Production of sulfur globules during sulfide or thiosulfate oxidation is a characteristic feature of some sulfur bacteria. Although their generation has been reported in *Acidithiobacillus ferrooxidans*, its mechanism of formation and deposition, as well as the physiological significance of these globules during sulfur compounds oxidation, are currently unknown. Under oxygen-sufficient conditions (OSC), *A. ferrooxidans* oxidizes thiosulfate to tetrathionate, which accumulates in the culture medium. Tetrathionate is then oxidized by a tetrathionate hydrolase (TTH) generating thiosulfate, elemental sulfur, and sulfate as final products. We report here a massive production of extracellular conspicuous sulfur globules in thiosulfate-grown *A. ferrooxidans* cultures shifted to oxygen-limiting conditions (OLC). Concomitantly with sulfur globule deposition, the extracellular concentration of tetrathionate greatly diminished and sulfite accumulated in the culture supernatant. *A. ferrooxidans* cellular TTH activity was negligible in OLC-incubated cells, indicating that this enzymatic activity was not responsible for tetrathionate disappearance. On the other hand, supernatants from both OSC- and OLC-incubated cells showed extracellular TTH activity, which most likely accounted for tetrathionate consumption in the culture medium. The extracellular TTH activity described here: (i) gives experimental support to the TTH-driven model for hydrophilic sulfur globule generation, (ii) explains the extracellular location of *A. ferrooxidans* sulfur deposits, and (iii) strongly suggests that the generation of sulfur globules in *A. ferrooxidans* corresponds to an early step during its adaptation to an anaerobic lifestyle.

**INTRODUCTION**

During oxidation of reduced inorganic sulfur compounds (RISCs), by some microaerophilic chemotrophic sulfur bacteria and by anaerobic phototrophic microorganisms, the deposition of intracellular or extracellular conspicuous sulfur globules as an important (and sometimes obligatory) intermediary occurs. It has been proposed that production of obligated intracellular sulfur deposits, during anaerobic sulfide and thiosulfate oxidation in photolithotrophic and facultative anaerobic chemolithotrophic bacteria, correlates with the lack of sulfur dehydrogenase (SoxCD), normally present in the thiobacilli. Tetrathionate is then oxidized by a tetrathionate hydrolase (TTH) generating thiosulfate, elemental sulfur, and sulfate as final products. We report here a massive production of extracellular conspicuous sulfur globules in thiosulfate-grown *A. ferrooxidans* cultures shifted to oxygen-limiting conditions (OLC). Concomitantly with sulfur globule deposition, the extracellular concentration of tetrathionate greatly diminished and sulfite accumulated in the culture supernatant. *A. ferrooxidans* cellular TTH activity was negligible in OLC-incubated cells, indicating that this enzymatic activity was not responsible for tetrathionate disappearance. On the other hand, supernatants from both OSC- and OLC-incubated cells showed extracellular TTH activity, which most likely accounted for tetrathionate consumption in the culture medium. The extracellular TTH activity described here: (i) gives experimental support to the TTH-driven model for hydrophilic sulfur globule generation, (ii) explains the extracellular location of *A. ferrooxidans* sulfur deposits, and (iii) strongly suggests that the generation of sulfur globules in *A. ferrooxidans* corresponds to an early step during its adaptation to an anaerobic lifestyle.

Production of sulfur globules during sulfide or thiosulfate oxidation is a characteristic feature of some sulfur bacteria. Although their generation has been reported in *Acidithiobacillus ferrooxidans*, its mechanism of formation and deposition, as well as the physiological significance of these globules during sulfur compounds oxidation, are currently unknown. Under oxygen-sufficient conditions (OSC), *A. ferrooxidans* oxidizes thiosulfate to tetrathionate, which accumulates in the culture medium. Tetrathionate is then oxidized by a tetrathionate hydrolase (TTH) generating thiosulfate, elemental sulfur, and sulfate as final products. We report here a massive production of extracellular conspicuous sulfur globules in thiosulfate-grown *A. ferrooxidans* cultures shifted to oxygen-limiting conditions (OLC). Concomitantly with sulfur globule deposition, the extracellular concentration of tetrathionate greatly diminished and sulfite accumulated in the culture supernatant. *A. ferrooxidans* cellular TTH activity was negligible in OLC-incubated cells, indicating that this enzymatic activity was not responsible for tetrathionate disappearance. On the other hand, supernatants from both OSC- and OLC-incubated cells showed extracellular TTH activity, which most likely accounted for tetrathionate consumption in the culture medium. The extracellular TTH activity described here: (i) gives experimental support to the TTH-driven model for hydrophilic sulfur globule generation, (ii) explains the extracellular location of *A. ferrooxidans* sulfur deposits, and (iii) strongly suggests that the generation of sulfur globules in *A. ferrooxidans* corresponds to an early step during its adaptation to an anaerobic lifestyle.

**Keywords:** *Acidithiobacillus ferrooxidans*, sulfur globules, extracellular tetrathionate hydrolase, thiosulfate oxidation
in aerated *A. ferrooxidans* suspensions incubated with tetrathionate (Steudel et al., 1987). Based on these results, a set of reactions involving the highly reactive disulfane monosulfonic acid were proposed, in which this compound reacts with itself in successive elongation chain reactions leading to the production elemental sulfur and sulfite (2HSO₃⁻ + H₂O → S₈ + H₂SO₄; 2HSO₃⁻ ↔ HS₂SO₄⁻ + HSO₃⁻; HS₂SO₄⁻ ↔ S₈ + HSO₃⁻; Figure 1).

The hydrophobic elemental sulfur generated can be “solubilized” by polythionates in a micelle-like structure, forming hydrophilic sulfur globules (Steudel et al., 1987). Due to the reversibility of the reactions involved in the higher polythionates pathway and because their formation does not explain oxidation of the sulfane-sulfur moiety from thiosulfate, the physiological significance of polythionates (and hence of hydrophilic sulfur globules) as intermediates during sulfur oxidation remains obscure (Kelly et al., 1997; Ghosh and Dam, 2009). The appearance of visible sulfur (sulfur globules) during *A. ferrooxidans* growth in a substrate-limited chemostat on tetrathionate under high substrate concentrations (above 400 μM) has been reported. Transmission electron microscopy (TEM) micrographs of these cells showed tiny globules located between the inner and outer membranes or in a discrete cytoplasmic vacuole-like structure (Hazeu et al., 1988). Despite the low concentration and small size of sulfur globules produced by thiosulfate-grown *A. ferrooxidans*, it was possible to identify polythionates as the main sulfur species present in them by using sulfur K-edge X-ray absorption near-edge spectroscopy (XANES) analysis (Prange et al., 2002). However, some controversy exists regarding the methodological approach used by Prange et al. (2002) in their sulfur K-edge XANES analysis (George et al., 2008) and other researchers have found elemental sulfur as the main sulfur species in *A. ferrooxidans* sulfur globules (He et al., 2010).

Sulfur globule deposition is a characteristic feature amongst anoxygenic sulfur bacteria. In the proposed model for hydrophilic sulfur globule production, TTH is the key enzyme involved and is responsible for the initial step of a physiological response to a decrease in oxygen availability. Furthermore, our results suggest that deposition of sulfur globules might be an early step of a physiological response to a decrease in oxygen availability.

**FIGURE 1 | Detailed structures of relevant sulfur compounds and reactions proposed for sulfur globules production.** (A) Enzymatically catalyzed reactions. TD, thiosulfate dehydrogenase; TTH, tetrathionate hydrolase. (B) Anoxygenic condensation of disulfane monosulfonic acid that leads to polythionates generation. (C) Successive condensation reactions of sulfane monosulfonic acids that leads to elemental sulfur production. TS, thiosulfate; TT, tetrathionate; DSMSA, disulfane monosulfonic acid; SO₃²⁻, sulfite; SO₄²⁻, sulfate; PT, pentathionate; TSMSA, tetrathionate monosulfonic acid; OSMSA, octosulfane monosulfonic acid; S₈, elemental sulfur. **MATERIALS AND METHODS**

**BACTERIAL STRAINS AND GROWTH CONDITIONS**

*Acidithiobacillus ferrooxidans* strain ATCC 23270 was grown in batch cultures by using thiosulfate-containing DSMZ medium 71 [in grams per liter: KH₂PO₄, 3.0; MgSO₄·7H₂O, 0.5; (NH₄)₂SO₄, 3.0; CaCl₂·2H₂O, 0.25; Na₂S₂O₃·5H₂O, 5.0; pH 4.4–4.7]. No ferrous sulfate was added to the medium according to the instructions given by DSMZ. *A. ferrooxidans* cells were washed with basal salts DSMZ 71 medium solution and inoculated at a density of 2.5 × 10⁶ cells/mL in Erlenmeyer flasks (2 L) containing 500 mL of DSMZ 71 medium (flask to culture volume ratio of 0.25) followed by incubation at 30°C with shaking (150 RPM). Once the culture reached the mid to late-exponential-phase, shifts to OLC were achieved by...
trespassing 200–250 mL of the grown culture to a 250-mL flask (culture to flask volume ratio of 0.8:1.0) followed by incubation at 30°C without shaking. The remaining *A. ferrooxidans* culture was kept in the 2-L Erlenmeyer flask (culture to flask volume ratio of 0.1:0.125) and was further incubated at 30°C with shaking. These cultures were used as the oxygen-sufficient condition (OSC). Cell and sulfur globule counting was carried out by using a Petroff-Hausser chamber in a phase-contrast Olympus BX50 microscope. Sulfur globules were identified as extracellular refringent structures viewed at a 600× magnification. After centrifugation of OLC- and OSC-cultures (5,000 × g at 4°C for 20 min) media supernatants were filtered through a 0.22-μm nitrocellulose filter and were used to determine presence of different thiols and enzymatic activities. 

**PREPARATION OF CELL-FREE EXTRACTS**

*A. ferrooxidans* cells were washed three times by centrifugation with 1 M ammonium sulfate pH 3.0 and finally resuspended in 500 μL of 1 M ammonium sulfate pH 3.0. To obtain cell-free extracts, cells were disrupted by sonication on ice (Misonix XL 2020, Farmingdale, NY, USA; 20% intensity cycles of 20 s on, 40 s off for 10 min total time). Unbroken cells and cellular debris were removed by centrifugation at 15,000 × g at 4°C for 10 min. 

**ANALYSIS OF SULFUR COMPOUNDS**

Thiosulfate was determined by the decolorization of methylene-blue at 670 nm in acidic conditions (Kletzin, 1989). Tetrathionate was determined by a cold-lysis protocol (Kelly et al., 1969). Production of extracellular sulfur in *A. ferrooxidans* cultures was estimated by the increase in absorbance at 430 nm (Hazeu et al., 1988). Elemental sulfur was quantitatively determined by extraction with acetone/water (19:1) followed by cyanolysis (Kelly and Wood, 1998) and normalized by the amount of total protein content of the cell pellet extracted. Analysis of low molecular thiols present in *A. ferrooxidans* growth medium supernatants was carried out by using HPLC after sample derivatization with THIOLYTE® monobromobimane reagent (Calbiochem, La Jolla, CA, USA) as previously described (Rethmeier et al., 1997).

**OXYGEN DETERMINATION**

Oxygen measurements were carried out in a liquid-phase oxygraph (Hansatech Instruments, Ltd., Norfolk, UK). The electrode cell was filled with 2.5 mL of a mid to late-exponential-phase culture of *A. ferrooxidans* and the oxygen concentration in the medium was recorded. To mimic oxygen-sufficient conditions, the electrode chamber lid was removed and 1.0 mL of the *A. ferrooxidans* culture was kept in the cell chamber. At different times, 0.1 mL aliquots were taken and the absorbance at 430 nm was measured.

**ENZYMATIC ASSAYS**

Thiosulfate dehydrogenase activity was determined spectrophotometrically by using ferricyanide as an artificial electron acceptor. The reaction was followed by the thiosulfate-dependent decrease in ferricyanide absorbance at 420 nm. The TD reaction mixture contained (in 1 mL final volume): 150 mM potassium acetate buffer pH 5.0, 1 mM ferricyanide, 10 mM sodium thiosulfate, and 50 μg mL⁻¹ of cell-free extract protein. One unit of activity (U) was defined as the amount of enzyme that catalyzes the reduction of 1 μmol ferricyanide min⁻¹. Tetrathionate hydrolase activity was determined in a continuous assay, measuring the increase in absorbance at 290 nm due to the production of long-chain sulfur intermediates derived from tetrathionate hydrolysis (de Jong et al., 1997). The reaction mixture contained (in 0.1 mL final volume): 1 M ammonium sulfate pH 3.0, 1 mM sodium tetrathionate, and 50 μg mL⁻¹ of cell-free extract protein. THH activity was determined in aliquots of filtrated growth medium supernatants from *A. ferrooxidans* cultures incubated under OLC and OSC. Units for THH activity were expressed as ΔAbs 290 nm min⁻¹. All enzymatic reactions were carried out at room-temperature. Data presented for sulfur compounds and enzymatic activities correspond to the mean values and SD of at least three independent experiments.

**RNA MANIPULATIONS**

*A. ferrooxidans* total RNA was prepared as previously reported for qRT-PCR analysis (Navarro et al., 2009). Primers tetH FW (TGCTGTCCAATGGATTCAA) and tetHR1 (TGATACGCCGGTTCCATATCC) were used for tetH amplification and 16SFW (TGTTGCCTAGCTAGTACTG) and 16SRR (CCGAAGGGCACCTCCGCA) for *A. ferrooxidans* 16S rRNA. Absolute copy numbers for tetH and 16S rRNA were determined by using standard curves obtained by serial dilutions of *A. ferrooxidans* genomic DNA. Copy numbers of tetH relative to 16S rRNA were determined at each OLC-incubation time from three independent experiments and the mean values and SD are shown.

**PRECIPITATION OF EXTRACELLULAR PROTEINS AND THEIR IDENTIFICATION BY MASS SPECTROMETRY ANALYSIS**

*A. ferrooxidans* cells were separated from their growth medium (400 mL) by centrifugation at 5,000 × g at 4°C for 20 min. Proteins present in the filtered supernatants were precipitated by using the PRMM method (Caldwell and Lattemann, 2004) as applied to *A. ferrooxidans* cells (Pagliai and Jerez, 2009). Precipitated proteins were electrophoresed on a Tris/Glycine SDS polyacrylamide gel and stained with Coomassie Blue G-250. Bands of interest were excised manually from the gels and the proteins present in them were identified by MALDI peptide mass fingerprinting and MALDI–TOF/TOF MS analysis as described before (Varela et al., 2010). Possible subcellular localization of identified proteins was predicted by using the SubCell 1.0 server at Center for Biological Sequence Analysis, BioCentrum-DTU, The Technical University of Denmark (http://www.cbs.dtu.dk/services/SubCell/). Protein measurements were carried out by using Bradford’s method (PIERCE, Rockford, IL, USA) and crystalline BSA as standard.

**RESULTS**

**GROWTH OF *A. FERROOXIDANS* IN THIOSULFATE AS ENERGY SOURCE**

As it has been previously shown (Hazeu et al., 1986) during thiosulfate oxidation by *A. ferrooxidans*, tetrathionate was accumulated in the culture medium, and in our experimental conditions it reached a maximum concentration of c.a. 5 mM (Figure 2A). The ratio between the rates of thiosulfate consumption and tetrathionate increase in the culture medium was c.a. 4:1. This ratio, and the stoichiometric relationship involved in tetrathionate formation by means of thiosulfate oxidation by TD, suggests that half of the tetrathionate formed from thiosulfate oxidation diffuses out of the cells and into the culture medium. Tetrathionate concentration
began to decrease only when thiosulfate was almost completely consumed (Figure 2A). Most likely, tetrathionate starts being oxidized by cells due to the lack of thiosulfate as an energy source.

**EFFECT OF OXYGEN AVAILABILITY IN THIOSULFATE-GROWN A. FERROXIDANS CULTURES**

When mid to late-exponential-phase thiosulfate-grown A. ferrooxidans cultures were shifted to OLC, their media became white and their absorbance at 430 nm was significantly increased compared to OSC-incubated cultures (Figure 2B). The increment in absorbance at 430 nm suggests the production of elemental sulfur in OLC-incubated cultures. This change in absorbance was not observed when cells were removed by filtration before shifting the culture to OLC (Figure 2B), indicating that the increase in absorbance was not due to the chemical reactivity of the thiosulfate/tetrathionate mixture present in the culture medium when the OLC-incubation started, but rather to a cell-dependent phenomenon. Moreover, after 20 h incubation of A. ferrooxidans under OSC or OLC pH values of culture supernatants were 2.30 ± 0.51 and 3.23 ± 0.44, respectively, indicating that the increment in absorbance at 430 nm observed was not due to a low pH-dependent decomposition of thiosulfate. Inspection of cells under the phase-contrast microscope showed a massive production of extracellular globular-shaped refringent structures (sulfur globules) only in OLC-incubated cultures (Figure 2C). Cell growth and production of sulfur globules were both directly counted under the phase-contrast microscope at different times during OSC- or OLC-incubations. 50% of the total specimens (bacteria and sulfur globules) counted by phase-contrast microscopy corresponded to sulfur globules after incubating cells for 5 h under OLC. They reached a maximum of 80% after incubating for 15 h. On the other hand, production of sulfur globules was not observed at all in cultures incubated under OSC (Figure 2D).

**EXTRACELLULAR A. FERROXIDANS SULFUR GLOBULES CONTAIN ELEMENTAL SULFUR**

The increase in absorbance at 430 nm observed in A. ferrooxidans cultures shifted to OLC (Figure 2B) suggests the production of elemental sulfur in the medium. To determine whether the extracellular globules produced by A. ferrooxidans contained elemental sulfur, A. ferrooxidans cells pelleted together with globules were extracted with acetone and sulfur was determined by cyanolysis. During incubation under OLC, the amount of sulfur extracted increased, whereas under OSC sulfur amounts remained unchanged (Figure 3A). Moreover, visual inspection of acetone-extracted A. ferrooxidans cells by phase-contrast microscopy showed that sulfur globules were completely extracted from OLC-incubated cultures.
after acetone treatment (Figure 3B). These results confirm that the refringent structures produced during OLC-incubations corresponded to elemental sulfur-containing globules.

Sulfur Globule Production Depends on Oxygen Concentration

To correlate extracellular sulfur globule production with the availability of oxygen, the concentration of oxygen dissolved in a thiosulfate-grown culture of A. ferrooxidans was determined by using a liquid-phase oxygraph. The absorbance at 430 nm of the culture incubated in the oxygraph-cell was recorded and used as an indicator of the production of sulfur globules. Oxygen initially dissolved in the culture medium dropped within the first 15 min of incubation, most likely due to its consumption by A. ferrooxidans cells. After the medium was depleted of oxygen absorbance at 430 nm began to increase (Figure 4). Moreover, when oxygen concentration increased again (by opening the oxygraph-cell lid), a concomitant decrease in absorbance at 430 nm was obtained (Figure 4). This suggests that sulfur compounds accumulated during OLC-incubation were readily oxidized most likely by A. ferrooxidans cells once oxygen was restored.

Analysis of Sulfur Compounds Oxidation During Sulfur Globules Production

To determine the mechanisms underlying extracellular sulfur globule production under OLC-incubations, concentrations of thiosulfate and tetrathionate in culture media, and enzymatic activities related to its oxidation (TD and TTH) under OLC- and OSC-incubations were measured. Thiosulfate was completely depleted from the culture media after 5 h of OLC-incubation (Figure 5A), almost certainly due to its consumption by the cells. Under OLC-incubation, thiosulfate concentration slightly increased within the first 5 h, and after that period it remained unchanged (Figure 5A). TD activity of cells incubated under OSC was c.a. six times lower than that of cells incubated under OSC (0.15 ± 0.06 and 0.99 ± 0.08 U mg protein⁻¹, respectively; Figure 5C). This result was expected since thiosulfate oxidation was not observed in the OLC-incubated culture and Northern-Blot analysis indicated the downregulation of both doxDA1 and doxDA2 genes in OLC-incubated cells (Beard and Jerez, results not shown). doxDA1 and doxDA2 coded in A. ferrooxidans ATCC 23270 genome are ortholog genes of Acidibium ambivalens thiosulfate:quinone oxidoreductase (TQO; Müller et al., 2004). On the other hand, tetrathionate concentration in the culture media decreased both in OSC- and OLC-incubated cultures (Figure 5B). Surprisingly, TTH activity found in OLC-cells was c.a. 25 times lower than the one in the OSC-incubated cells (0.007 ± 0.004 and 0.167 ± 0.05 U mg protein⁻¹, respectively; Figure 5D). To assess whether the decrease in TTH activity was due to a possible transcriptional regulation of tetH gene, its transcription was determined by qRT-PCR. Transcriptional levels of tetH were highly downregulated in A. ferrooxidans cells subjected to OLC-incubations during 5–20 h (Figure 5E). A set of housekeeping genes has been proposed for qRT-PCR transcriptome analysis in A. ferrooxidans (Nieto et al., 2009). However, none of those genes have been tested under the OSC/OLC-conditions used in this study. Although 16S rRNA transcript levels can vary due to growth conditions, we have normalized the qRT-PCR values by using 16S rRNA as previously reported (Vera et al., 2008; Navarro et al., 2009). The very low TTH activity and expression level of the TTH coding gene in OLC-incubated microorganisms suggest cells do not have enough TTH activity to account for either the decrease in extracellular tetrathionate concentration or the sulfur globule production observed. Since hydrolysis of tetrathionate by a TTH is proposed as the key step during biological formation of hydrophillic sulfur globules (Steudel, 2003), lack of TTH activity in OSC-incubated cells was unexpected and suggests the existence of a mechanism independent of cellular TTH activity for generation of sulfur globules by A. ferrooxidans.

TTH Activity is Present in A. Ferrooxidans Culture Supernatants

Due to the extracellular nature of sulfur globules produced by A. ferrooxidans, supernatant fractions from OSC- and OLC-incubated cultures were further investigated. To determine the low molecular weight thiol composition of supernatants from A. ferrooxidans
cultures subjected to OLC-incubation, they were directly derivatized with monobromobimane and analyzed by HPLC. Unlike OSC culture supernatants, the OLC-incubated \textit{A. ferrooxidans} supernatants showed the presence of sulfite (Figure 6A). During the incubation of \textit{A. ferrooxidans} cultures under OLC sulfite accumulated in the supernatants (Figure 6B). Due to the oxygen requirement for sulfur-oxidizing enzymes from thiobacilli (Suzuki, 1994) it is not likely that sulfite arose from elemental sulfur oxidation under OLC-incubation. TTH activity was detected both in OSC- and OLC-incubated culture supernatants (Figure 6C). The proteins present in the growth medium of OLC-incubated cells were precipitated and analyzed by SDS-PAGE (Figure 6D). Two of the three main protein bands present in the SDS-PAGE could be correctly identified by MALDI–TOF/MS (Table 1).

Protein band No. 1 corresponded to TetH protein of \textit{A. ferrooxidans} ATCC 53993, which is identical to TetH from \textit{A. ferrooxidans} ATCC 23270 used in this study and actually corresponds to \textit{A. ferrooxidans} TTH (Buonfiglio et al., 1999; Kanao et al., 2007). Although TetH has a predicted Sec-type signal peptide, to date its subcellular location is not clear.

Protein band No. 2 was identified as the phosphate-binding protein PstS2 of \textit{A. ferrooxidans} ATCC 23270. This protein belongs to the phosphate starvation responding Pho regulon of this microorganism (Seeger and Jerez, 1993; Vera et al., 2003). Phosphate-binding proteins have also been reported in the medium of other bacteria (Tjalsma et al., 2004; Diaz et al., 2005; Meneses et al., 2010). Besides its obvious role in phosphate uptake, its possible relationship with extracellular TTH function in \textit{A. ferrooxidans} cannot be anticipated at present.

The evidence presented here suggests that the TetH protein found in \textit{A. ferrooxidans} culture supernatants corresponded to an active TTH and its activity would be related to extracellular sulfur globule production under OLC-incubations.

**DISCUSSION**

Thiosulfate is relatively unstable at pH values below 4.0. As the culture medium becomes acid due to thiosulfate oxidation, sulfite, and elemental sulfur formation is usually observed. For this reason it has been suggested that batch cultures are not adequate to study growth of thiobacilli on thiosulfate (Pronk et al., 1990). However, when washed \textit{A. ferrooxidans} cells are used as inoculum at low cell densities (2.5 × 10⁶ cells/mL), neither the precipitation of elemental sulfur nor the formation of sulfur globules take place in batch cultures. Therefore, we have used these conditions to study the effect of oxygen availability in thiosulfate-grown \textit{A. ferrooxidans} cells.
Figure 6 | Tetrahionate hydrolase activity is present in A. ferrooxidans culture supernatants. (A) Identification of low molecular weight thiols in A. ferrooxidans culture supernatants by HPLC. Thiols present in the culture supernatants from A. ferrooxidans subjected to 5 h OLC-incubation were derivatized with the monobromobimane reagent and separated by using HPLC. \( \text{SO}_3^2 \), sulfite; TS, thiosulfate; R, reagent or water-derived peaks. (B) Changes in sulfite concentrations in thiosulfate-grown A. ferrooxidans culture supernatants during OSC-(♦) or OLC-(◊) incubations. \(^b\)Deduced from aminoacidic sequences.

\(^c\)Subcellular localization predicted by using the SubCell 1.0 server (http://www.cbs.dtu.dk/services/SubCell/).
Cell densities did not change under OLC, indicating that cells did not grow or lyse during the conditions used in the experiments. Therefore, it is not likely that sulfur globules were released to the culture medium by a cell-lysis mechanism, as it has been proposed in *Thermoanaerobacterium sulfurigenens* JW/SL-NZ826T (Lee et al., 2007). To assess whether the lack of oxygen affects in general the gene expression pattern in *A. ferrooxidans* during OLC-incubations, transcriptional levels of a group of genes related to stress response and other cellular processes were measured by using a DNA-microarray system as described before (Orell et al., 2010). Levels of transcripts of most *A. ferrooxidans* genes measured showed no significant differences. The only significant change observed in *A. ferrooxidans* cultures subjected to OLC-incubations was the downregulation of the cydA gene coding for a subunit of a bd-type terminal quinol-oxidase, suggesting that cells were actually responding rather specifically to changes in the availability of oxygen under the experimental set-up used (results not shown).

To date the subcellular location of TetH is not clear. It has been previously described as an outer membrane protein (Buonfiglio et al., 1999), a soluble and probably periplasmic protein (de Jong et al., 1997; Chi et al., 2007), and as a membrane-associated protein (Kanao et al., 2007). The gene coding for TetH contains a Sec-secretion signal (Kanao et al., 2007), strongly suggesting that it is a protein secreted into the periplasm (Table 1). The extracellular location of TetH reported here corresponds to a new finding and opens the question about the mechanism involved in its secretion from the periplasm into the growth medium. The sequence of the N-terminal end of the protein was not obtained during its identification by mass spectrometry in our studies. Therefore, the cleavage site of the Sec-type signal peptide could not be confirmed in the extracellular TetH. Nevertheless, bioinformatic analyses have shown that *A. ferrooxidans* ATCC 23270 genome contains genes coding for six of the eight secretion systems known in bacteria (Pagliai and Jerez, 2009), several of which would be capable of secreting proteins by using the Sec system.

The current model for thiosulfate oxidation by the S4I-pathway (Pront et al., 1990; Ghosh and Dam, 2009) explains intracellular sulfur globule production as some of the disulfane monosulfonic acid derived from periplasmic tetrathionate oxidation can follow the “higher polythionates pathway” that leads to the formation of intracellular sulfur deposits (Hazeu et al., 1988; Figure 7). However, this model does not explain the deposition of extracellular sulfur by *A. ferrooxidans* shown in this report. Since TTH activity was found in the extracellular medium of both OSC- and OLC-conditions, sulfur deposition was expected in both kinds of cultures. However, sulfur globule formation was seen only under OLC-conditions. The extracellular TTH activity could account for tetrathionate disappearance from the growth medium. The concomitant extracellular sulfur globule production in OLC-incubated *A. ferrooxidans* cells could be explained by the negligible periplasmic TD and TTH activities. Under these conditions, the only reaction that could take place is the extracellular hydrolysis of tetrathionate (Figure 7). An additional possible explanation for the lack of sulfur globules in OSC-incubated cells is that sulfur is indeed produced by extracellular TTH but is followed by its immediate oxidation by the cells.

To understand the significance of sulfur globule generation under OLC-incubations, some issues regarding enzymatic activities as well as some physiological considerations must be taken into account. The lack of TD activity in OLC-incubated cells is probably due to the fact that in *A. ferrooxidans* this activity should be directly coupled to molecular oxygen reduction by a terminal oxidase, as it has been shown in *A. ambivalens* (Müller et al., 2004). *A. ferrooxidans* is a facultative anaerobe bacterium and can use ferric iron as an electron acceptor during anaerobic oxidation of elemental sulfur (Pront et al., 1992). Moreover, it was recently reported that *A. ferrooxidans* TTH has ferric iron reductase activity (Sugio et al., 2009). Although ferric iron may act as an alternative electron acceptor in anoxicogenic tetrathionate oxidation, the physiological electron acceptors for this reaction are unknown. Once *A. ferrooxidans* cells switch to anaerobic metabolism, elemental sulfur stored into sulfur globules may be further oxidized by means of ferric iron respiration.

Our preliminary observations indicate that TetH protein is also present in supernatants obtained from elemental sulfur and pyrite-grown *A. ferrooxidans* cultures, suggesting that extracellular TTH activity may play a role during elemental sulfur oxidation and bioleaching of sulfide ores. In this regard, it is noteworthy that during pyrite oxidation in acidic environments and in excess ferric iron, thiosulfate is formed as the key intermediary (Schippers et al., 1996). The rate of chemical oxidation of thiosulfate is several orders of magnitude faster than that for tetrathionate oxidation. Therefore, tetrathionate can persist in the environment and may be metabolized by sulfur-oxidizing microorganisms (Druschel et al., 2003). This gives a geochemical relevance to the biochemical pathways related to tetrathionate oxidation. Interestingly, the production of colloidal sulfur particles within *A. ferrooxidans* capsule was observed during incubation of cells grown on synthetic pyrite films (Rojas-Chapana et al., 1996).

To the best of our knowledge, the present report is the first evidence for an enzymatic activity existing in *A. ferrooxidans* culture supernatants. Furthermore, this finding suggests a mechanism for extracellular sulfur globule deposition in a microorganism that does not use the branched-PSO pathway for thiosulfate oxidation. In addition, a physiological role for *A. ferrooxidans* extracellular sulfur globule production is proposed as a response allowing cells to overcome a
momentary decrease in oxygen availability, probably as an early step during the metabolic switch to anaerobic lifestyle. Further investigation using non-invasive methods for *in situ* analysis of sulfur globules (such as sulfur K-edge XANES or Laser Raman spectroscopy) will be needed in order to unveil the exact chemical nature of the sulfur species generated by *A. ferrooxidans* in its extracellular sulfur globules and whether they are different from the composition previously reported for *A. ferrooxidans* globules (Prange et al., 2002). In this regard, a recent study on sulfur speciation using sulfur K-edge XANES shows that the extracellular globules from thiostate-grown *A. ferrooxidans* are composed mainly of elemental sulfur rings (He et al., 2010), which is consistent with the results reported here.

**CONCLUSION**

*Acidithiobacillus ferrooxidans* produce extracellular sulfur globules when thiostate-grown cultures are shifted to OLC. The finding of TetH protein in the *A. ferrooxidans* growth medium represent a novel issue regarding both the subcellular location and the function of this enzyme, suggesting its involvement in an extracellular sulfur globule deposition mechanism in a microorganism that does not use the branched-PSO pathway for RISCs oxidation. Although demonstration of the mechanism proposed here will require further studies with purified TTH, we believe it may have a physiological as well as geochemical relevance during sulfur compounds cycling in microaerophilic metal sulfide rich environments, in which *A. ferrooxidans* can be normally found.

**ACKNOWLEDGMENTS**

This work was supported by ICM-P05-001-F project and a doctoral fellowship from CONICYT to Simón Beard. We thank A. Hokeer for her help with the English language and S. Rubio and F. Perez (Laboratory of Vegetal Biochemistry, Faculty of Sciences, University of Chile) for their support in the oxygraph measurements and A. Banderas for encouraging us to start this work.
