Social and biological contagions are influenced by the spatial embeddedness of networks. Historically, many epidemics spread as a wave across part of the Earth’s surface; however, in modern contagions long-range edges—for example, due to airline transportation or communication media—allow clusters of a contagion to appear in distant locations. Here we study the spread of contagions on networks through a methodology grounded in topological data analysis and nonlinear dimension reduction. We construct ‘contagion maps’ that use multiple contagions on a network to map the nodes as a point cloud. By analysing the topology, geometry and dimensionality of manifold structure in such point clouds, we reveal insights to aid in the modelling, forecast and control of spreading processes. Our approach highlights contagion maps also as a viable tool for inferring low-dimensional structure in networks.
Considerable research during the past few decades has aimed to understand spreading dynamics on networks—
a widespread phenomenon that occurs in diverse settings that range from biological epidemics to collective social processes such as social movements and innovation diffusion. To study spreading, it is useful to contrast two classes of networks: 'geometric networks,' in which nodes lie in a metric space and are connected by short-range 'geometric edges' that are constrained by the nodes' locations (for example, lattices that describe discretized partial differential equations), and networks that are not geometric, in the sense that their edges are not constrained or defined by distances between nodes. Although the embedding of nodes in a metric space is ubiquitous for spatial networks on Earth’s surface, recent studies have explored the mapping of nodes in a network to locations in a (potentially) latent and (typically) low-dimensional metric space for an extensive variety of applications. Such applications include inferring missing and spurious edges in networks, efficiently routing information across the internet, identifying node-specific attributes that are responsible for edge formation in social networks, and nonlinear dimension reduction of proximity networks inferred from point-cloud data (for example, images, videos and time series) for data storage and signal-processing applications.

When dynamics such as contagions occur on a geometrically embedded network, it is fundamental to question the extent to which the dynamics follow the underlying low-dimensional structure. This question is particularly important and difficult for geometric networks that are supplemented with long-range 'non-geometric edges,' which directly connect nodes that are distant from each other with respect to an underlying metric space. Long-range edges arise in numerous applications, either by chance (for example, subways that connect distant parts of cities) or as a result of merging distinct layers in multilayer networks. In some scenarios, they can also be construed as a source of ‘noise’ in an otherwise geometric network (for example, when edges arise due to the presence of noise for inferred proximity networks). They also play important roles in small-world network models such as Watts–Strogatz, Newman–Watts and Kleinberg networks. Because we are interested in the geometric embeddedness of such networks, we use the term ‘noisy geometric networks’ for networks that include non-geometric edges as supplements to geometric edges. (See Figs 1 and 2 for examples.)

The presence of long-range edges can significantly alter how processes spread. For example, it is traditional to characterize contagions in a geometric setting using ‘wavefront propagation’ (WFP), which agrees with the qualitative properties of historical epidemics such as the Black Death. By contrast, refs 6–8 and numerous other sources have highlighted that modern biological epidemics tend to be dominated by long-range transportation networks, such as airline networks or railway networks, rather than by geographic proximity. Spreading across long-range edges can result in the ‘appearance of new clusters’ (ANC) of a contagion that are spatially distant, which is an important phenomenon in the dynamics of recent global epidemics. Indeed, it has been reported that prominent strains of influenza (for example, H1N1/09) exhibited a pattern of ‘skip-and-resurgence’ (in which some countries avoided outbreaks in some years) during recent worldwide outbreaks.

In addition, long-range edges can also have significant effects on social contagions. Given the (either implicit or explicit) geometric embeddedness for so many of the networks on which ideas and diseases spread, an improved understanding of contagions on noisy geometric networks is important for numerous applications, which range from the identification of influential spreaders of information to control of biological epidemics.

WFP and ANC can be very different in social versus biological contagions. One important difference arises from phenomena such as social reinforcement, which occurs only for social contagions. In Fig. 2, we illustrate the prominent effect of social reinforcement for the Watts threshold model (WTM) of complex contagions by studying node activation times (that is, the times at which nodes adopt the contagion), which depend on the WTM thresholds (for example, for moderate T, little to no ANC occurs and WFP leads to slow dissemination. For large T, there is no spreading. For a given network, activation times across multiple realizations of a contagion (with varying initial conditions) map the nodes to a point cloud via what we call a ‘WTM map’.

**Figure 1** | Examples of noisy geometric networks. Nodes are embedded in three manifolds: (a) a ring (1D) embedded as a circle in R; (b) a spherical surface (2D) in R; and (c) a bounded plane (2D) embedded (nonlinearly) in R in a configuration known as the ‘swiss roll’. Given a network with ‘geometric edges’ (blue), in a and b, we add ‘non-geometric edges’ (red) uniformly at random. In c, by contrast, we add noise to the nodes’ locations in the ambient space and place edges between nodes that are nearby in that space. In this scenario, we interpret edges between nodes that are nearby with respect to the ambient space, but not the manifold, as the non-geometric edges.

**Figure 2** | Wavefront propagation and the appearance of new clusters. (a) Contagions on a noisy geometric network containing geometric edges along a manifold (in this case, a two-dimensional lattice, which we indicate with the blue edges) and non-geometric edges (red edges), which introduce shortcuts in the network. We study two phenomena in the evolution of contagion clusters (shaded areas): ‘wavefront propagation’ (WFP) describes the outward expansion of a contagion cluster’s boundary, and the ‘appearance of a new contagion cluster’ (ANC) occurs when a contagion spreads exclusively along non-geometric edges (dashed arrow). (b,c) We examine WFP and ANC for the Watts threshold model (WTM) for complex contagions by studying node activation times (that is, the times at which nodes adopt the contagion), which depend on the WTM thresholds {T}, which we take to be identical for every node (that is, T = T for all i). (b) For small T, frequent ANC leads to rapid dissemination of a contagion. (c) For moderate T, little to no ANC occurs and WFP leads to slow dissemination. For large T, there is no spreading. For a given network, activation times across multiple realizations of a contagion (with varying initial conditions) map the nodes to a point cloud via what we call a ‘WTM map’.
social contagions. The WTM is a generalization of bootstrap percolation and is based on the idea that each node $i$ has some threshold $T_i \geq 0$ for adopting a social contagion (that is, for becoming infected). The threshold dynamics gives rise to the characterization of the WTM as a so-called ‘complex’ contagion, because the dynamics at each node $i$ depend on the states of all neighbouring nodes, and it might be necessary for multiple neighbours to be infected before node $i$ adopts a contagion. Importantly, for some threshold values, WCP can dominate ANC even in the presence of many ‘noisy’ edges—a phenomenon that has widespread applications (see Discussion and our Supplementary Discussion).

In the present paper, we study bifurcations in WFP and ANC dynamics by examining data that are generated by several contagions on a given noisy geometric network. Our methodology is grounded in the field of computational topology, and we note that there has been rapidly intensifying interest (see, for example refs 50–53) in using tools from computational topology to study structural features in networks and for machine learning. In taking this perspective, we introduce a map from the network nodes to points in a metric space based on contagion dynamics.

By analogy to diffusion maps and similar ideas in nonlinear dimension reduction and manifold learning, we use the term ‘contagion maps’ for these maps. We investigate the topology, geometry and dimensionality properties of these maps, and we find for the contagion regime that predominantly exhibits WFP versus ANC that these properties correspond to the manifold that underlies the noisy geometric network. We examine both synthetic and empirical networks, including a transit system in London (see the section ‘Contagions on a London transit network’, Supplementary Note 1 and Supplementary Figs 1–5).

Given that the manifold structure in a contagion map can reflect the underlying manifold structure of a noisy geometric network, contagion maps also help for the identification of such underlying structure. This has numerous applications, including the denoising of networks (see Supplementary Note 2 and Supplementary Figs 6 and 7).

Results

Noisy geometric networks. Noisy geometric networks are a class of networks that arise from geometric networks but also include non-geometric, ‘noisy’ edges. Consider a set $V$ of network nodes that have intrinsic locations $\{w^{(i)}\}_{i \in V}$ in a metric space. We restrict our attention to nodes that lie on a manifold $\mathcal{M}$ that is embedded in an ambient space $\mathcal{A}$ (that is, $w^{(i)} \in \mathcal{M} \subset \mathcal{A}$). We use the term ‘node-to-node distance’ to refer to the distance between nodes in this embedding space $\mathcal{A}$, which we equip with the Euclidean norm $||\cdot||_2$ (although one can also use other metrics$^4$). To create a noisy geometric network, we place the nodes in the underlying manifold and add two families of edges: (1) a set $\mathcal{E}^{(G)}$ of geometric edges, such that $(i,j) \in \mathcal{E}^{(G)}$ when nodes $i$ and $j$ are sufficiently close to one another (that is, the length of shortest path along the manifold $\mathcal{M}$ that connects the two nodes is less than some distance threshold); and (2) a set $\mathcal{E}^{(NG)}$ of non-geometric edges, which we place using some random process between pairs of nodes $(i,j)$, where $i \neq j$ and $(i,j) \notin \mathcal{E}^{(G)}$. In Fig. 1a,b, we show examples of constructing noisy geometric networks by adding non-geometric edges uniformly at random. In Fig. 1c, we show a construction that is motivated by nonlinear dimension reduction of point-cloud data$^{22–26}$.

As an illustrative example, consider the noisy ring lattice in Fig. 1a, which is similar to the Newman–Watts variant of the Watts–Strogatz small-world model. Specifically, we consider $N$ nodes that are uniformly spaced along the unit circle in $\mathbb{R}^2$. We then add geometric edges so that every node $i$ is connected to its $d^{(G)}$ nearest-neighbour nodes. (Note that there are no self-edges.) We then add $d^{(NG)}$ non-geometric edges to each node and connect the ends of these edges (that is, the stubs) uniformly at random while avoiding self-edges and multi-edges. The resulting network is a $(d^{(G)} + d^{(NG)})$-regular network that contains $N_d^{(G)}/2$ geometric edges and $N_d^{(NG)}/2$ non-geometric edges. We can thus specify this class of random networks using three parameters: $N$, $d^{(G)}$ and $d^{(NG)}$. It is also useful to define the ratio $x = d^{(NG)}/d^{(G)}$ of non-geometric to geometric edges. Our construction assumes that $N$ and $d^{(G)}$ are even. In Fig. 1a, we depict a noisy ring network with $N = 20$ and $(d^{(G)}, d^{(NG)}) = (4, 2)$.

In Supplementary Note 3 (see also Supplementary Figs 8 and 9), we study models of noisy geometric networks on a ring manifold that incorporate heterogeneity in the nodes’ degrees and/or locations.

Watts threshold model. We analyse a well-known dynamical system for social contagions: the WTM for complex contagions. In addition to allowing analytical tractability, we have two other motivations for using the WTM. First, WTM contagions yield ‘filtrations’ of a network and thereby allow us to develop a methodology grounded in computational topology. Second, the WTM is a simple-but-insightful model for social influence that has the virtue of explicitly considering social reinforcement.

We define a WTM contagion as follows. Given an unweighted network (which we represent using an adjacency matrix $A$) with a set $V$ of nodes and a set $\mathcal{E}$ of edges, we let $\eta(t)$ denote the state of node $i \in V$ at time $t$, where $\eta(t)=1$ indicates adoption (that is, infection) and $\eta(t)=0$ indicates non-adoption. We initialize a contagion at time $t=0$ by choosing a set of nodes $S \subset V$ and setting $\eta(0)=1$ for $i \in S$ and $\eta(0)=0$ for all other nodes. We refer to $S$ as the ‘contagion seed.’ We consider synchronous updating in discrete time$^4$, so a node $i$ that has not already adopted the contagion at time $t$ (that is, $\eta(t)=0$) will adopt it during the next time step (that is, $\eta(t+1)=1$) if and only if $f_i(T_i)$, where $T_i$ is a node-specific adoption threshold, $f_i = d_i^{-1} \sum_{j \neq i} A_{ij} \eta_j(t)$ denotes the fraction of neighbours that are infected and $d_i = \sum_{j \neq i} A_{ij}$ is the degree of node $i$. (Note that this is a slight modification from the original WTM, which uses the adoption criterion $f_i \geq T_i$.) We repeat this process until the system reaches an equilibrium point at some time $t^* < N$ (that is, no further adoptions occur). For each node $i$, we let $x^{(i)}$ denote the node’s ‘activation time,’ which is the time $t$ at which the node adopts the contagion. Given $T$ and the contagion seed, a WTM contagion on a network is a deterministic process. In addition, a node’s adoption of the contagion is irreversible (that is, there is no unadoption in this model), so the dynamics are monotonic in the sense that the subset $I(t) \subset V$ of infected nodes at time $t$ is non-decreasing with time (that is, $I(t) \subset I(t+1)$). One can thus use the contagion to construct a ‘filtration’ of the network nodes $V$. (See refs 48,49 and our discussion in Supplementary Note 4.)

Contagion maps. We study contagion maps based on WTM contagions, and we refer to these maps as ‘WTM maps.’ A WTM map is a nonlinear map of nodes in a network to a point cloud in a metric space, based on the activation times from several realizations of a WTM contagion. Given $J$ realizations of a WTM contagion on a network with different initial conditions, the associated WTM map is a function from $V$ to $\mathbb{R}^J$ that records the activation time $x^{(i)}_j$ of the $i$th node in the $j$th realization. More precisely, we define a ‘regular’ WTM map as $\mathcal{V} \rightarrow \{x^{(i)}\}_{i \in V} \subset \mathbb{R}^J$, where $x^{(i)}_j = [x^{(i)}_1, x^{(i)}_2, \ldots, x^{(i)}_J]^T$. In practice, we enumerate the contagions $j = 1, 2, \ldots, J \leq N$, and we initialize the $j$th contagion
at a contagion seed \( \mathcal{S}(i) \) such that \( \{j\} \subseteq \mathcal{S}(i) \) for each \( j \). (Note that one can select any \( J \) nodes as seeds by relabelling the nodes.) In addition to the regular WTM map \( \mathcal{V} \rightarrow \{x^{(i)}\}_{i \in \mathcal{V}} \), we also define ‘reflected’ and ‘symmetric’ versions of the WTM map for the subset of nodes \( \mathcal{J} = \{1, 2, \ldots, J\} \subseteq \mathcal{V} \). Letting \( y^{(i)} = x^{(i)} + x^{(i)} \) and \( z^{(i)} = x^{(i)} + x^{(i)} \), we define the reflected WTM map \( \mathcal{J} \rightarrow \{y^{(i)}\}_{i \in \mathcal{J}} \in \mathbb{R}^J \) and symmetric WTM map \( \mathcal{J} \rightarrow \{z^{(i)}\}_{i \in \mathcal{J}} \in \mathbb{R}^J \). For a given network and a given set \( \{T_i\} \) of thresholds, the regular, reflected and symmetric WTM maps are deterministic.

The choice of contagion seeds \( \{\mathcal{S}(i)\} \) plays a crucial role in determining the dynamics of WTM contagions and a WTM map. In practice, we use \( J = N \) realizations of a WTM contagion for an \( N \)-node network, for which we initialize the \( j \)th realization with a contagion seed \( \mathcal{S}(i) = \{j\} \cup \{k \mid A_{jk} \neq 0\} \) that includes node \( j \) and its network neighbours. We use the term ‘cluster seeding’ to describe this type of initial condition, which we illustrate in Fig. 3. By contrast, we use the term ‘node seeding’ to refer to the initialization of a contagion at a single node: \( \mathcal{S}(i) = \{i\} \). In addition, note that setting \( J = N \) yields \( \mathcal{J} = \mathcal{V} \), and then the complete set of nodes is mapped by all versions of a WTM map.

In Supplementary Note 5 (see also Supplementary Fig. 10 and Supplementary Table 1), we show that the typical computational complexity for constructing a WTM map is \( O(NM) \), where \( M \) is the number of edges. We have made our code for constructing WTM maps publicly available. (See the Methods section ‘Data and code availability’.)

We now motivate our choice for contagion initialization. The requirement that \( \{j\} \subseteq \mathcal{S}(i) \) is convenient because it allows us to think of the activation time \( x^{(i)} \) as a notion of distance from node \( j \) to node \( i \) (that is, it describes the time that is required for a contagion to travel from node \( j \) to \( i \)). This choice is akin to the diffusion distance\(^{22}\) and commute-time distance\(^{21}\) derived from diffusion dynamics (although the latter is known to have shortcomings for certain classes of networks\(^{20}\)). To illustrate this point, suppose that contagion seeds are individual nodes (that is, \( \mathcal{S}(i) = \{j\} \) for \( j \in \mathcal{V} \)), and suppose that we construct the WTM map \( \mathcal{V} \rightarrow \{x^{(i)}\}_{i \in \mathcal{V}} \) with \( T_i = T \) for each node \( i \in \mathcal{V} \). In this case, the activation time \( x^{(i)} \) exactly recovers the length of the shortest path between nodes \( i \) and \( j \), and this in turn defines a metric on the discrete space \( \mathcal{V} \). In fact, the \( N \times N \) matrix \( X = \{x^{(i)}\}_{i, j} \) is a dissimilarity matrix, which is central to many algorithms for dimension reduction\(^{22–26}\) (including Isomap\(^{22}\), which implements the mapping of nodes based on shortest paths). Letting \( T = 0 \) and still assuming that each \( x^{(i)} \) is finite, we show in Supplementary Note 4 that the symmetric WTM map induces a metric on \( \mathcal{V} \). More generally, we show that a set of ‘filtrations’ induces a metric under certain conditions. Consequently, we find that one can also use topological data analysis of networks to study the embedding geometry of networks.

Although node seeding has wonderful mathematical properties, cluster seeding is very useful in practice because it can allow a contagion to infect a larger fraction of the nodes in a network. When \( T_i > 0 \) for each \( i \in \mathcal{V} \), it is common for WTM contagions to reach equilibria that do not saturate the network with a contagion. This implies that \( x^{(i)} = \infty \) for some \( i, j \in \mathcal{V} \). Activation times of infinity pose a problem, because WTM maps are well defined only for activation times \( x^{(i)} \) that are finite (see the section ‘Activation times of infinity in WTM maps’). Contagions initialized with clusters of a contagion are more likely to spread than those that are initialized at a single node\(^{20}\), so cluster seeding increases the range of threshold choices that yield activation times that are finite. Although WTM maps that we construct using cluster seeding no longer automatically induce a metric on the node set \( \mathcal{V} \), one can still construe \( x^{(i)} \) as a distance from node \( j \) to \( i \) if the contagion seeds are sufficiently small, \( |\mathcal{S}(i)| < |\mathcal{V}| \).

**WTM contagions on noisy ring lattices.** To guide our experiments on using WTM maps to study WFP and ANC on noisy ring lattices, we conduct a bifurcation analysis for WTM contagions with \( T_i = T \) that are initialized with cluster seeding. We present our analysis in detail in the section ‘Bifurcation analysis’ and in Supplementary Note 6, and we summarize our results here.

Our primary results are two sequences of critical values for the WTM threshold \( T \) that depend on the non-geometric degree \( d^{NG} \) and geometric degree \( d^{G} \). These critical values determine the presence versus absence of WFP and ANC, as well as their rates. The qualitative features of ANC behaviour are determined by the thresholds

\[
T_k^{(ANC)} = \frac{d^{NG} - k}{d^{G} + d^{NG}}, \quad k = 0, 1, \ldots, d^{NG},
\]

Whenever \( T \in \{T_k^{(ANC)}\}_{k=0}^{d^{NG}} \), a node requires at least \( (d^{NG} - k) \) neighbours from non-geometric edges to be infected before it adopts the contagion. This subsequently determines the rate at which new clusters of contagion appear. For \( T \geq T_k^{(ANC)} \), there is no ANC. The qualitative features of WFP are determined by the thresholds

\[
T_k^{(WFP)} = \frac{d^{G} + 2 - k}{2d^{G} - d^{NG}}, \quad k = 0, 1, \ldots, d^{NG},
\]

where a wavefront propagates at a speed of \( k + 1 \) nodes per time step for \( T \in \{T_k^{(WFP)}\}_{k=0}^{d^{NG}} \). For \( T \geq T_0^{(WFP)} \), there is no WFP.

In Fig. 4a, we show a bifurcation diagram that summarizes the WTM dynamics for various values of the contagion threshold \( T \) and ratio \( \pi = d^{NG}/d^{G} \) of non-geometric edges to geometric edges. The dashed and solid curves, respectively, describe
equations (1) and (2) for $k = 0$. That is, $T_0^{(WFP)} = 1/2 + 2z$ and $T_0^{(ANC)} = x/(x+1)$, which intersect at $(z, T) = (1/2, 1/3)$ and yield four regimes of contagion dynamics that we characterize by the presence versus absence of WFP and ANC. In Fig. 4b, we plot equations (1) and (2) with other $k$ values for $d^G = 6$, where we note that lower curves correspond to larger $k$. Observe that increasing $T$ for fixed $z$ leads to slower WFP and less-frequent ANC. In particular, for $(d^G, d^{NG}) = (6, 2)$ (which implies that $z = 1/3$), we find four qualitatively different regimes of WFP and ANC (see the regions that we label I–IV).

In Fig. 4c,d, we illustrate dynamics from these regimes by choosing $T \in \{0.05, 0.2, 0.3, 0.45\}$ and plotting the size $q(t)$ of the contagion (see Fig. 4c) and the number of contagion clusters $C(t)$ (see Fig. 4d) versus time $t$. Note that the number $C(t)$ of contagion clusters is equal to the number of connected components in the subgraph of the original network that only includes infected nodes and geometric edges. The values of $q(t)$ and $C(t)$ that we determine numerically (for $N = 200$) agree with our analysis. For $T = 0.05$, the WTM contagion saturates the network (that is, $q(t) \to N$) very rapidly due in part to the appearance of many contagion clusters early in the contagion process. For $T = 0.2$, the contagion saturates the network relatively rapidly due to the appearance of some new contagion clusters. For $T = 0.3$, the contagion saturates the network slowly, as no new contagion clusters appear, and the contagion spreads only via WFP. For $T = 0.45$, the contagion does not saturate the network, as neither WFP nor ANC occurs.

**Analysing WTM maps for noisy ring lattices.** In this section, we analyse symmetric WTM maps $Y = \{x^{(i)}\}$ for noisy ring lattices in several ways: geometrically, topologically and in terms of dimensionality. Our point-cloud analytics identify parameter regimes in which characteristics of a network’s underlying manifold also appear in the WTM maps. This makes it possible to do manifold learning and to assess the extent to which a contagion exhibits WFP (along a network’s underlying manifold) versus ANC.

In Fig. 5, we study WTM maps for a noisy ring lattice with $N = 200$ and $(d^G, d^{NG}) = (6, 2)$. We give each node $i$ an intrinsic location $w^{(i)} = [\cos(2\pi i/N), \sin(2\pi i/N)]^T$ on the unit circle $\mathcal{M} = \{(a, b) \mid a^2 + b^2 = 1\} \subset \mathbb{R}^2$. In Fig. 5a, we illustrate the point clouds $\{x^{(i)}\}_{i \in \mathcal{V}} \subset \mathbb{R}^N$ that result from WTM maps with thresholds of $T \in \{0.05, 0.2, 0.3, 0.45\}$, which correspond to the four regimes of contagion dynamics that are predicted by
equations (1) and (2) for \( \alpha = 1/3 \). (See labels I–IV in Fig. 4b.) To visualize the \( N \)-dimensional point clouds \( \{z^{(i)}\}_{i=1}^{N} \) we use principal component analysis (PCA) to project onto \( \mathbb{R}^2 \) (refs 22,26,58). The colour of each node at location \( w^{(i)} \) and point \( z^{(i)} \) reflects the activation time for node \( i \) during one realization of the WTM contagion that we use to generate the WTM map. In particular, dark-blue nodes (points) indicate the contagion seed under cluster seeding. Grey nodes (points) never adopt the contagion and thus have activation times that are infinite. For practical purposes, we set these activation times to be \( 2N \) rather than \( \infty \). (See the Methods section ‘Activation times of nodes’ for additional discussion.) Regime III is the regime for which the point cloud \( \{z^{(i)}\} \) appears to best resemble (up to rotation) the nodes’ intrinsic locations \( \{w^{(i)}\} \). This is expected, as this regime corresponds to WFP and no ANC. (In other words, the contagion follows the network’s underlying manifold \( \mathcal{M} \).)

In Fig. 5c, we summarize the characteristics of WTM maps for different thresholds \( T \in \{0.05, 0.2, 0.3, 0.45\} \), which correspond, respectively, to regimes I–IV (shaded region in c). As expected for regime III, \( \rho \approx 1 \), \( P \approx 2 \) and \( \Delta \) indicate that the geometry, dimensionality and topology, respectively, of the point cloud recover those of a ring manifold. See sections ‘Geometry of WTM maps’, ‘Dimensionality of WTM maps’ and ‘Topology of WTM maps’ as well as Supplementary Note 7 for discussions of these approaches for analyzing point clouds.

In Supplementary Note 8, we describe additional numerical results that compare a WTM map with Isomap\(^{22}\) and a Laplacian eigenmap\(^{23}\) for generalizations of the noisy ring lattice by (1) allowing the node locations to be a random sampling of points on the unit circle and (2) allowing heterogeneity in their geometric and non-geometric degrees. We define these other network structures in Supplementary Note 2. Our results (see Supplementary Figs 14–21) reveal large parameter regimes in which the ring manifold that underlies the noisy ring lattice is much more apparent (that is, as indicated by large \( \rho \), small \( P \) and
large $\Delta$) for maps based on WTM contagions versus those based on shortest-path or diffusion dynamics (that is, as in the Laplacian eigenmap). We stress that any applications of dimension reduction (for example, manifold learning) in networks should use an approach that is appropriate for the question of interest. This is why we use contagions in this paper instead of other types of spreading dynamics.

**Contagions on a London transit network.** In addition to synthetic networks, we study WTM maps for a London transit network (see Fig. 7a). Nodes in the network represent intersections of known latitude and longitude (their coordinates are $w(j)$), geometric edges represent roads (from data used in ref. 59) and non-geometric edges represent metropolitan lines (from data used in ref. 60). We have made the network publicly available (see the Methods section ‘Data and code availability’). We present our results in detail in Supplementary Note 1, and we summarize them here.

Our central finding is that the qualitative dynamical regimes that we observe for synthetic noisy geometric networks also occur in the London transit network. More specifically, we observe both WFP and ANC. In addition, as we illustrate in Fig. 7b,c, these phenomena can be very sensitive to the WTM threshold $T$. We study WFP and ANC by examining the geometry of WTM maps. However, we do not study their one-dimensional (1D) homology, as computations of homology (which remain a very active area of research$^{61,62}$) have a much higher computational cost than our calculations of geometry and dimensionality.

In Fig. 7d, we plot the Pearson correlation coefficient $\rho$ that compares the distance between mapped nodes with their actual distance from each other (according to latitude and longitude) for various values of $T$. We show results for the regular, reflected and symmetric versions of a WTM map (curves with symbols), and the horizontal dotted and dashed lines, respectively, indicate $\rho$ for the mapping of nodes based on shortest-path distances (that is, as in the Isomap algorithm$^{22}$) and a two-dimensional Laplacian eigenmap$^{23}$. 

![Figure 6](image1.png) **Figure 6** | Analysing manifold structure in contagion maps. We analyse the point clouds of WTM maps for various thresholds $T$ for noisy ring lattices with $N = 200$ and various ratios $x = d(G)/d(G)$. (As an example, we show results for $d(G) = 20$ and various values of $d(G)$.) For each point cloud, we study (a) geometry through $\rho$, (b) dimensionality through $P$ and (c) topology through $\Delta$ (see the text and the Methods section). The transitions between qualitatively different structures in the WTM maps (that is, as seen through $\rho$, $P$ and $\Delta$) closely resemble the bifurcation structure from equations (1) and (2), which we show for $k = 0$ using solid and dashed curves, respectively. In (d), we fix $a = 1/3$ and plot $\rho$, $P$ and $\Delta$ as a function of threshold $T$. We show results for ($d(G)$, $d(G)$) = (6, 2) (blue dashed curves) and (24, 8) (red solid curves). Note that there are activation times that are infinite for $T > T_0^{WFP} = 3/8$ (shaded region in d). The arrows indicate the $\rho$, $P$ and $\Delta$ values that we obtain for the embedding of nodes based on shortest paths, which (as we discuss in the text) one can construe as a variant of the dimension-reduction algorithm Isomap$^{22}$.

![Figure 7](image2.png) **Figure 7** | Complex contagions on a London transit system. (a) London transit network with $N = 2,217$ nodes (that is, intersections), 2,854 roads$^{59}$ (which we interpret as geometric edges) and 15 metropolitan lines$^{60}$ (which we interpret as non-geometric edges). (b) Node activation times for a WTM contagion initialized with cluster seeding illustrate for small $\rho$ that contagions quickly spread by skipping across the metro lines; this leads to ANC. (c) In contrast, for moderate $T$, the contagion spreads via slow WFP. (d) Although not all contagions exhibit such extreme sensitivity to $T$ (see Supplementary Note 5), the dependence of ANC and WFP on $T$ is captured by the geometry of WTM maps if one appropriately handles the activation times that are infinite (that is, nodes that never adopt the contagion). See the discussion in the text. The curves with symbols indicate the values of $\rho$ for WTM maps (curves with symbols), and the horizontal dotted and dashed lines, respectively, indicate $\rho$ for the mapping of nodes based on shortest-path distances (that is, as in the Isomap algorithm$^{22}$) and a two-dimensional Laplacian eigenmap$^{23}$. 

We present our results in detail in Supplementary Note 1, and we summarize them here. We note our central finding is that the qualitative dynamical regimes that we observe for synthetic noisy geometric networks also occur in the London transit network. More specifically, we observe both WFP and ANC. In addition, as we illustrate in Fig. 7b,c, these phenomena can be very sensitive to the WTM threshold $T$. We study WFP and ANC by examining the geometry of WTM maps. However, we do not study their one-dimensional (1D) homology, as computations of homology (which remain a very active area of research$^{61,62}$) have a much higher computational cost than our calculations of geometry and dimensionality.

In Fig. 7d, we plot the Pearson correlation coefficient $\rho$ that compares the distance between mapped nodes with their actual distance from each other (according to latitude and longitude) for various values of $T$. We show results for the regular, reflected and symmetric versions of a WTM map (curves with symbols), and the horizontal dotted and dashed lines, respectively, indicate $\rho$ for the mapping of nodes based on shortest-path distances (that is, as in the Isomap algorithm$^{22}$) and a two-dimensional Laplacian eigenmap$^{23}$. For each type of WTM map, we handle the activation times that are infinite (see the Methods section ‘Activation times of infinity in WTM maps’) using two methods. In the method that we label ‘full,’ we keep the entire matrix that encodes activation times, and we set the activation times that are infinite to be 2N. (Recall that we used this approach when studying WTM maps for synthetic networks.) In the method that we label ‘part,’ we neglect contagions that do not saturate a network, so we use only a portion of the values in the matrix that encode activation times. In Fig. 7d, we see that these
choices give contrasting results. For the ‘full’ option, activation times of infinity (which arise when $T \geq 0.1$) distort the WTM map and lead to a drop in $p$. In contrast, the ‘part’ method neglects activation times of infinity, and we find that there is a range of $T$ values for which there is a pronounced increase in $p$. Such improved agreement between the geometry of WTM contagions and the transit network’s inherent latitudinal and longitudinal embedding on Earth’s surface is characteristic of an increase in WFP versus ANC. Interestingly, we find that the small node degrees (for example, $d_i \geq 2.59$) and the significant heterogeneity (for example, with respect to node locations, node degrees and the length of roads) in the London transit network cause WFP and ANC to be extremely sensitive to the value of $T$ for only a few of the contagion seeds $S^0$ (see Supplementary Note 1 and Supplementary Fig. 5). Nevertheless, as we have demonstrated, such minority cases still have a significant effect on WTM maps.

Our numerical experiments for the London transit network highlight additional complexities that can arise for networks that are constructed from empirical data, and they offer complementary insights to our investigation of synthetic networks. In particular, the synthetic networks that we examine either are homogeneous or are only slightly heterogeneous, so the WFP and ANC behaviour tends to be similar for contagions that are initialized in different parts of a network. This is not the case for the London transit network, which has significant heterogeneity and very small node degrees (which seem to exacerbate the effect of heterogeneity). Infections that start in some parts of the network have rather different properties than those that start in others, and one also needs to consider multiple strategies for how to handle activation times of infinity. There are also other interesting phenomena that our approach can examine for heterogeneous networks. For example, in Supplementary Note 1, we study the geometry of WTM contagions for individual nodes (rather than averaging our results over an entire network) in what amounts to an ‘ego-centric’ analysis of geometry. We find that the local geometry of WTM maps (and hence of contagions) at a given node relates strongly to its proximity to a metro line.

**Discussion**

Many empirical networks include a combination of geometric edges between nearby nodes and non-geometric, long-range edges\(^{12}\). Such situations can arise when nodes are restricted by their locations in a physical space (such as in a city) or in terms of latent underlying spaces\(^{16–26}\). When considering a spreading process on a noisy geometric network, it is important to understand the extent to which a contagion follows the underlying structure. (Additionally, one can also consider the possibility of WFP in a latent structure\(^6\), which need not look like WFP with ordinary observations.) To address this question, we conducted a detailed investigation using the WTM of complex contagions (with uniform threshold $T$) on noisy geometric networks. The spreading dynamics exhibit both WFP, which follows the underlying manifold structure of a network, as well as the ANC of contagion in distant locations. To investigate the extent to which a WTM contagion adheres to a network’s underlying manifold, we introduced the notion of WTM maps (and contagion maps more generally) and showed when a contagion predominantly spreads via WFP that WTM maps recover the topology, geometry and dimensionality of a network’s underlying manifold even in the presence of many non-geometric (that is, ‘noisy’) edges.

Our methodology of constructing and analysing contagion maps has important implications not only for the analysis, modelling and control of contagions, but also for other dynamics\(^{63–65}\) that can be used to construct filtrations of networks. Moreover, by studying manifold structure in contagion maps, we have shown that such maps can also be used to identify and study manifold structure in networks. We have compared WTM maps with Laplacian eigenmaps\(^{23}\) and Isomap\(^{22}\) (see Supplementary Note 8 for additional discussion) and found that WTM maps—which are based on a nonlinear and nonconservative dynamical process—yield results that contrast with those from the other methods. This is sensible, as nonconservative and conservative dynamics (for example, diffusion) are known to give different results for which nodes are central\(^{66}\) and what network structures constitute bottlenecks to the dynamics\(^{67}\).

In the Supplementary Discussion, we further consider the implications of our work on three important fields of research: (i) studying contagions and other dynamics from the perspective of high-dimensional data analysis (that is, computational topology and nonlinear dimension reduction), (ii) identifying low-dimensional (for example, manifold) structure in networks and (iii) identifying low-dimensional (for example, manifold) structure in point-cloud data.

**Methods**

**Data and code availability.** The London transit network that we study in the section ‘Contagions on a London transit network’ and the code that we use to construct WTM maps are available as Supplementary Data 1 and Supplementary Software 1, respectively.

**Bifurcation analysis.** To guide our study of WTM maps, we set $T_i = T$ for each node $i \in \mathcal{V}$, and we perform a bifurcation analysis of WTM contagions on noisy ring lattices. In particular, we investigate the dependence of ANC and WFP on the contagion threshold $T$ and on the network parameters $d^0(G), d^0(NG)$ and $N$. In Fig. 3, we illustrate ANC and WFP for this class of networks with $d^0(G) = 4$, $d^0(NG) = 1$ and $N = 40$ by considering a WTM contagion at time $t = 0$. The light-blue nodes are in the contagion seed $S^0 = \{s\} \cup \{k \mid A_k \neq 0\}$, which is centred at node $s \in \mathcal{V}$. Because node $s$ is incident to both geometric and non-geometric edges, the contagion is initialized with $1 + d^0(NG) = 2$ contagion clusters. We denote these clusters by $C_1$ and $C_2$. Cluster $C_1$ is more likely to grow via WFP than $C_2$. The orange nodes in Fig. 3 are what we call contagion cluster $C_2$’s ‘boundary’—the set of nodes that have yet to adopt the contagion but that are exposed to it via a geometric edge that is incident to an infected node in $C_1$. As we show in the magnification on the right, nodes in the boundary can adopt the contagion via WFP. Nodes that are not infected and not on the boundary can become infected via ANC. (See the dark-blue nodes and dashed edges.)

If node $i$ adopts a contagion via ANC, then by definition it is not in the boundary of a contagion cluster, so its neighbours due to geometric edges have yet to adopt the contagion. Consequently, node $i$ potentially has 0, 1, . . . , $d^0(NG)$ neighbours that are infected, and its fraction of infected neighbours is restricted to $f_i \in \{0, \frac{1}{d^0(NG)}, \frac{2}{d^0(NG)}, \ldots, \frac{d^0(NG)}{d^0(NG)}\}$. This observation yields the critical thresholds

$$T^0_i(ANC) = \frac{d^0(NG) - k}{d^0(NG) + d^0(NG) - k}, \quad k = 0, 1, \ldots, d^0(NG).$$

The contagion dynamics changes abruptly at the critical values of $T$, so the qualitative dynamics of ANC for any $T \in (T^0_i(ANC), T^0_i(ANC))$ are similar to each other, but there are abrupt changes at the end points of the interval. In particular, whenever $T \in (T^0_i(ANC), T^0_i(ANC))$, a node requires at least $(d^0(NG) - k)$ neighbours due to non-geometric edges to be infected before it adopts the contagion. In Supplementary Note 6, we study the probability that a node has exactly $(d^0(NG) - k)$ infected non-geometric neighbours at time $t$. For large networks, this probability is approximately $(d^0(NG) - k) q(t) / N^{d^0(NG) - k}[1 - q(t) / N]$, where $q(t)$ denotes the number of nodes that have adopted the contagion at or before time $t$. Note that the probability is an expectation over the ensemble of noisy ring lattices, because it uses the fact that non-geometric edges are generated uniformly at random in our model. Therefore, it does not matter which of the $q(t)$ nodes happen to be infected.

Turning to WFP, we now study contagion transmissions exclusively across geometric edges. That is, given a node $i$ in a contagion cluster’s boundary, we assume that the node’s neighbours due to non-geometric edges are not infected. Note that this assumption does not always hold, but it is insightful to first examine this ideal case and then consider more general situations as perturbations of such a baseline analysis of WFP.
To facilitate our discussion, we will use the example contagion illustrated in Fig. 3. In particular, we consider WFP in the clockwise direction for cluster 1, Nodes a, b, and c are exposed, respectively, to 2, 1 and 0 nodes that have adopted the contagion, so their fractions of neighbours that are infected are \(f_a = 2/5, f_b = 1/5\) and \(f_c = 0/5\), respectively. Note that we assume that the non-geometric edges for nodes a, b and c are incident to nodes that are not infected (that is, which have not adopted the contagion). Because \(f_j < T\) for node \(j\) to adopt the contagion, the three situations can occur at time \(t = 1\): (1) if \(0 < T < 1/5\), then nodes a and b adopt the contagion; (2) if \(1/5 < T < 2/5\), then node a adopts the contagion; and (3) if \(2/5 < T\), then the contagion cluster \(C_3\) does not increase in size via WFP. Node c cannot adopt the contagion via WFP at time \(t = 1\) for any \(T > 0\). We find that WFP is governed by the critical thresholds

\[
y_{k}^{(WFP)} = \frac{D(G) - 2 - k}{D(G) - D(\mathcal{N})} \quad k = 0, 1, \ldots, \frac{D(G)}{2},
\]

where a wavefront propagates at a speed of \(k + 1\) nodes per time step for \(T \in [T_{k}^{(WFP)}, \infty)\). Whenever \(T > T_{k}^{(WFP)}\), there is no WFP.

We now include additional discussion of the assumptions in our analysis of WFP. Specifically, when considering whether or not node \(i\) in a contagion cluster’s boundaries: (1) if a contagion cannot spread, none of its non-geometric edges are incident to an infected node. Obviously, this assumption is valid for \(D(\mathcal{N}) = 0\). However, as we discuss in Supplementary Note 6, the expected probability (over an ensemble of noisy geometric networks with non-geometric edges generated uniformly at random) that a node’s non-geometric edge is incident to an infected node is \(q(\theta)/(\mathcal{N} - 1)\). Similarly, the probability that a node has \(D(\mathcal{N})\) non-geometric neighbours of them are infected is approximately \(1 - \theta(1 - \theta)^{D(\mathcal{N})}\), which is therefore the probability that our assumption is valid. In particular, whenever \(q(\theta) < N\), which necessarily requires \(N \gg 1\) and describes the scenario of an early stage of a contagion on a large network, the probability that our assumption is valid is approximately equal to 1. Therefore, equation (2) accurately describes the speed of WFP in this scenario to high probability. (Note that we also assume that \(D(\mathcal{N}) \ll N\), so there cannot be too many non-geometric edges.)

Equation (2), which one can construe as a ‘local’ result, is also very useful for predicting the ‘global’ behaviour of WFP. To see this, we make the following two observations: (1) if a contagion cannot spread, none of its non-geometric edges are incident to an infected node. Provided that \(a \leq n\) and that none of the nodes lie (that is, \(\mathcal{N} = \pi^2/4\)) and computing the smallest \(\Delta_i\) between the two largest lifetimes of such 1D features. We normalize all lifetimes by the diameter of the point cloud so that \(\Delta_i\) is meaningful. (Note that sometimes it can be preferable to use the ‘bottleneck distance’ between persistence diagrams rather than \(\Delta_i\).) See Supplementary Note 7 for further discussion.
