Endoplasmic Reticulum Stress in Diabetic Hearts Abolishes Erythropoietin-Induced Myocardial Protection by Impairment of Phospho–Glycogen Synthase Kinase-3β–Mediated Suppression of Mitochondrial Permeability Transition

Takayuki Miki, Tetsuji Miura, Hiroyuki Hotta, Masaya Tanno, Toshiyuki Yano, Takahiro Sato, Yoshiaki Terashima, Akifumi Takada, Satoko Ishikawa, and Kazuaki Shimamoto

OBJECTIVE—Alteration in endoplasmic reticulum (ER) stress in diabetic hearts and its effect on cytoprotective signaling are unclear. Here, we examine the hypothesis that ER stress in diabetic hearts impairs phospho–glycogen synthase kinase (GSK)-3β–mediated suppression of mitochondrial permeability transition pore (mPTP) opening, compromising myocardial response to cytoprotective signaling.

RESEARCH DESIGN AND METHODS—A rat model of type 2 diabetes (OLETF) and its control (LETO) were treated with tauroursodeoxycholic acid (TUDCA) (100 mg · kg⁻¹ · day⁻¹ for 7 days), an ER stress modulator. Infarction was induced by 20-min coronary occlusion and 2-h reperfusion.

RESULTS—Levels of ER chaperones (GRP78 and GRP94) in the myocardium and level of nonphospho–GSK-3β in the mitochondria were significantly higher in OLETF than in LETO rats. TUDCA normalized levels of GRP78 and GRP94 and mitochondrial GSK-3β in OLETF rats. Administration of erythropoietin (EPO) induced phosphorylation of Akt and GSK-3β and reduced infarct size (% risk area) from 47.4 ± 5.2% to 23.9 ± 3.5% in LETO hearts. However, neither phosphorylation of Akt and GSK-3β nor infarct size limitation was induced by EPO in OLETF rats. The threshold for mPTP opening was significantly lower in mitochondria from EPO-treated OLETF rats than in those from EPO-treated LETO rats. TUDCA restored responses of GSK-3β, mPTP opening threshold, and infarct size to EPO receptor activation in OLETF rats. There was a significant correlation between mPTP opening threshold and phospho–GSK-3β–to-total GSK-3β ratio in the mitochondrial fraction.

CONCLUSIONS—Disruption of protective signals leading to GSK-3β phosphorylation and increase in mitochondrial GSK-3β are dual mechanisms by which increased ER stress inhibits EPO-induced suppression of mPTP opening and cardioprotection in diabetic hearts. Diabetes 58:2863–2872, 2009

Despite recent progress in coronary intervention strategies, diabetes is associated with higher mortality after acute myocardial infarction due to more extensive atherosclerotic lesions and hypertrophied and dysfunctional left ventricle (1–3). Therefore, diabetic patients with coronary artery diseases are patients who most require novel protective strategies against myocardial ischemia reperfusion injury. However, diabetes is known to impair responses of the myocardium to protective interventions. Protection afforded by preinfarct angina is lost in diabetic patients (4). In animal models, ischemic preconditioning (IPC) and some pharmacological agents failed to reduce infarct size in diabetic hearts (5–8). Recently, Gross et al. (7) have reported that responses of Akt, extracellular signal–related kinase (ERK), and glycogen synthase kinase (GSK)-3β to opioid receptor stimulation were blunted in streptozotocin-induced diabetes. GSK-3β has been shown to regulate a variety of cellular functions (9,10), and recent studies (10–14) have indicated that inactivation of GSK-3β by phosphorylation at Ser9 enhances myocardial tolerance against ischemia reperfusion injury. Furthermore, accumulating evidence indicates that phospho–GSK-3β–mediated cytoprotection is achieved by elevation of the threshold for opening of the mitochondrial permeability transition pore (mPTP), a probable final common step in stress-induced cell necrosis (11,15–17). However, derangements in GSK-3β regulation and its downstream targets in type 2 diabetes have not yet been clarified.

The endoplasmic reticulum (ER) has received much attention recently for its role in signal transduction relevant to cell survival and death. Various pathophysiological conditions induce Ca²⁺ overload and/or accumulation of unfolding or misfolding proteins within the ER, a condition referred to as ER stress (18). ER stress induces multiple responses, including adaptive changes in translation, protein folding, secretion, and degradation. Prolonged ER stress can trigger apoptosis by induction of C/EBP homologous protein (CHOP), activation of c-JUN NH₂-terminal kinase (JNK), or caspase 12–dependent pathways. ER stress has been reported to be involved in the pathogenesis of diabetes (18–20), neurodegenerative disease, immune response, atherosclerosis, ischemia reperfusion injury, and heart failure (18,21–25).

We hypothesized that ER stress is increased in the diabetic myocardium and that increased ER stress in diabetic hearts impairs phospho-GSK-3β-mediated suppression of mPTP opening, leading to loss of myocardial response to cytoprotective signaling. The rationale for this hypothesis is threefold. First, increased ER stress has been observed in epididymal fat tissue in obese diabetic mice (26). Second, an increase in GSK-3β activity induced by ER stress through dephosphorylation of phospho-Ser9 has been reported in cardiomyocytes (27). Finally, elevated levels of GSK-3 protein and activity were observed in skeletal muscle of type 2 diabetic patients (28). To test our hypothesis, we investigated changes in anti-infarct tolerance, myocardial ER stress, cytoprotective signaling, and mPTP opening threshold in a rat model of type 2 diabetes. ER stress modulators, sodium tauroursodeoxycholic acid (TUDCA), and 4-phenylbutyric acid (4-PBA) (29) were used to suppress ER stress. Erythropoietin (EPO) was used to induce GSK-3β phosphorylation in this study, since we have characterized signaling pathways from the EPO receptor leading to myocardial protection and modification of the pathways by concurrent pathological conditions (13,30,31).

RESEARCH DESIGN AND METHODS

This study was conducted in accordance with The Guide for the Care and Use of Laboratory Animals published by the U.S. National Institutes of Health (NIH) (NIH publication no. 85–23, revised 1996) and approved by the animal use committee of Sapporo Medical University.

Animal model and surgical preparation. Male Otsuka Long-Evans-Tokushima fatty rats (OLETF) (32), a rat model of obese type 2 diabetes, and their controls (Long-Evans-Tokushima-Otsuka rats [LETO]), both at ages between 25 and 30 weeks, were used in this study. In OLETF and LETO rats, TUDCA (100 mg·kg\(^{-1}\)·day\(^{-1}\)) or the same volume of a vehicle (saline) was administered intraperitoneally for 7 days before the experiments. In a post hoc series of experiments, we examined whether 4-PBA (40 mg·kg\(^{-1}\)·day\(^{-1}\)) i.p. for 7 days) could mimic effects of TUDCA and whether Goto-Kakizaki (GK) rats, a model of nonobese type 2 diabetes (33), respond to EPO similarly to OLETF rats. Rats were prepared for induction of myocardial infarction as in our previous studies (13) (see expanded methods section in the online appendix [available at http://diabetes.diabetesjournals.org/cgi/content/full/db09-0158/DC1]).

Infarct size experiments. After a 20-min stabilization period, blood samples were collected from the jugular vein, and the left coronary artery was occluded for 20 min and then reperfused for 2 h to induce infarction. EPO (5,000 units/kg) was administered 15 min before ischemia, and SB216763 (1.2 mg/kg), a GSK-3 inhibitor, and PD98059 (2.5 mg/kg), a mitogen-activated protein kinase inhibitor, were injected at 10 and 25 min before ischemia, respectively. After 2-h reperfusion, hearts were excised, and infarct and areas at risk were visualized by tetrazolium staining and by fluorescent microspheres, respectively, as previously reported (13,30,31). Since pretreatment with TUDCA did not modify infarct size in LETO rats with or without EPO administration (see results section), a group of TUDCA-treated LETO rats were not included in the following series of experiments (i.e., immunoblot experiments and Ca\(^{2+}\)-induced mPTP opening experiments).

Immunoblot experiments

Tissue sampling protocols. In protocol 1, hearts were isolated and perfused with Krebs-Henseleit buffer at 75 mmHg, as previously reported (13,30,31). Biopsy samples (0.2–0.3 g) were taken from the left ventricle at baseline (after stabilization) or at 15 min after EPO infusion (10 units/ml). Ca\(^{2+}\)-induced mitochondrial permeability transition. Opening of the mPTP was assessed following in vitro Ca\(^{2+}\)-overload using isolated mitochondria according to a method by Argaud et al. (35) with some modification, as detailed in the expanded methods section (online appendix).

Statistics. All data are presented as means ± SE. Differences between treatment groups were tested by one-way or two-way ANOVA, and Student-Newman-Keuls post hoc test was used to test for multiple comparisons when ANOVA indicated significant differences. The difference was considered significant if the P value was <0.05.

RESULTS

Body weight and plasma glucose level. As shown in Table 1, body weight was larger in OLETF than in LETO rats. Blood glucose and plasma insulin levels were higher in OLETF than in LETO rats, confirming phenotypes of type 2 diabetes in OLETF rats. In LETO rats, treatment with TUDCA did not modify body weight, blood glucose, and plasma insulin level. However, treatment with TUDCA for 7 days significantly reduced blood glucose and plasma insulin levels in OLETF rats, suggesting an improvement in insulin sensitivity. We measured blood glucose levels at baseline, before ischemia (i.e., after treatment), and 60 min after reperfusion, and none of treatments, including EPO, modified blood glucose and plasma insulin levels at baseline, before ischemia, and 60 min after reperfusion following a 20-min coronary occlusion, hearts were isolated and perfused with ice-cold saline, and the tissue in the risk region was sampled and snap-frozen in liquid nitrogen.

Samples for electrophoresis were prepared from total tissue homogenate or cytosolic and mitochondrial fractions as in our previous studies (16,30), and proteins of interest were immunoblotted and quantified by image analysis as detailed in the expanded methods section (online appendix).

Ca\(^{2+}\)-induced mitochondrial permeability transition. Opening of the mPTP was assessed following in vitro Ca\(^{2+}\)-overload using isolated mitochondria according to a method by Argaud et al. (35) with some modification, as detailed in the expanded methods section (online appendix).

Statistics. All data are presented as means ± SE. Differences between treatment groups were tested by one-way or two-way ANOVA, and Student-Newman-Keuls post hoc test was used to test for multiple comparisons when ANOVA indicated significant differences. The difference was considered significant if the P value was <0.05.

Infarct size data. Heart rate and mean blood pressure levels were comparable in all study groups under baseline conditions, during ischemia, and after reperfusion, except for slightly lower heart rate in LETO rats after SB216763 administration (see the online appendix Table). In LETO rats, pretreatment with EPO significantly reduced infarct size as a percentage of risk area (%/R) from 47.4 ± 5.2% in controls to 23.9 ± 3.5% (Fig. 1A). This EPO-induced protection was not blocked by PD98059, a mitogen-activated protein kinase inhibitor, and this blocker by itself had no effect on infarct size. Treatment with SB216763, a GSK-3 inhibitor, mimicked the infarct size-limiting effect of EPO. In TUDCA-treated LETO rats, infarct sizes with and without EPO pretreatment (%/R =...
19.2 ± 4.1 and 45.7 ± 4.0%, respectively) were similar to those in LETO rats.

In OLETF controls, infarct size was 14% larger than that in LETO rats, but this difference was not statistically significant due to the small number of hearts used in the experiments. Thus, we performed post hoc experiments in which four hearts were added to each of the OLETF control and LETO control groups. The pooled data (n = 10 in each group) showed a statistically significant difference between %I/Rs in the OLETF control group and LETO control group (57.4 ± 3.0 vs. 47.7 ± 3.1%, P < 0.05). In contrast to its effect in LETO rats, EPO failed to limit infarct size in OLETF rats, though SB216763 afforded significant protection in OLETF rats as well (Fig. 1B). Comparison of %I/Rs in LETO control, TUDCA-treated LETO control, OLETF control, and TUDCA-treated OLETF control groups by one-way ANOVA indicated that TUDCA alone reduced infarct size in OLETF but not in LETO rats. More importantly, TUDCA prevented loss of myocardial response to EPO in OLETF rats, %I/R being reduced by EPO to 17.0 ± 5.0%, and this EPO-induced protection was sensitive to PD98059. Failure of EPO to limit infarct size was observed also in GK rats (supplemental data in the online appendix), suggesting that this is a common feature in diabetic animals.

To confirm that loss of myocardial protection by EPO in OLETF rats is derived from lack of response in Jak2-mediated protective mechanisms, we further assessed effects of [D-Ala², D-Leu⁵]-enkephalin acetate (DADLE), a δ-opioid receptor agonist, on infarct size (online appendix Fig. 1). Pretreatment with DADLE (1 mg/kg) significantly reduced infarct size in LETO but not in OLETF rats. Treatment with TUDCA restored myocardial response to DADLE also in OLETF rats.

Immunoblot experiments

Protocol 1: ER stress markers and response of protein kinases to EPO receptor activation. Protein levels of GRP78 and GRP94, ER stress chaperone proteins, were significantly elevated in OLETF rats (Fig. 2A and B), indicating that ER stress was enhanced in the diabetic myocardium. One-week treatment with TUDCA reduced the elevation of myocardial GRP78 and GRP94 levels in OLETF rats.
OLETF rats. This effect of TUDCA was mimicked by 4-PBA, a structurally different ER stress modulator (29,36) (data not shown). Levels of CHOP protein, an ER-medi-
adiated proapoptotic transcription factor (37), in the myocar-
dium were similar in OLETF and LETO rats (Fig. 2).

EPO receptor protein levels in the myocardium were similar in LETO and OLETF rats (data not shown). As shown in Fig. 3A, administration of EPO significantly increased the level of phospho-Akt in LETO hearts. However, such phosphorylation of Akt by EPO was not observed in OLETF rats, and pretreatment with TUDCA did not restore Akt response in OLETF rats (Fig. 3A). In contrast, EPO-induced ERK1 and ERK2 phosphorylation occurred similarly in LETO and OLETF rats (Fig. 3B). Effects of 4PBA on EPO-induced Akt and ERK phosphorylation were similar to those of TUDCA (online appendix Fig. 2A and B). A JNK inhibitor, SP600125, had no effects on responses of Akt and ERK to EPO receptor activation in OLETF rats (online appendix Fig. 2A and B).

GSK-3β level in total myocardial homogenates in OLETF rats was 25% higher than that in LETO rats, though this difference did not reach statistical significance (Fig. 4A). However, a significant difference between the two groups was observed for mitochondrial GSK-3β. As shown in Fig. 4B, GSK-3β level in the mitochondrial fraction was significantly higher in OLETF than in LETO rats, while phospho–Ser9–GSK-3β level in the mitochondrial fraction was comparable between LETO and OLETF rats. The upregulation of non–Ser9–phosphorylated GSK-3β in the mitochondria was attenuated by TUDCA pretreatment.

Infusion of 1 μmol/l thapsigargin for 20 min increased tissue GRP78 level by 70% and prevented phosphorylation of Akt and GSK-3β in response to EPO infusion in LETO hearts (online appendix). However, these effects of thapsigargin were associated with 40% reduction in left ventricular–developed pressure.

**Protocol 2: phosphorylation of protein kinases after ischemia reperfusion in vivo.** EPO administration before ischemia significantly increased levels of phospho-Akt and phospho–GSK-3β upon reperfusion in LETO rats (Fig. 5A and B). However, such phosphorylation of Akt and GSK-3β by EPO was not observed in OLETF rats. Treatment of OLETF rats with TUDCA restored GSK-3β phosphorylation response to EPO (Fig. 5B), whereas Akt phosphorylation by EPO was not recovered by TUDCA (Fig. 5A). These effects of TUDCA in OLETF rats were mimicked by 4-PBA but not by SP600125 (online appendix Fig. 2). Phospho-ERK levels upon reperfusion were not different in LETO, OLETF, and TUDCA-treated OLETF rats (data not shown). Interestingly, restoration by TUDCA of EPO-induced GSK-3β phosphorylation was abrogated by PD98059 (Fig. 5C), as was infarct size limitation by EPO after TUDCA pre-
treatment (Fig. 1B). Infarct size limitation was corre-
lated with phospho–GSK-3β–to–total GSK-3β ratio (Fig. 5D), which is consistent with our previous findings in Sprague-Dawley rats (13).

**Ca2+-induced mitochondrial permeability transition.** The amount of Ca2+ required to open the mPTP in the mitochondria isolated after EPO treatment was 483.3 ± 3.3 μmol/mg mitochondrial protein in LETO rats, but it was significantly decreased to 411.1 ± 19.8 μmol/mg mitochondrial protein in OLETF rats (Fig. 6B). In TUDCA-treated OLETF rats, a significantly larger amount of Ca2+ was required to induce mPTP opening (510.0 ± 26.5 μmol/mg) than in untreated OLETF rats. To confirm that mPTP opening was accurately monitored by the present method, we assessed the effect of cyclosporine A, an inhibitor of mPTP opening. Mitochondria isolated from LETO rats were treated with cyclosporin A (0.3 μmol/l) for 5 min before Ca2+ challenge. The amount of Ca2+ required to induce mPTP opening in the cyclosporine A–treated mitochondria was much larger (740.0 ± 90.2 μmol/mg, n = 3).
than that in untreated mitochondria. Using some of the mitochondria isolated for mPTP experiments, we determined levels of phospho– and total GSK-3β by immunoblotting. As shown in Fig. 6C, phospho–GSK-3β–to–total GSK-3β ratio in the mitochondria was significantly correlated with the amounts of Ca²⁺ required to open the mPTP. These results suggest that level of mitochondrial GSK-3β phosphorylation at reperfusion is a determinant of the threshold for mPTP opening.

**DISCUSSION**

The present study showed for the first time that ER stress marker proteins, GRP78 and GRP94, were significantly elevated in the myocardium of a model of type 2 diabetes (Fig. 2), while CHOP protein level was not elevated unlike that in a model of type 1 diabetes. To assess the contribution of increased ER stress to cell signaling and mPTP regulation, we utilized TUDCA and 4-PBA to reduce ER stress in the present study. TUDCA, a derivative of an endogenous bile acid (38), and 4-PBA, a low–molecular weight fatty acid (36), have been demonstrated to suppress ER stress elevated in the liver and fat in ob/ob mice (29). Efficacy of TUDCA and 4-PBA in the OLETF myocardium was confirmed by findings that these agents normalized protein levels of both GRP78 and GRP94.

Phosphatidylinositol-3 kinase (PI3K)-Akt–GSK-3β signaling is crucial in cytoprotection afforded by EPO and other Jak2-activating ligands (13,30,39). In the present study, not only EPO but also DADLE failed to protect the myocardium of OLETF rats from infarction, suggesting that Jak2-mediated protection is dysfunctional. In fact, EPO failed to activate PI3K-Akt signaling in OLETF rats (Fig. 3), whereas activation of ERK was spared. This pattern of modification in cytoprotective signaling is apparently similar to the pattern that we observed in postinfarct remodeled hearts (30,31). However, EPO could limit infarct size in an ERK-dependent manner in the remodeled hearts (31) in contrast with its failure in OLETF hearts (Fig. 1B). These findings suggest that there is a pathological factor in the OLETF myocardium that prevents phosphorylated ERK from compensating the role of Akt in myocardial protection. Interestingly, pretreatment with TUDCA or 4-PBA restored the response of GSK-3β phosphorylation to EPO receptor activation (Fig. 5B) (online appendix Fig. 2C), without having an effect on Akt phosphorylation, and restored the myocardial response to EPO-induced protection. The GSK-3β phosphorylation by EPO in TUDCA-treated OLETF rats was inhibited by PD98059 (Fig. 5C), as was the infarct size–limiting effect of EPO in the same treatment group (Fig. 1B). Taken together, these results suggest that increased ER stress in OLETF rats inhibits the compensatory function of ERK to phosphorylate GSK-3β in the presence of a defect in PI3K-Akt signaling from the EPO receptor.

The lack of Akt signaling from activated EPO receptors and disruption of ERK–GSK-3β signaling were not the only modifications of the GSK-3β–linked signal pathway in OLETF rats. GSK-3β level in the mitochondria was 45%
higher in OLETF than in LETO rats under baseline conditions, whereas phospho–GSK-3β levels were similar in the two groups, indicating an increase in nonphospho–GSK-3β in OLETF mitochondria. The increased nonphospho–GSK-3β in the mitochondria may be responsible for slight enlargement of infarct size in OLETF rats compared with that in LETO rats. The nonphosphorylated form of GSK-3β is constitutively active, forms a complex with two major subunits of mPTP (adenine nucleotide translocase [ANT] and voltage-dependent anion channel [VDAC]) after ischemia/reperfusion (16), and reduces the threshold for mPTP opening (10,14). Phosphorylation of GSK-3β at Ser9 reduces its activity and elevates the mPTP opening threshold (10,14). Thus, the ratio of phospho–GSK-3β to total GSK-3β can be used as a surrogate index of threshold for mPTP opening. Critical timing of mPTP opening is within several minutes after reperfusion, we focused on phospho–GSK-3β–to–total GSK-3β ratio at 5 min after reperfusion. There was a correlation between increases in phospho–GSK-3β levels by EPO from control and mean infarct size reduction by EPO in each treatment group. See data of infarct size experiments (Fig. 1) and immunoblot experiments (Fig. 5B and C). □, LETO; ○, OLETF; △, OLETF+TUDCA; ▲, EPO+PD98059 treatment in OLETF and TUDCA rats.

mPTP opening and cell necrosis. Our current hypothesis based on the present observations is schematically presented in Fig. 7.

Ischemia/reperfusion induces ATP depletion, Ca\(^{2+}\) overloading, and production of reactive oxygen species (ROS) in cardiomyocytes, and these events are known to promote mPTP opening and also to induce ER stress (10,18,23,40). As recently reviewed by Lamarca and Scorrano (41), cross-talks have been proposed between ER-derived and mitochondria-derived cell death/survival pathways. The results of the present study suggest that ER stress associated with diabetes modulates the mPTP in mitochondria via modification of GSK-3\(\beta\) phosphorylation signaling (Fig. 5) and mitochondrial translocation of GSK-3\(\beta\) (Fig. 4). However, it remains unclear whether ischemia/reperfusion-induced ER stress in the myocardium differs between LETO and OLETF rats.

A link between change in the threshold for mPTP opening by GSK-3\(\beta\) phosphorylation and change in the extent of myocardial necrosis in situ is difficult to directly demonstrate. However, several lines of circumstantial evidence indicate that elevation of the threshold for mPTP opening results in limitation of infarct size. First, multiple agents that induce phosphorylation of GSK-3\(\beta\) have been shown to induce both infarct size limitation and elevation of the threshold for mPTP opening in response to ROS (11,15). Second, level of phospho–GSK-3\(\beta\) upon reperfusion was shown to be inversely correlated with infarct size in a previous study (13), and such a correlation was confirmed in the present study as well (Fig. 5D). Third, pharmacological inhibitors of GSK-3\(\beta\), which mimic the effect of phosphorylation of GSK-3\(\beta\) at Ser9, significantly limited infarct size in earlier studies (12,13) and in the present experiments. It is notable that SB216763 limited infarct size to similar extents in LETO and OLETF rats, suggesting that the protective mechanism downstream of GSK-3\(\beta\) remains intact in the diabetic myocardium. Thus, GSK-\(\beta\) inhibitors are potentially useful agents for myocardial salvage in patients with acute myocardial infarction and diabetes.

It is unclear how phospho–GSK-3\(\beta\) elevates the threshold for opening of the mPTP in response to oxygen radicals and calcium overload at the time of reperfusion (10,11,14,15). Recently, we found that phosphorylation of GSK-3\(\beta\) at Ser9 by IPC and EPO treatment induced physical interaction of phospho–GSK-3\(\beta\) with ANT, and this phospho–GSK-3\(\beta\)–ANT interaction inhibited binding of ANT to cyclophilin D (10,16). Since cyclophilin D increases sensitivity of ANT to Ca\(^{2+}\), inhibition of ANT-cyclophilin D interaction should suppress mPTP opening. In addition to this possible mechanism, suppression of hexokinase release from the mitochondria and reduction in ATP hydrolysis during ischemia have been suggested to be involved in inhibition of mPTP opening by phospho–GSK-3\(\beta\) (14).

Alterations in signal transduction and ER stress in the myocardium of OLETF rats, a model of type 2 diabetes, are unlikely to be extrapolated to type 1 diabetes. Disruption in PI3K-Akt signaling and elevation of GRP78 protein level were observed in the myocardium of streptozotocin-induced diabetes as well (7,42). However, in this model of type 1 diabetes, protein levels of CHOP and JNK were significantly elevated, and ERK phosphorylation was also impaired in the myocardium (7,42). In contrast, CHOP protein was not significantly elevated and ERK phosphorylation was intact in OLETF rats (Figs. 2 and 3). Involve-

FIG. 7. Schematic presentation of alteration in EPO-provoked signaling in diabetic myocardium. A: In the normal myocardium (i.e., LETO), EPO phosphorylated both Akt and ERK, but phosphorylation of Akt is sufficient to phosphorylate GSK-3β, resulting in infarct size limitation. B: In diabetic rats (i.e., OLETF rats), Akt phosphorylation by EPO and phosphorylation of GSK-3β by ERK were impaired. Constitutively active GSK-3β is increased, particularly in the mitochondria, which blunts the effect of intracellular signaling leading to GSK-3β phosphorylation.
No potential conflicts of interest relevant to this article were reported.
