**Podostroma cornu-damae** is a rare fungus that houses a fatal toxin in its fruit body. In this case report, two patients collected and boiled the wild fungus in water, which they drank for one month. One patient died, presenting with desquamation of the palms and soles, pancytopenia, severe sepsis and multiple organ failure. The other patient recovered after one month of conservative care after admission. We found a piece of *Podostroma cornu-damae* in the remaining clusters of mushrooms. Mushroom poisoning by *Podostroma cornu-damae* has never been previously reported in Korea.

**Key Words:** *Podostroma cornu-damae*, mushroom, poisoning, pancytopenia

**INTRODUCTION**

Among thousands of species of mushrooms worldwide, about 30 species are known to be fatally poisonous.1 Amateur hunters often mistake poisonous mushrooms for edible mushrooms. They then harvest them to eat and give to others, leading to a string of poisonous events and even deaths. Fatal poisonings commonly occur when mushrooms belonging to the genus *Amanita*, such as *Amanita phalloides*, are consumed, as these mushrooms contain the lethal toxin, amatoxin.2 However, other cases of poisoning by other species of mushrooms have been reported.3-5

*Podostroma cornu-damae* is a rare species of fungus belonging to the Hyocreaeeae family. Its fruit body is highly toxic, containing trichothecene mycotoxins. Several fatal cases of poisoning by *Podostroma cornu-damae* have been reported in Japan,4 but to our knowledge no cases have ever been reported in Korea. Here, we report two cases of poisoning by *Podostroma cornu-damae*.

**CASE REPORT**

**Case 1**
A 64-year old man visited the emergency department with a 10-day history of fever, desquamation on his palms, soles and scalp (Fig. 1). He had a medical history...
On hospital day (HD) 2, the patient’s high temperature was sustained and pancytopenia was aggravated with a WBC count of 90/μL (ANC 20/μL), Hb of 6.3 g/dL, and a platelet count of 5000/μL, despite the administration of granulocyte-colony stimulating factor and a transfusion of packed red blood cell and platelet concentrate. However, because of prolonged shock and high inotropic demand, bone marrow aspiration and biopsy could not be performed. Multiple organ failure developed with elevated BUN/Cr (56.8/2.51 mg/dL), AST/ALT (3414/873 IU/L), total bilirubin (4.6 mg/dL) and ferritin (>15000 μg/L). The patient complained of dyspnea, and his respiratory rate was 30 times per minute. Arterial blood gas analysis revealed mild hypoxemia (PaO2 73 mm Hg under administration of 2 liters per minute of oxygen through nasal cannula). Chest X-ray showed newly developed consolidations in both lower lung fields. We then changed the patient’s antibiotics to piperacillin/tazobactam (2.25 g, q 6 hrs) and vancomycin (1 g, q 24 hrs) for the treatment of pneumonia and neutropenic severe sepsis.

Methicillin sensitive *Staphylococcus aureus* and *Klebsiella pneumoniae*, which were susceptible to the given antibiotics, were grown in a blood culture upon admission. The patient received mechanical ventilation and continuous renal replacement therapy beginning on HD 4 because of acute respiratory distress syndrome and acute renal failure in the intensive care unit. On HD 6, the patient expired as a result of intractable multiple organ failure. The patient’s severe pancytopenia was not recovered until death.

**Case 2**

A 60-year old woman, the wife of Case 1, was admitted to our hospital due to a sore throat on the first day and a fever on the third day of the husband’s hospitalization. Upon admission, her vital signs included a blood pressure of 131/67 mm Hg, heart rate of 102 beats/min, respiratory rate of 18 times/min and a body temperature of 39.2°C. She did not have any previous medical or medication history. There were no symptoms of dyspnea, abdominal pain, vomiting, diarrhea or paresthesia. Physical examination showed alert mentality, a dried tongue and lips, mild throat injection, desquamation on his palms and soles, and hair loss. Initial laboratory tests showed pancytopenia with a white blood cell (WBC) count of 120/μL [absolute neutrophil count (ANC) 20/μL], hemoglobin (Hb) of 11.2 g/dL, and a platelet count of 5000/μL; elevated erythrocyte sedimentation rate (135 mm/hr) as well as C-reactive protein (159 mg/L) and ferritin (898 μg/L); and normal blood urea nitrogen (BUN), serum creatinine (Cr) (20.4/0.82 mg/dL), aspartate aminotransferase (AST)/alanine aminotransferase (ALT) (15/20 IU/L) and total bilirubin (0.8 mg/dL). A simple chest X-ray did not reveal any abnormal findings, and an abdominal-pelvic CT scan, which was performed to evaluate the causes of the pancytopenia and intraabdominal infection focus, did not show any hepatosplenic or infiltrating mass lesion in the liver or spleen, abnormal enlargement of intraabdominal lymph nodes, or any abnormal finding as to the cause of the severe sepsis. Treatment comprising fluid resuscitation with crystalloid and the use of norepinephrine was also performed. Also, intravenous penicillin G (400 million IU, q 4 hrs), clindamycin (600 mg, q 8 hrs), and intravenous immunoglobulin (2 g/kg) were administered considering the possibility of streptococcal toxic shock syndrome.

tratoxin H 13’-acetate, satratoxin H, roridin E, and verucarin J. If poisoned by *Podostroma cornu-damae*, the common symptoms are diarrhea, vomiting and dehydration in the early stage. This is followed by hypotension, oliguria, changes in perception, and disturbance of consciousness. Without treatment, leukopenia, thrombocytopenia, lamellar desquamation on the palms and face, as well as hair loss can develop. Patients usually die of multiple organ failure, including acute renal injury, disseminated intravascular coagulation and liver necrosis. Despite our understanding of the conditions and the chemical background of this poison, there is still no curative treatment available, although one report stated continuous hemodiafiltration, plasma exchange and granulocyte colony stimulating factor with a large volume of intravenous fluid resuscitation resulted in recovery in one patient.

Unlike other previously reported cases, the cases in this report involved symptoms that appeared one month after first ingesting the poisonous mushrooms. The first patient

**DISCUSSION**

*Podostroma cornu-damae* was first discovered in China in 1895. It was originally described as *Hypocrea cornu-damae* and then later renamed *Podostroma* by a Japanese mycologist. The fungus is known to exist in Japan, China, Java, and also in Korea. It is shaped like a deer’s red horn, but in its immature period, it resembles *Ganoderma lucidum*, which is well known as a health-food.

In 1999, a group of five people in Japan ate 1 gram of *Podostroma cornu-damae* soaked in sake. One of these five people died two days after ingesting the sake. Another report included information on 13 cases of ingestion of several centimeters of *Podostroma* from 1983 to 2008, two of which had died. In 2001, Saikawa, et al. discovered the chemical components of the macrocyclic trichothecene group of toxins in the fruit body of this fungus, including satratoxin H 12’-18’-diacetate, satratoxin H 12’-acetate, satratoxin H 13’-acetate, satratoxin H, roridin E, and verucarin J. If poisoned by *Podostroma cornu-damae*, the common symptoms are diarrhea, vomiting and dehydration in the early stage. This is followed by hypotension, oliguria, changes in perception, and disturbance of consciousness. Without treatment, leukopenia, thrombocytopenia, lamellar desquamation on the palms and face, as well as hair loss can develop. Patients usually die of multiple organ failure, including acute renal injury, disseminated intravascular coagulation and liver necrosis. Despite our understanding of the conditions and the chemical background of this poison, there is still no curative treatment available, although one report stated continuous hemodiafiltration, plasma exchange and granulocyte colony stimulating factor with a large volume of intravenous fluid resuscitation resulted in recovery in one patient.

Unlike other previously reported cases, the cases in this report involved symptoms that appeared one month after first ingesting the poisonous mushrooms. The first patient...
presented with hypotension, desquamation and multiple organ failure, and died despite undergoing intensive treatment. The second patient complained of only mild symptoms and recovered after conservative care, irrespective of the prolonged severe pancytopenia. According to the analysis of the patients' remaining mushrooms, most of them were *Ganoderma lucidum*, and only one piece of the dried mushroom turned out to be *Podostroma cornu-damae*. Therefore, the patients seemed to have ingested only a very small amount of *Podostroma cornu-damae*. They also did not consume the mushroom directly, but boiled them in water with other pieces of mushrooms. Both patients drank the mushroom water instead of regular drinking water. The second patient said that her husband drank more water than she had. Therefore, we surmised that the small amount of toxin intake over a long period of time influenced the clinical course of the poisoning; however, the exact mechanism by which the toxins poisoned the body at clinical presentation is still unknown.

The information obtained from these two cases can be used to help better treat future patients that present with an unknown cause of neutropenic fever with pancytopenia and desquamation on the palms and soles. Furthermore, physicians should be sure to ask patients about any history of ingesting wild mushrooms, all the while considering the possibility of *Podostroma cornu-damae* poisoning, when such symptoms appear.
