Abstract. Background/Aim: Placenta percreta is a rare event, but it poses serious problems due to potential hemorrhagic events. We report a particular case of placenta percreta with massive hematuria due to maternal bladder invasion, and describe the surgical protocol performed that resulted in an excellent outcome. Case Report: A 33-year-old patient, at 27th weeks gestational age, presented in the emergency room of the Urology Department with urinary blood clot acute retention, because of massive hematuria from a placenta percreta with bladder invasion. After extracting the clots from the bladder, and coagulation of an area of venous ectasies of the posterior wall, hematuria ceased, but appeared after two days, necessitating again the bladder clots removal and coagulation. A surgical team with gynecologists, urologists, anesthesiologists and a neonatologist was composed, and after bilateral ureteral double J insertion, cesarean section was performed followed by hemostatic hysterectomy and partial cystectomy, bilateral internal iliac artery ligature and repair of the bladder wall. The postoperative evolution was without incidents; the Foley catheter was removed in the 14th postoperative day. Conclusion: In the context of a massive hematuria of a pregnant woman, the urologist must always consider a diagnosis of complicated placenta percreta.

Placenta percreta represents the most severe form of abnormal trophoblastic adherence beyond the decidua basalis, among the three representatives of the placenta accreta spectrum (PAS), a rare condition with reported incidence of 1/500 to ½/500 pregnancies (1, 2). PAS includes 75-80% cases of placenta accreta vera (less than 50% myometrial invasion by the trophoblast), 17% cases of placenta increta (more than 50% myometrial invasion by the trophoblast), and 5% cases of percreta (invasion of uterine serosa and neighboring pelvic organs) (2, 3). Moreover, the abnormal adherence can be complete (throughout the entire placenta), partial (limited to only one or more cotyledons), or focal (in isolated areas) (4).

More than 2 caesarean sections (CS), including shorter intervals between previous CS and current pregnancy (less than 2 years), and concurrent placenta praevia (in 75% of cases) are the most common known risk factors, followed by advanced maternal age, multiparity, endometritis, hypertension, assisted reproductive technology, submucosal leiomyomas, other uterine surgeries and anomalies (poor quality of scarring and CS performed on long time ruptured membranes leading to chorioamnionitis), smoking (3, 5-9). Because of the rise in the numbers of CS performed in recent years, the risk of PAS disorders is increasing up to 10 times in the last 50 years (10, 11).

The information regardless of treatment of the placenta percreta with bladder invasion are limited, because of the exceptional rarity of this event. Approximately 70 cases are reported as case presentation, the largest series comprising 54 patients (12).
The suspicion or the early diagnosis of PAS disorders is based on the theoretical knowledge of the risk factors in relation with the patient’s obstetrical and general medical history. Supplementary, the ultrasonography or magnetic resonance imaging (MRI), when ultrasound cannot provide specific data, contribute to the clinical diagnosis.

Most placenta accreta are asymptomatic to term and if diagnosed by ultrasound during pregnancy, can be scheduled in special centers and resolved in multidisciplinary teams (2, 3, 13). The review of the literature shows that it is mandatory for the placenta percreta to be diagnosed early during pregnancy, because of the serious fetal and maternal implications of this condition. These pregnancies can be complicated at birth, during the detachment of the placenta from the uterus, producing massive hemorrhage and trauma to neighboring organs in which the invasion occurred (bladder and rarely the ureters, rectum, iliac vessels). After birth, postpartum hemorrhage manifested by vaginal bleeding (10, 14) and more rarely hematuria (8, 11, 12, 15, 16) can appear. Therefore, an optimal therapeutic strategy is mandatory (3, 13).

Life-threatening hematuria, a fatal complication, manifests in the 25% of the cases of placenta percreta, in the second trimester, when the placenta invades the maternal bladder wall, which requires premature evacuation, leading to challenges in surgical management (2, 3, 13, 16). Maternal and fetal mortality in cases of percreta with hematuria is high, especially because of intraoperative and postoperative complications (up to 5% maternal deaths) (12), but our case was successfully resolved by cesarean section - hysterectomy with bilateral ligations of hypogastric arteries.

Although the evidence of the urinary bladder involvement is mostly intraoperatively confirmed, during the delivery (2), the gold-standard certification comes only after the histopathological examination (3). We present a particular case of placenta percreta with massive hematuria due to maternal bladder invasion and the surgical protocol performed, with excellent outcome.

**Case Report**

A 33-year-old woman, at 27 weeks gestational age, secundiparous, presented into the emergency room of the Urology Department with intermittent macroscopic hematuria and acute urinary retention. The COVID-19 test was negative. The case history revealed no specific follow-up of the pregnancy, due to a low socio-economical status of the gravida.

The ultrasound obstetrical examination confirmed a good evolution of the fetus but described a solid mass in the bladder of 13.68/9.74 cm, without Doppler vascularization (Figure 1 and Figure 2). The problem of differential diagnosis between a solid bladder tumor and a clot has been raised, but the localization of the placenta praevia, with anterior extension on the uterine scar and the absence of Doppler vascularization at the level of the intravesical solid mass, supported the second hypothesis.

Hemoglobin (Hb) at admission was 11.4 g/100 ml. In the first hours after admission, she developed massive hematuria, with urinary acute retention due to intravesical clots, with a drop of Hb till 5g/100ml. Emergency cystoscopy and evacuation of the clots were performed. On the posterior wall of the bladder, venous ecstasies were seen with active bleeding, which were coagulated. Urine became clear on urethral Foley catheter, with no need of bladder irrigation. Four units of iso-group, iso-Rh were administrated. After 48 h, the Foley catheter was removed due to clear aspect of the urine. The
The patient developed once again, with spontaneous urination, gross hematuria, with a drop of Hb from 7 to 5.3 g/100 ml. A new cystoscopy was performed, with clots extraction, coagulation of the same venous ecstasies of the posterior wall and administration of three units of blood. The urine cleared and a Foley catheter was reinserted. The team composed of gynecologists, urologists, anesthesiologists and a neonatologist decided to perform the cesarean section after 72 h from the last intervention. First, bilateral 7CH ureteral double J stents were inserted, after which cesarean section was performed. The child was born with 980 grams and Apgar 7, with a good postoperative evolution in our tertiary neonatal department. Intraoperatively, placenta was attached to the posterior wall of the bladder, and hemorrhage started during decollation of the uterus, vagina and bladder, necessitating hemostatic hysterectomy and bilateral ligature of the internal iliac arteries. During hysterectomy, the bladder wall was opened, to permit the extraction of the placenta with a portion of invaded bladder wall (Figure 3 and Figure 4). After thorough hemostasis at the level of vaginal stump, broad ligament and the bladder, cystotomy was sutured with running uninterrupted 2-0 Vicryl, in one plane. At the end, the tightness of the suture was verified with methylene blue. Intraoperatively 8 units of blood were necessary. Forty-eight hours after the operation, Hb was 7.6 g/100 ml. Postoperative evolution was uneventful, the patient was discharged in the 8th postoperative day, the Foley catheter was removed ambulatory in the 14th postoperative day.

The placenta percreta was documented on the hysterectomy specimen, which was grossly and microscopically examined, revealing stem and terminal placental villi completely invading the whole thickness of gestational myometrium, which was globally thinned, as well as the uterine serosa, penetrating focally the external surface. The placental villi were attached to myometrial layer, and decidua basalis was reduced or absent (Figure 5). Intermediate trophoblast dissected the myometrium, involving also the arterial wall and contributing to their remodeling. Two of the examined fragments presented villi and intermediate trophoblast lining the serosa of the urinary bladder, reaching the external half of the bladder muscularis propria, with focally involvement of the vascular walls (Figure 6). The placenta praevia was pathologically diagnosed by the trophoblast invasion in the lamina propria and fibromuscular layer of the isthmus and endocervical internal os (Figure 7).

**Ethics approval and consent to participate.** The study has been approved by the Ethics Committee of the Clinical Hospital “Dr. C. I. Parhon” Iași, based on the patients’ informed consent.

**Consent for publication.** Written informed consent was obtained from the patient for publication of this case report and the accompanying images.
Discussion and Conclusion

Unlike normal pregnancies, in which trophoblastic invasion ceases when the cells reach the spongiosum layer of the decidua (Nitabuch’s layer) (17), in PAS the abnormal adherence of the trophoblastic cells produce damage of the decidua basalis, with thoroughly gradual invasion of the uterine wall (3).

Although placenta percreta is the least frequent form of PAS and can sustain a full-term pregnancy with normal fetal development, it is considered the most severe of the three conditions, sometimes causing premature labor or heavy peripartum bleeding, and moreover, greater complications if diagnosed intraoperatively or if trophoblastic invasion involves neighboring organs or structures (4, 5). Within this context, the invasion of the urinary bladder with subsequent life-threatening hematuria represents a rare complication of placenta percreta.

To the best of our knowledge, only Washecka et al. (12), in 2002, reported a series of 54 cases after a review of the literature, in which 17 (31%) patients presented hematuria, reporting 3 maternal and 17 fetal deaths. There are also few case reports that present peculiar aspects of the surgical management of placenta percreta with bladder wall involvement (8, 10, 11, 15, 16). Thus, we presented a successful treatment of a placenta percreta associated with placenta praevia and complicated with massive hematuria, with a very good outcome.

The best therapeutic option is still controversial (9, 13). In case of placenta percreta with bladder wall involvement, the elective approach is cesarean hysterectomy, followed by cystotomy or partial cystectomy, with the risk of urinary fistula and prolonged catheterization (3, 11, 13).

In our case, primary hysterectomy was mandatory, as reported in other studies (2, 3, 10, 14, 15), because uterus preservation is associated with the hemorrhagic risk, even months after CS. We also proposed, for a good hemostasis, bilateral internal iliac artery ligature, strategy already reported in the literature (5). To avoid intraoperative ureteral injuries, we inserted bilateral, ureteral double J stents (10, 13). Our multidisciplinary team composed of gynecologists, urologists and neonatologists achieved a good postoperative outcome, with a progressive recovery of mother and the improvement of the newborn health.

Because of the increasing frequency of short-term and long-term consequences due to radical surgical techniques
used in the management of maternal complications of the PAS, the surgical strategy has progressively evolved towards more conservative techniques, such as: the “triple P procedure” (ultrasound perioperative placental localization, pelvic devascularization, and placental non-separation), intentional placental retention or partial myometrial excision (3, 13). The *in situ* maintenance of the placenta adherent to the uterine and urinary bladder wall, respectively, implies the use of methotrexate for placental involution (spontaneously resorbed in 9-12 months), as well as a careful follow-up at least 20 weeks because of the high risk of sepsis, delayed hematuria and massive hemorrhage, with subsequent peripartum hysterectomy (3, 12, 13). If the abnormal placental penetration is partial or focal, a possible surgical option is one-step conservative surgery, that consists in the resection of myometrium and bladder tissues invaded by placenta, concomitantly with the reconstruction of the affected areas (3, 13). However, this procedure presents several disadvantages, namely: sepsis, multiple organ failure, intravascular disseminated coagulopathy, and vesicovaginal fistula (3, 13).

The key particularity of our case is the existence of only one previous CS, these varieties of placenta percreta appearing on multiscar uteri, the risk increasing geometrically with the number of scars. The presence of the placenta praevia, as an important risk factor of placental accretion, associated in our case with the placenta percreta is also remarkable, considering that previous CS was more than two years apart (5 years ago) and without scarring defects. Moreover, no data of pregnancy evolution were documented, as patient addressed directly to the Urology service for intermittent hematuria and acute urinary retention. Another challenge of the case was featured by the fact that abdominal ultrasound, which revealed a solid intravesical mass of 13.68/9.74 cm, had to perform the differential diagnosis between a solid bladder tumor and a giant blood clot. The conservative therapeutic option could not be applied in our case, because it would not have stopped the hematuria. It is worth mentioning that the attempt to coagulate by cystoscopy the vessels of the bladder mucosa developed by the abnormal placental invasion failed, by the hematuria recurrence, after the first suppression of the Foley catheter. A distinct feature of our report consists in the histological documentation of the abnormal placentation into the muscular layer of the urinary bladder, as the literature provides few typical microscopic images for this condition.
To conclude, placenta percreta associated with bladder invasion is a rare but serious, life-threatening problem. The urologist should consider a massive hematuria of a pregnant woman as key diagnostic feature for placenta percreta.

Conflicts of Interest
The Authors declare no conflicts of interest.

Authors’ Contributions
VDR, RA, SEG and PO have designed and have written the report, including the literature search; VDR, CC, CR, DP, MO and AT have performed the surgery; DS and RP have performed the ultrasound obstetrical examination; RA, SEG and IDC have performed the histopathological examination; DS and IDC have revised critically the manuscript for important intellectual content. All authors have read and approved the final manuscript.
