.e. cross the stable manifold of the saddle state on the boundary of the region \cite{8}. An “optimal” perturbation is one that can trigger turbulence and at the same time is a minimum of a prescribed functional. Popular is an optimization based on amplification or energy gain over a given interval in time \cite{9–17} or on the total time-averaged dissipation \cite{18,19}. Because they take the time-evolution into account, they connect to optimization problems in control theory \cite{20,21}.

We simplify matters here and focus on a geometric optimization by identifying initial conditions that will eventually become turbulent, without regard of the time it takes for them to become turbulent. The states are optimized so that a certain quadratic function, such as energy content or dissipation, is extremal: it is a maximum in the sense that all initial conditions with a lower value of the quadratic function will not become turbulent, and it is minimal in that the first initial conditions that become turbulent have values larger than this optimum. At the optimal value there will then be at least one trajectory which neither becomes turbulent nor returns to the laminar profile: it lies on the stable manifold of the edge state \cite{8}, so that the optimum is reached when the iso-contours of the optimization functional touch the stable manifold of the edge state (similar descriptions of the state space structure can be found in \cite{14,16,22,23}).

THE MODEL

To fix ideas and to keep the mathematics as simple as possible, we take the 2-d model introduced by Baggett and Trefethen \cite{24}. The model we use is one of a set of many low-dimensional models of various levels of complexity \cite{20,22,23,24,51}. It has a non-normal linear part and an energy conserving nonlinearity, and, this being the most important feature for the present application, it is 2-d so that the entire phase space can be visualized (a property it shares with the illustrative model of \cite{20}). Despite its simplicity, the model can be used to illustrate several features of the transition mechanisms in shear flows.

The model has two variables, which may be thought of as measuring the amplitudes of streaks $x$ and vortices $y$ (see also \cite{32}), and one parameter $R$ that plays the role of the Reynolds number:

$$\dot{x} = -x/R + y - y\sqrt{x^2 + y^2}$$ \quad (1)
$$\dot{y} = -2y/R + x\sqrt{x^2 + y^2}$$ \quad (2)

In order to highlight more clearly what happens near the origin, we magnify by rescaling the variables with the Reynolds number $R$ (see \cite{32}), i.e. we redefine the amplitudes $x = x'/R^2$, $y = y'/R^2$ and the time $t = R't$ such that (with the primes dropped)

$$\dot{x} = -x + Ry - y\sqrt{x^2 + y^2}/R$$ \quad (3)
$$\dot{y} = -2y + x\sqrt{x^2 + y^2}/R$$ \quad (4)

Time evolution under the nonlinear terms alone preserves $x^2 + y^2$, which may be thought of as a kind of energy, so that the nonlinear terms are “energy” conserving. For $R < R_c = \sqrt{8}$ the only fixed point is $x = y = 0$, henceforth referred to as the “laminar” fixed point. At
Fig. 1. State space of the 2-d model for the transition to turbulence for $R = 3$. The open symbols mark the stable fixed point at the origin (“laminar” state) and the two nodes from the bifurcation (“turbulent” states). The full symbols are the edge states, and the red lines indicate the stable manifolds of the edge states. The black circle and the grey ellipsoid indicate the states where the energy (7) and the noise functional (12) are minimal, respectively. The points where they touch the stable manifolds are indicated by stars.

$R = R_c$, symmetry related fixed points appear at $(x_c, y_c)$ and $(-x_c, -y_c)$, with

$$x_c = R(2R \pm 2\sqrt{R^2 - 8})/D_\pm$$
$$y_c = R(R^2 - 4 \pm R\sqrt{R^2 - 8})/D_\pm$$

where $D_\pm = \sqrt{8 + 2R^2 \pm 2R\sqrt{R^2 - 8}}$. The two fixed points closest to the origin are unstable, hence are saddle states, and the two further out are stable and hence nodes. The saddle states are the “edge states” and the node states are in the regions where turbulence would form, if more degrees of freedom were available. Nevertheless, we will refer to them as the “turbulent” states.

As $R \to \infty$, the saddles are to leading order in $1/R$ located at $\pm (2, 2/R)$, which in the original coordinates represents an approach to the origin like $\pm (2/R^2, 2/R^3)$. The stable manifolds rotate so as to become parallel to the $x$-axis, as we will see in the following.

**OPTIMAL INITIAL CONDITIONS OF MINIMAL ENERGY**

The Euclidean distance to the origin can be obtained from a quadratic form

$$E = (1/2)(x^2 + y^2)$$

which has the form of a kinetic energy. This assignment is further supported by the observation that $E$ is preserved under time evolution by the nonlinear terms alone. In the sense described in the introduction, optimality with respect to this energy functional thus means the largest value up to which all trajectories return to the laminar state, and the smallest one where the first trajectories that evolve towards the turbulent state become possible.

On the boundary between these two cases are states that neither return to laminar nor become turbulent, that lie on the stable manifold of the edge state. Geometrically, we are thus looking for the circle with largest radius that we can draw around the origin that just touches the stable manifold. Algorithmically, we find this point by a modified edge tracking which minimizes the energy as described in the appendix.

An example of such an optimal circle is given in Figure 1, and its variation with $R$ is shown in Figure 2. As the Reynolds number increases, the fixed point moves towards $(2, 0)$ on the abscissa, and the stable manifold rotates to being parallel to the abscissa. The point of contact between circles of equal energy and the stable manifold moves away from the edge state, approaches the $y$-axis and moves inwards to the origin like $1/R$.

In an insightful discussion of the energy functional, Cossu [23] notes that in the time-derivative of the energy functional only the linear parts of the equations of motion remain and that the nonlinear ones drop out because energy is preserved. This observation allows to define a necessary condition for the location of the extremum, which for the two-dimensional example studied here implies that the optimum lies along the line connecting the laminar and the turbulent fixed points. One could then find the optimum by a one-dimensional search along this line. However, we did not pursue this further, as we also want to find optima with respect to other functionals that are not preserved by the nonlinear terms.

**OPTIMAL INITIAL CONDITIONS OF MINIMAL ENERGY DISSIPATION**

The diagonal terms in the linear part of the equations of motion correspond to the dissipation in the original Navier-Stokes equation. Accordingly, we can define a dissipation functional

$$\epsilon = (1/2)(x^2 + 2y^2).$$
and study initial conditions that are minimal or optimal with respect to this functional. As in the previous example, the geometrical condition is that we now have to find the point where an ellipse touches the stable manifolds. This gives the ellipses shown for different $R$ in Figure 3. Note that the points where the ellipses touch the stable manifolds are different from the ones of the energy functional, but their asymptotic behaviour for large $R$ seems to be similar (see below).

**OPTIMAL NOISY TRANSITIONS**

As a third example we consider noise-driven transitions. To this end, the equations of motion are expanded to include a stochastic forcing of the individual terms,

\[
\begin{align*}
\dot{x} &= -x + Ry - y\sqrt{x^2 + y^2}/R + \xi_x \\
\dot{y} &= -2y + x\sqrt{x^2 + y^2}/R + \xi_y
\end{align*}
\]

(9) (10)

where the noise is characterized by $\langle \xi_i \rangle = 0$ and $\langle \xi_i(t)\xi_j(t') \rangle = D_{ij}\delta_{ij}$. We consider the case $D_{11} = D_{22} = D$, so that both components are driven with equal noise amplitude. In a linear approximation around the laminar fixed point, the non-normal coupling between the two components results in a probability density function (pdf) for the two components that is Gaussian with a covariance matrix given by

\[
p(x, y) = \frac{1}{\pi D\sqrt{\text{det}(Q)}} \exp\left(-\frac{Q_N(x, y)}{D}\right)
\]

(11)

with

\[
Q = \frac{1}{2(R^2 + 9)} \begin{pmatrix} 9 & -3R \\ -3R & 3R^2 + 18 \end{pmatrix}
\]

(12)

and

\[
Q_N(x, y) = x^T Q x
\]

\[
= \frac{3}{2(R^2 + 9)}(3x^2 - 2Rxy + (R^2 + 6)y^2)
\]

(13) (14)

Asymptotically, for $R \to \infty$, the quadratic form becomes $Q_N(x, y) \to 3y^2/2$, so that the Gaussian stretches out along the $x$-direction for increasing $R$.

In the noisy case, transition is induced when a fluctuation carries the system across the stable manifold. A good estimate of the likelihood of transition can be obtained by considering the probability density at the transition point. Given the functional form of the pdf, the biggest contribution to its variations comes from the quadratic form in the exponent. The equation shows that the iso-contours $p = \text{const}$ are ellipsoids determined by $Q_N = \text{const}$ that decrease or increase with the noise.
It can be seen that the iso-contours touch the stable manifold of the edge state. The star indicates the point where the noise functional $Q$ touches the stable manifold. Here more than 75 points lay in the interesting region of phase space. We note that the shape of the iso-contours of the pdf is independent of the noise amplitude $D$ (within the linear approximation), so that changes in $D$ will predominantly influence the likelihood of a transition, but not the path it takes.

Fig. 4. Probability density for the linearized equations with noise for $R = 6$ in the region of phase space where the transition is expected to occur. For the statistics we calculated the time evolution of $20000$ initial conditions starting at the laminar state for 20 time units with a step size of $dt = 10^{-3}$. It can be seen that the iso-contours $p = \text{const}$ are of elliptical shape. The star indicates the point where the noise functional touches the stable manifold of the edge state.

More examples of such iso-contours are shown in Figures 4 and 5 for different values of $R$. With increasing $R$ the ellipsoids become more elongated in $x$-direction, as a result of the asymptotic behaviour of the quadratic form noticed above (14). As they are rotated in the direction opposite to the rotation of the stable manifolds, the point of contact stays close to the edge state. Within the hydrodynamic interpretation, the transition is dominated by the streaks $(x$-component) that form as a result of the vortices $(y$-component), not by the vortices themselves.

Fig. 5. Probability density as in Figure 4 but for the full nonlinear equations with noise. Note that the iso-contours of equal probability are stretched out towards the turbulent state and that they cross the stable manifold close to the point of contact indicated as the optimal state.

The calculations illustrate how different optimization criteria select different optimal initial conditions for the transition to turbulence. Geometrically, this is to be expected since different quadratic forms give rise to different ellipsoids in their iso-contours and hence also different points of contact with the stable manifolds. We note that the results of [13] suggest that for optimization with a time-integrated functional the difference between energy and dissipation functionals are smaller and may actually vanish. However, we have not pursued this question further.

The variation of the optimal points of contact is summarized in Fig. 7. The data indicates that while the optimal perturbations are vortex like for the energy and the dissipation functional, they are streak like for the noisy transition. The difference can be rationalized by the different dynamics. In the deterministic cases, with the energy and the dissipation functional, small vortex like initial conditions can grow in time to develop the streaks which then drive the transition. The noisy system is always exposed to small perturbations which can grow to develop streaks, so that the pdf is elongated in

**SUMMARY AND CONCLUSIONS**

The variation of the optimal points of contact is summarized in Fig. 7. The data indicates that while the optimal perturbations are vortex like for the energy and the dissipation functional, they are streak like for the noisy transition. The difference can be rationalized by the different dynamics. In the deterministic cases, with the energy and the dissipation functional, small vortex like initial conditions can grow in time to develop the streaks which then drive the transition. The noisy system is always exposed to small perturbations which can grow to develop streaks, so that the pdf is elongated in...
Fig. 6. Isocontours of the probability density function for different $R$. Note that as $R$ increases, the ellipsoids of the isocontour become narrower in the $y$-direction and stretch out along the $x$-direction. In combination with the rotation of the stable manifolds (red lines) the point of contact (stars) now stays close to the edge state (full symbols) and moves towards the $x$-axis. This is physically plausible, as a small perturbation in $y$ (in the vortex direction) will produce a strong streak in the $x$-direction, and it is then the streak that triggers the transition.

Fig. 7. Location of the points of contact. The top graph shows that for the energy and dissipation functional the optimal perturbations are vortex like and move towards the origin along the $y$-axis. The noise-optimals are more streak-like and move towards the $x$-axis, and actually remain close to the edge state. The edge state (red bullets) approaches $(2,0)$ as $R \rightarrow \infty$.

Fig. 8. Scaling of the functionals for the optimal perturbations. Even though the point of contact moves differently, the critical values decay like $1/R^2$ in all three cases.
to elucidate many features of the transition to turbulence in shear flows, and to develop tools to explore them. It is in this spirit that we have used a forward integration technique to find the optimal points on the stable manifolds for different functionals and to explore the changes with Reynolds number. We expect that many of the features described here can also be found in the high-dimensional state spaces of realistic shear flows, perhaps after suitable modifications and adaptations of the methods used to explore the high-dimensional spaces.

**APPENDIX**

In this appendix we discuss the modification of the edge tracking algorithm used for the determination of the initial conditions on the edge that optimize a prescribed quadratic functional $Q_N(x, y)$. The functional may be the energy, the dissipation or the argument in the pdf. To keep the notation compact, we denote the equations of motion in vectorial notation as $\dot{x} = f$.

We begin with an arbitrary initial condition in the vicinity of the edge and we let it evolve in time towards the edge state. Unlike other edge tracking methods, where trajectories are integrated until they are sufficiently close to the laminar or the turbulent state, we here stop the integration at the time when the distance to the edge state is minimal. The trajectory’s velocity at the turning point is then projected onto the normal of the stable eigenvector to decide if the tested initial condition moves upwards or downwards, towards the turbulent or the laminar state. With this criterion we can determine a point $x_0$ on the edge also when the point is very close to the edge and the time needed to pass the edge state becomes excessively large.

We then propagate this point along the time direction, $x_1 = x_0 + s f(x_0)$ by an amount $s$ that is chosen such that $Q(s)$ is minimized. Formally,

$$s = -\frac{f^T(x_0) Q x_0 + x_0^T Q f(x_0)}{2 f^T(x_0) Q f(x_0)}.$$  \hspace{1cm} (15)

In numerical implementations, $\|sf\|$ is kept below a certain threshold to stay in a region where linear approximations are possible. Then a new edge tracking is started from $x_1$ and the process is repeated until the norm of the total shift $\|sf\|$ falls below a convergence threshold, here $10^{-5}$.
