Abstract. Coral reefs are constructed by calcifiers that precipitate calcium carbonate to build their shells or skeletons through the process of calcification. Accurately assessing coral calcification rates is crucial to determine the health of these ecosystems and their response to major environmental changes such as ocean warming and acidification. Several approaches have been used to assess rates of coral calcification, but there is a real need to compare these approaches in order to ascertain that high-quality and intercomparable results can be produced. Here, we assessed four methods (total alkalinity anomaly, calcium anomaly, ⁴⁵Ca incorporation, and ¹³C incorporation) to determine coral calcification of the reef-building coral Stylophora pistillata. Given the importance of environmental conditions for this process, the study was performed under two starting pH levels (ambient: 8.05 and low: 7.2) and two light (light and dark) conditions. Under all conditions, calcification rates estimated using the alkalinity and calcium anomaly techniques as well as ⁴⁵Ca incorporation were highly correlated. Such a strong correlation between the alkalinity anomaly and ⁴⁵Ca incorporation techniques has not been observed in previous studies and most probably results from improvements described in the present paper. The only method which provided calcification rates significantly different from the other three techniques was ¹³C incorporation. Calcification rates based on this method were consistently higher than those measured using the other techniques. Although reasons for these discrepancies remain unclear, the use of this technique for assessing calcification rates in corals is not recommended without further investigations.

1 Introduction

Calcification is the fundamental biological process by which organisms precipitate calcium carbonate. Calcifying organisms take up calcium and carbonate or bicarbonate ions to build their biomineral structures (aragonite, calcite, and/or vaterite) which have physiological, ecological, and biogeochemical functions. Moreover, calcium carbonate plays a major role in the services provided by ecosystems to human societies. The ocean has absorbed large amounts of anthropogenic CO₂ since the start of the industrial revolution and is currently sequestering about 22 % of CO₂ emissions (average 2008–2017; Le Quéré et al., 2018). This massive input of CO₂ in the ocean impacts seawater chemistry with a decrease in seawater pH and carbonate ion concentrations [CO₃²⁻] and an increase in CO₂ and bicarbonate concentrations [HCO₃⁻]. These fundamental changes to the carbonate system are referred to as “ocean acidification” (OA; Gattuso and Hansson, 2011). Models project that the average surface water pH will drop by 0.06 to 0.32 pH units by the end of the century (IPCC, 2014).
The effect of OA is currently the subject of intense research with particular attention to organisms producing CaCO₃. For instance, coral communities have already proven to be particularly vulnerable to rapidly changing global environmental conditions (e.g., Albright et al., 2018). In order to help project the future of coral reefs, accurate estimates of calcification rates during realistic perturbation experiments are necessary in order to produce high-quality and intercomparable results (Cohen et al., 2017; Gazeau et al., 2015; Langdon et al., 2010; Riebesell et al., 2010; Schoepf et al., 2017).

Several methods are available to quantify rates of coral calcification. Calcification can be measured as the increase in CaCO₃ mass (e.g., the buoyant weight technique; Jokiel et al., 1978) or following the incorporation of radio-labeled carbon or calcium in the skeleton (Goreau, 1959), but also through the quantification of changes in a seawater constituent that is stoichiometrically related to the amount of CaCO₃ precipitated. For instance, the alkalinity anomaly technique (Smith and Key, 1975) has been widely used to estimate net calcification of organisms and communities, especially of corals and coral reef environments (e.g., Smith and Kinsey, 1978; Gazeau et al., 2015; Albright et al., 2016; Cyronak et al., 2018). Total alkalinity (Aₜ) is directly influenced by bicarbonate and carbonate ion concentrations together with a multitude of other minor compounds (Wolf-Gladrow et al., 2007). Calcification consumes carbonate or bicarbonate, following the reversible reaction

\[ \text{Ca}^{2+} + 2\text{HCO}_3^- \leftrightarrow \text{CaCO}_3 + \text{CO}_2 + \text{H}_2\text{O}. \]  

(R1)

Calcification consumes 2 mol of HCO₃⁻, hence decreasing Aₜ by 2 mol mol⁻¹ of CaCO₃ produced (Reaction R1). It is possible to derive the rate of net calcification (gross calcification – dissolution) by measuring Aₜ before and after incubating an organism or a community. This method assumes, however, that calcification is the only biological process influencing Aₜ (Smith and Key, 1975). Nitrogen assimilation through photosynthetic activities, nitrification, and aerobic and anaerobic remineralization of organic matter is known to impact Aₜ through the consumption or release of nutrients (ammonium, nitrate, and phosphate) and protons (Wolf-Gladrow et al., 2007). While for some group of species (e.g., bivalves, sea urchins), corrections appear necessary to take into account the effect of nutrient release on Aₜ, changes in nutrient concentrations during incubations of isolated corals are too low (i.e., several orders of magnitude lower than changes in Aₜ) to introduce a significant bias in the calculations (Gazeau et al., 2015).

In contrast to Aₜ, the concentration of calcium (Ca²⁺) in seawater is only biologically influenced by net calcification, and a 1 : 1 relationship can be used to derive net calcification rates (Reaction R1). The depletion of Aₜ and Ca²⁺ needs to be corrected for gains of Aₜ and Ca²⁺ resulting from evaporation. These corrections can be applied through the incubation of seawater in the absence of coral (Schoepf et al., 2017). Both the alkalinity anomaly and calcium anomaly methods are nondestructive and typically show a good agreement (Chisholm and Gattuso, 1991; Murillo et al., 2014; Gazeau et al., 2015).

The ⁴⁵Ca incorporation technique has been used since the 1950s (Goreau and Bowen, 1955; Goreau, 1959). While earlier techniques showed low reproducibility, methodological improvements led to a significant reduction of the deviations between replicates (see Tambutté et al., 1995, for more details). The strength of this method is that it is extremely sensitive for measuring short-term variations in gross calcification rates. However, in contrast to the Aₜ and Ca²⁺ anomaly techniques, it is a sample-destructive method.

Previous studies designed to compare calcification rate estimates using the ⁴⁵Ca incorporation and Aₜ anomaly methods revealed subtle discrepancies. For example, Smith and Kinsey (1978) reported an overestimation of rates based on the ⁴⁵Ca method. In contrast, Tambutté et al. (1995) and Cohen et al. (2017) reported a decrease in Aₜ without concomitant incorporation of ⁴⁵Ca, therefore suggesting an over-estimation of calcification derived from Aₜ measurements. However, during these studies, in order to avoid radioactive contamination of laboratory equipment, estimates of calcification were not performed during the same incubations, but rather during incubations performed over 2 consecutive days.

In contrast to the ⁴⁵Ca incorporation method, to the best of our knowledge, no studies have used carbon-based incorporation techniques to estimate coral calcification rates in the framework of ocean acidification. Past studies that compared carbon and calcium incorporation rates in coral skeletons based on a double labeling technique with H¹⁴CO₃⁻ and ⁴⁵Ca showed that only a minor proportion of the labeled seawater carbon is incorporated in the skeleton (e.g., Marshall and Wright, 1998) and that the major source of dissolved inorganic carbon for calcification is metabolic CO₂ (70 %–75 % of the total CaCO₃ deposition; Furla et al., 2000). Consequently, under both light and dark conditions, the rate of ⁴⁵Ca deposition appears greater than the rate of ¹⁴C incorporation (Furla et al., 2000). To the best of our knowledge, only one study estimated calcification rates of a benthic calcifier (coralline algae) using a stable carbon isotopic technique through addition of ¹³C-labeled bicarbonate (McCoy et al., 2016). The present study aimed at comparing calcification rates measured using the alkalinity and calcium anomaly methods, as well as the ⁴⁵Ca and ¹³C incorporation techniques, under different pH and light conditions.

2 Material and methods

Colonies of the reef-building coral Stylophora pistillata were incubated in the laboratory, in both the light and dark, under ambient and lowered pH conditions. At ambient pH (experiment conducted in July–August 2017), two sets of incubations were performed using either ⁴⁵Ca or ¹³C additions, and
calcification rates based on these techniques were compared to those derived, during the same incubations, by the alkalinity and calcium anomaly techniques. At lowered pH (experiment conducted in August 2018), no incubations with \(^{13}\text{C}\) addition were conducted and only the three other techniques were compared.

### 2.1 Biological material and experimental set-up

Specimens used in this experiment originated from colonies of the coral *Stylophora pistillata* (Esper 1797) initially sampled in the Gulf of Aqaba (Red Sea, Jordan) and transferred to the Scientific Centre of Monaco where they were cultivated under controlled conditions for several years. In June 2017, 40 terminal portion branches of *S. pistillata*, free of boring organisms, were cut from four different parent colonies (10 branches per parent colony) and suspended by nylon lines to allow tissues to fully cover the exposed skeleton for at least 5 weeks (Tambutté et al., 1995; Houlbrèque et al., 2015). The nubbins were fed with rotifers (once a day) and *Artemia nauplii* (twice a week; ca. 1 nauplius mL\(^{-1}\)) and kept in 70 L aquaria (water renewal: 2 L min\(^{-1}\)) under an irradiance of 200 µmol photons m\(^{-2}\) s\(^{-1}\) (12 : 12 light : dark photoperiod, light banks: HQI 250W Nepturion – BLV, Germany), a seawater temperature of 25 ± 0.5°C, and a salinity of 38 ± 0.5. Water motion was provided by a submersible pump (Mini-jet MN 606; RENA©). Before the start of the experiment, specimens were transferred to the International Atomic Energy Agency (IAEA). For the second set of experiments in 2018, nubbins were prepared in June 2018 and cultured, under the conditions described above, at IAEA except that colonies were fed twice a week with newly hatched brine shrimp nauplii (ca. 1 nauplius mL\(^{-1}\)). Biometric parameters (size, weight) of the biological material are shown in Table 1.

Different types of incubations were conducted. In July–August 2017; one set of incubations was performed under ambient pH conditions with the addition of radioactive calcium dichloride (\(^{45}\text{CaCl}_2\)). During the same period, another set of incubations was performed, under ambient pH conditions, with the addition of \(^{13}\text{C}\)-labeled sodium bicarbonate (\(^{13}\text{C}-\text{NaHCO}_3\) 99%). Finally, in August 2018, one set of incubations was performed under lowered pH conditions (see thereafter for more details) with the addition of \(^{45}\text{CaCl}_2\). For all sets of incubations, organisms were incubated for 5 to 11 h (Table 1), in both the light and dark, in 500 mL polyethylene beakers equipped with a magnetic stirrer (Fig. 1). Six and five replicates were used, respectively, at ambient and low pH. Furthermore, for all sets of incubations, one beaker was incubated, under the same conditions as the other beakers, without coral and served as a control.

For each set of incubations, 2.4 L of seawater, pumped continuously from offshore of the IAEA Monaco premises at 60 m depth, was filtered onto 0.2 µm (GF/F, 47 mm). For incubations performed at lowered pH conditions, pure CO\(_2\) was bubbled in the 2.4 L initial seawater batch using an automated pH-stat system (IKS Aquastar©) until the target pH was reached. The pH electrode from the pH-stat system was intercalibrated using a glass combination electrode (Metrohm, Ecotrode Plus) calibrated on the total scale using a TRIS buffer solution with a salinity of 35 (provided by Andrew Dickson, Scripps Institution of Oceanography, San Diego). Initial pH\(_T\) (total scale) levels were set to ∼7.2. It must be stressed that pH levels were not regulated during the incubations. For \(^{45}\text{Ca}\) incubations, this initial batch was spiked with \(^{45}\text{CaCl}_2\) to reach a nominal activity of ∼15 Bq mL\(^{-1}\). As we anticipated lower calcification rates during the set of experiments conducted at low pH, initial nominal activity was set to ∼30 Bq mL\(^{-1}\). Before distributing seawater to the experimental beakers, a 1 mL aliquot of seawater was removed for the precise determination of the initial activity. Samples were stored, in the dark, in high-performance glass vials for 24 h before counting. For \(^{13}\text{C}\) incubations, to determine the seawater background isotopic level (δ\(^{13}\text{C}\) of the dissolved inorganic carbon pool (δ\(^{13}\text{C}\)-C\(_T\)), three 27 mL samples were collected and gently transferred to glass vials avoiding bubbles. Then, ∼8.95 mg of \(^{13}\text{C}\) NaHCO\(_3\) was added to the batch of filtered ambient seawater to increase δ\(^{13}\text{C}\)-C\(_T\) to ca. 1500‰. For the determination of δ\(^{13}\text{C}\)-C\(_T\) after enrichment, two 27 mL samples were handled as described above. The vials were then sealed after being poisoned with 10 µL of saturated mercuric chloride (HgCl\(_2\)) and stored upside-down at room temperature in the dark for subsequent analysis.

For all sets of incubations, samples for the measurements of pH\(_T\), A\(_T\) (200 mL), and Ca\(^{2+}\) concentrations (50 mL) were taken before distributing seawater to the experimental beakers. While pH\(_T\) was measured immediately after sampling, samples for A\(_T\) measurements were poisoned with 40 µL of 50% saturated HgCl\(_2\) and stored in the dark at 4°C pending analysis less than 2 weeks later. Samples for [Ca\(^{2+}\)]...
Table 1. Experimental details for the series of incubations of the coral Stylophora pistillata performed under ambient and low pH, and in the light and dark following $^{45}$Ca or $^{13}$C labeling. The ratio $W_w : W_c$ corresponds to the ratio between seawater weight (g) and skeletal dry weight (g). Values represent mean ± standard deviation (SD); $n$ is the number of true replicates considered for each experiment. All incubations were conducted at 25 ± 0.5 °C.

| pH conditions | Added label | Ambient ($n = 6$) | Lowered ($n = 5$) |
|---------------|-------------|------------------|------------------|
|               | $^{45}$Ca   | $^{13}$C         | $^{45}$Ca        |
|               | Light | Dark | Light | Dark | Light | Dark |
| Light conditions |       |       |       |       |       |       |
| Coral size (mm)     | 33.2 ± 1.5 | 44.7 ± 1.5 | 36.3 ± 2.2 | 50.2 ± 1.7 | 26.0 ± 1.6 | 28.9 ± 1.9 |
| Coral skeleton dry weight (g) | 2.5 ± 0.5 | 3.8 ± 0.7 | 2.6 ± 0.5 | 4.7 ± 0.5 | 2.1 ± 0.2 | 2.8 ± 0.4 |
| Ratio $W_w : W_c$ | 126.4 ± 25.6 | 81.9 ± 14.7 | 106.9 ± 24.5 | 67.8 ± 7.5 | 146.5 ± 14.3 | 110.0 ± 12.4 |
| Incubation time (h) | 8 | 8 | 9.12 | 9.12 | 5 | 11 |

measurements were not poisoned and were stored in the dark at 4 °C pending analysis less than 2 weeks after sampling. Gravimetrically determined amounts of filtered seawater (ca. 300 g) were transferred to the incubation containers which were placed in a temperature-controlled (IKS Aquastar®) water bath maintained at 25 ± 0.5 °C. Coral nubbins were suspended with a nylon line in the experimental beakers 5 cm below the water level covered with transparent film to limit evaporation (Fig. 1). During the low-pH incubations conducted in 2018, to avoid physiological stress, coral nubbins were acclimated by gradually lowering pH to the target levels during 24 h. This acclimation was performed in an open-flow 20 L aquarium (one full water renewal per hour) using a pH-stat system as previously described and with a pH decrease of ca. 0.03 units h⁻¹.

In incubations in the light were performed at an irradiance of 200 µmol photons m⁻² s⁻¹ during daytime whereas dark incubations were conducted at night. Incubation times were not fixed based on scientific considerations and differed between the different incubations due to practical constrains (i.e., access to the lab). Before the beginning of the incubations, all beakers (containing corals) were precisely weighed at ±0.01 g (Sartorius BP 3105).

At the conclusion of the incubations, all beakers were precisely weighed to evaluate evaporation, and seawater samples were analyzed for pH$_T$, $A_T$, and [Ca$^{2+}$] as well as for $^{45}$Ca activity or $\delta^{13}$C-$C_T$ depending on the type of incubations. pH$_T$ was measured immediately and samples for $A_T$ and [Ca$^{2+}$] determinations were filtered at 0.2 µm (GF/F, Ø 47 mm), poisoned with saturated HgCl$_2$ (only for $A_T$), and stored in the dark at 4 °C pending analysis (within 2 weeks). The corals were then removed from the beakers for the analysis of incorporated $^{45}$Ca or $^{13}$C. Three additional corals which were not incubated were processed for carbon isotopic composition of the previously accreted calcium carbonate (see Sect. 2.3).

2.2 Analytical techniques

Immediately after sampling, pH$_T$ was measured on a Metrohm 826 mobile pH logger, and a glass electrode (Metrohm, Ecotrode Plus) was calibrated on the total scale using a TRIS buffer of salinity 35 (provided by Andrew Dickson, Scripps University, USA). $A_T$ was determined in triplicate 50 mL subsamples by potentiometric titration on a titrator Titrando 888 (Metrohm) coupled to a glass electrode (Metrohm, Ecotrode Plus) and a thermometer (pt1000). The pH electrode was calibrated before every set of measurements on the total scale using a TRIS buffer of salinity 35 (provided by Andrew Dickson, Scripps University, USA). Measurements were carried out at a constant temperature of 25 °C and $A_T$ was calculated as described in Dickson et al. (2007). Certified reference material (CRM; batches 143 and 156) provided by Andrew Dickson (Scripps University, USA) was used to check precision (standard deviation within measurements of the same batch) and accuracy (deviation from the certified nominal value). Over the six series of $A_T$ measurements performed during the experiment, mean accuracy and precision (± SD) were respectively 7.2 ± 1.2 and 1.2 ± 0.2 µmol kg⁻¹. [Ca$^{2+}$] was determined in triplicate using the ethylene glycol tetra acetic acid (EGTA) potentiometric titration (Lebel and Poisson, 1976). About 10 g of sampled seawater and 10 g of HgCl$_2$ solution (ca. 1 mmol L⁻¹) were accurately weighed out. Then, about 10 g of a concentrated EGTA solution (ca. 10 mmol L⁻¹, also by weighing) was added to completely complex Hg$^{2+}$ and to complex nearly 95% of Ca$^{2+}$. After adding 10 mL of borate buffer (pH$_{NAS} \sim 10$) to increase the pH of the solution, the remaining Ca$^{2+}$ was titrated by a diluted solution of EGTA (ca. 2 mmol L⁻¹) using a titrator (Titrando 888, Metrohm) coupled to an amalgamated silver combined electrode (Ag Titrode, Metrohm). Following Cao and Dai (2011), the volume of EGTA necessary to titrate the remaining ca. 5% of Ca$^{2+}$ was obtained by manually fitting a polynomial function to the first derivative of the titration curve using the function “loess” of the R software (R Development Core Team, 2018). The EGTA solution was calibrated prior to each measurement series using International Association for the Physical Sciences of the Oceans (IAPSO) standard seawater (salinity = 38.005). Mean [Ca$^{2+}$] precision obtained us-
ing this technique was 2.9 µmol kg\(^{-1}\) (\(n = 40\)), corresponding to a coefficient of variation (CV) of 0.026 %.

To determine the specific activity in radio-labeled seawater, the 1 mL aliquots were transferred to 20 mL glass scintillation vials and mixed in proportion 1 : 10 (\(v : v\)) with scintillation liquid Ultima Gold\textsuperscript{TM} XR. According to a method adapted from Tambutté et al. (1995), at the end of incubation sampled nubbins were immersed for 30 min in beakers containing 300 mL of unlabelled seawater to achieve isotopic dilution of the \(^{45}\text{Ca}\) contained in the gastrovascular cavity. Constant water motion was provided in the efflux medium by magnetic stirring bars. Tissues were then dissolved completely in 1 mol L\(^{-1}\) NaOH at 90 °C for 20 min. The skeleton was rinsed twice in 1 mL NaOH and twice in 5 mL of Milli-Q water. It was then dried for 72 h at 60 °C, precisely weighed at ±0.01 g using a Sartorius BP 310S (referred to thereafter as skeleton dry weight), and dissolved in 12 N HCl. Three 200 µL aliquots from each skeleton dissolution were transferred to 20 mL glass scintillation vials and mixed with 10 mL scintillation liquid Ultima Gold\textsuperscript{TM} XR. Radioactive samples were thoroughly mixed to homogenize the solution and kept in the dark for 24 h before counting. The radioactivity of \(^{45}\text{Ca}\) was counted using a Tri-Carb 2900 liquid scintillation counter. Counting time was adjusted to propagate a counting error of less than 5 % (maximal counting duration was 90 min). Radioactivity was determined by comparison of standards of known activities, and measurements were corrected for counting efficiency and physical radioactive decay.

The analyses of seawater \(\delta^{13}\text{C-C}_T\) as well as of the \(^{13}\text{C}\) signature of coral calcified tissues were performed at Leuven University. For \(\delta^{13}\text{C-C}_T\) analyses, a helium headspace (5 mL) was created in the vials and samples were acidified with 2 mL of phosphoric acid (H\(_3\)PO\(_4\), 99 %). Samples were left to equilibrate overnight to transfer all \(C_T\) to gaseous CO\(_2\). Samples were injected in the carrier gas stream of an EA-IRMS (Thermo EA1110 and Delta V Advantage), and data were calibrated with NBS-19 and LSVEC standards (Gillikin and Bouillon, 2007). Corals were treated following the same protocol as for \(^{45}\text{Ca}\) incorporation measurements and powdered. Triplicate subsamples of carbonate powder (\(\sim 100 \mu g\)) were placed into gas-tight vials, flushed with helium, and converted into CO\(_2\) with H\(_3\)PO\(_4\). After 24 h, subsamples of the released CO\(_2\) were injected into the EA-IRMS system as described above. Data were calibrated with NBS-19 and LSVEC. Carbon isotope data are expressed in the delta notation (\(\delta\)) relative to the Vienna Pee Dee Belemnite (VPDB) standard and were calculated as

\[
R_{\text{sample}} = \frac{\delta^{13}\text{C}_{\text{sample}}}{1000 + 1} \cdot R_{\text{VPDB}}.
\]

### 2.3 Computations and statistics

The carbonate chemistry was assessed using pH\(_T\) and \(A_T\) and the R package seacarb (Gattuso et al., 2019). Propagation of errors on computed parameters was performed using the new function “error” of the package seacarb (Orr et al., 2018) on the R software, considering errors associated with the estimation of \(A_T\) as well as errors on dissociation constants.

Estimates of coral calcification rates based on changes in \(A_T\) and \([\text{Ca}^{2+}]\) during incubations were computed following Eqs. (2) and (3), respectively. As shown in these equations, initial levels of \(A_T\) and \([\text{Ca}^{2+}]\) are not necessary to compute calcification rates and only final values in the incubations with corals and without corals (controls) were used:

\[
G_{A_T} = \frac{(A_{T2} - A_{T1}) - (A_{T2c} - A_{T1c})}{2t} \cdot \frac{W_w}{W_c} \\
= \frac{-A_{T2c} - A_{T2c}}{2t} \cdot \frac{W_w}{W_c}, \tag{2}
\]

\[
G_{Ca} = \frac{(\text{Ca}_2 - \text{Ca}_1) - (\text{Ca}_2c - \text{Ca}_1c)}{t} \cdot \frac{W_w}{W_c} \\
= \frac{-\text{Ca}_2c - \text{Ca}_2c}{t} \cdot \frac{W_w}{W_c}, \tag{3}
\]

where \(A_{T1}\) and \(A_{T1c}\) are \(A_T\) and \([\text{Ca}^{2+}]\) concentrations at the start of the incubations (\(\mu\text{mol kg}^{-1}\); not used in the computations); \(A_{T2}/A_{T2c}\) and \(\text{Ca}_2/\text{Ca}_2c\) are \(A_T\) and \([\text{Ca}^{2+}]\) concentrations at the end of the incubations, respectively with and without corals; \(t\) is the incubation duration in hours; and \(W_w\) and \(W_c\) are respectively the mass of seawater (average between initial and final weights) and the coral skeleton dry weight (g DW). \(G_{A_T}\) and \(G_{Ca}\) are therefore expressed in \(\mu\text{mol} \text{CaCO}_3 \text{g DW}^{-1} \text{h}^{-1}\). Error propagation was used to estimate errors.

\[
\text{SE}_{G_{A_T}} = \frac{\sqrt{\text{SE}_{A_{T2}}^2 + \text{SE}_{A_{T2c}}^2}}{2t} \cdot \frac{W_w}{W_c}, \tag{4}
\]

\[
\text{SE}_{G_{Ca}} = \frac{\sqrt{\text{SE}_{\text{Ca}_2}^2 + \text{SE}_{\text{Ca}_2c}^2}}{t} \cdot \frac{W_w}{W_c} \tag{5}
\]

Here \(\text{SE}_{A_{T2}}/\text{SE}_{A_{T2c}}\) and \(\text{SE}_{\text{Ca}_2}/\text{SE}_{\text{Ca}_2c}\) correspond to standard errors associated with the measurement of three analytical replicates per sample for \(A_T\) and \([\text{Ca}^{2+}]\) at the end of the incubations, respectively with and without corals; \(t\) is the incubation duration in hours; and \(W_w\) and \(W_c\) are respectively the mass of seawater (average between initial and final weights) and the coral skeleton dry weight (g DW).

Coral calcification rates based on \(^{45}\text{Ca}\) incorporation were estimated using measured seawater activity and activity recorded in the skeleton digest. Rates were then normalized per gram of skeleton dry weight using the formula

\[
G_{Ca} = \frac{\text{Activity}_{\text{sample}} \cdot \text{Ca}}{W_c \cdot t}, \tag{6}
\]
where \( \text{Activity}_{\text{Sample}} \) is the average of counts per minute (CPMs) of three 200 µL aliquots from the dissolved skeleton sample, \( \text{Activity}_{\text{Seawater}} \) is the total CPMs in the 1 mL seawater samples, \( \text{Ca} \) is the \([\text{Ca}^{2+}]\) measured in the corresponding samples (average between initial and final values, \( \mu\text{mol kg}^{-1} \)) and further converted to \( \mu\text{mol L}^{-1} \) considering a temperature of 25°C and a salinity of 38, \( W_{c} \) is the skeleton dry weight (in grams), and \( t \) is the incubation duration (in hours). \( G_{\text{MCa}} \) is therefore expressed in \( \mu\text{mol CaCO}_3 \text{ g DW}^{-1} \text{ h}^{-1} \). The standard errors for these calcification rate estimates were propagated based on standard errors associated with the measurements of triplicate samples for both \( \text{Activity}_{\text{Sample}} \) and \([\text{Ca}^{2+}]\).

The precipitation of calcium carbonate minerals (\( G \)) during the incubation interval was also estimated using measured \( \delta^{13}C \) values and isotope mass balance calculations (Eqs. 7 and 8 below). The \( \text{CO}_2 \) released during phosphoric acid digestion is derived from two sources: new coral \( \text{CaCO}_3 \) and previously accreted skeletal carbonate mineral. The new carbon acquired in each measured nubbin (\( \delta^{13}C_{N} \)) was assumed to have the same carbon isotope composition as the labeled seawater \( C_{T} \) (average between initial and final level, \( \delta^{13}C_{T} \approx 1400 \%e-1700 \%e \)). The previously accreted skeletal material was assumed to have a \( \delta^{13}C \) value equal to the measured value for the background sample (\( \delta^{13}C_{P} \)). The \( \delta^{13}C \) value (\( \delta^{13}C_{M} \)), representing the mixture of new calcified material and previously accreted carbonate mineral, is then calculated with the following mixing equation:

\[
\delta^{13}C_{M} = f_{G} \cdot \delta^{13}C_{N} + (1-f_{G}) \cdot \delta^{13}C_{P},
\]

(7) where \( f_{G} \) is the fraction of the calcium carbonate mineral precipitated during the experiment, and \( \delta^{13}C_{N} \) and \( \delta^{13}C_{P} \) are the carbon isotope compositions of the newly precipitated and previously accreted calcium carbonate, respectively. Equation (7) was solved for \( f_{G} \) to determine the calcium carbonate precipitated during the incubation using

\[
G_{\text{MCa}} = \frac{f_{G} \cdot M_{\text{CaCO}_3}}{t} \times 10^{6},
\]

(8) where \( M_{\text{CaCO}_3} \) is the molar mass of calcium carbonate (g mol\(^{-1}\)) and \( t \) is the incubation duration in hours. \( G_{\text{MCa}} \) is therefore expressed in \( \mu\text{mol CaCO}_3 \text{ g DW}^{-1} \text{ h}^{-1} \). The standard errors for these calcification rate estimates were calculated based on standard errors associated with the triplicate measurements of \( \delta^{13}C_{P} \) and \( \delta^{13}C_{N} \).

Model II linear regressions (Sokal and Rohlf, 1995) were used to compare net calcification rates obtained with the different methods. All regressions were performed using the function “lmodel2” of the package lmodel2 (Legendre and Oksanen, 2018) with the R software.

### 3 Results

Environmental conditions at the start of the different incubations are shown in Table 2. All values in Table 2 as well as in the text below correspond to the average between replicates (or incubations) ± standard deviation (SD). All incubations performed under ambient pH\(_T\) (\( \sim 8.05 \)) were conducted under carbonate chemistry favorable to calcification with saturation states with respect to aragonite (\( \Omega_{A} \)) well above 1 (average of 4.0 ± 0.1 over the four incubations). In contrast, during experiments at low pH\(_T\) (initial pH\(_T\) \( \sim 7.2 \)), seawater was corrosive with respect to aragonite (\( \Omega_{A} \) \( \sim 0.75 \)). However, as pH was not regulated during the incubations (see previous section), it increased, at lowered pH, to an average of 7.75 ± 0.03 (\( n = 5 \)) in dark conditions and to an average of 7.84 ± 0.03 in light conditions (\( n = 5 \)). Evolution of pH in control beakers (final pH\(_T\) of 7.78 and 7.48; \( n = 1 \) in both the light and the dark, respectively) showed that the observed increase in beakers with corals was due to the additive effects of biological control (photosynthesis minus respiration and calcification) and exchanges at the interface in the light, and mostly due to CO\(_2\) exchange with air during the much longer incubations performed in the dark. Assuming linear variations with time, the average conditions of the carbonate chemistry in the lowered pH experiments were slightly favorable to aragonite production (\( \Omega_{A} \) = 1.4 ± 0.2 in the dark, \( n = 5 \) and 1.6 ± 0.05 in the light, \( n = 5 \)). Under ambient pH conditions (for both \( ^{45}\text{Ca} \) and \( ^{13}\text{C} \) incubations), pH did not change during incubations in the light (average final pH\(_T\) of 8.05 ± 0.03, \( n = 12 \), data not shown) while it decreased in the dark, due to respiration and calcification, to reach an average pH\(_T\) level of 7.62 ± 0.07, \( n = 12 \) (data not shown). In control beakers under ambient pH, pH\(_T\) slightly increased in the light (8.09, \( n = 2 \)) and did not change in the dark (8.05, \( n = 2 \)).

\( ^{45}\text{Ca} \) activities in seawater did not change during the incubations, reaching a final activity of 16.1 ± 1.2 (\( n = 12 \)) and 28.5 ± 0.6 (\( n = 10 \)) Bq mL\(^{-1} \) under ambient and lowered pH conditions, respectively (including both dark and light incubations, data not shown). Furthermore, for all incubations, these values were similar to those measured in beakers without corals (control, data not shown). Under ambient pH levels (no incubation at lowered pH), seawater was enriched in \( ^{13}\text{C} \) (\( \delta^{13}C_{T} \)) from a background level of 0.26 ± 0.05 ‰ (\( n = 3 \)) to 1740 ± 4.7 ‰ (\( n = 2 \)) and 1634 ± 11 ‰ (\( n = 2 \)) in the light and dark, respectively. During light-condition incubations, \( \delta^{13}C_{T} \) levels decreased to an average of 1636 ± 10 ‰ (\( n = 6 \), data not shown) while they decreased to an average of 1466 ± 24 ‰ in dark conditions (\( n = 6 \), data not shown). Incubations in control beakers (without corals) showed that the majority of \( \delta^{13}C_{T} \) loss for both types of incubations (light and dark) was due to \( ^{13}\text{C} \) incorporation by corals with a minor effect of gas exchanges at the interface (data not shown).

Both \( A_T \) and \([\text{Ca}^{2+}]\) declined in all incubations as a consequence of coral calcification (Table 3). Changes in \( A_T \) during incubations in control beakers (data not shown) comprised between 0.1 % and 1.1 % of the initial level. Similar results were observed for \([\text{Ca}^{2+}]\) with a relative change that comprised between 0.05 % and 1.15 % of the initial value. These minimal changes were corroborated with no measur-
able changes in seawater weight between the start and the end of all incubations (data not shown), showing that evaporation, if any, was minimal using our experimental setup over the considered incubation times. At ambient pH levels, decreases in $A_T$ and $[Ca^{2+}]$ (average of $-380 \pm 97$ and $-194 \pm 51 \text{ mmol} \cdot \text{kg}^{-1}$ for both parameters, respectively, $n = 24$ including both $^{45}$Ca and $^{13}$C incubations) were roughly similar under light and dark conditions although coral specimens used for dark incubations were ca. 166% heavier (skeleton dry weight; see Table 1). Incubations performed under lowered pH levels showed much lower $A_T$ and $[Ca^{2+}]$ net consumption rates than under ambient pH levels. Under these pH conditions, an extremely high $A_T$ consumption rate was observed in one beaker (dark incubation; see Table 3) while no changes in $[Ca^{2+}]$ were observed in a total of three beakers (see Table 3). These estimates ($n = 4$) have been considered as outliers, marked with an asterisk in Table 3 and not included in the following analyses.

$^{45}$Ca activities in coral skeleton reached maximum levels under ambient pH and light conditions (average of $87.5 \pm 9.1 \text{ Bq}, n = 6$). Although seawater was more enriched in $^{45}$Ca at the lower pH levels (see above), $^{45}$Ca activity in corals incubated under these conditions was much lower, with the lowest values measured in the dark (average of $19.6 \pm 9.1 \text{ Bq}, n = 5$). $^{13}$C levels measured in coral skeletons ($-3.69 \%$ to $8.92 \%$) showed significant enrichment compared to background levels ($-3.97 \pm 0.35 \%$, $n = 9$).

Calcification rates using the different techniques were higher in the light than in the dark and much lower rates were estimated at lowered pH (Table S1 in the Supplement, Figs. 2, 3 and 4). The rates measured by alkalinity anomaly ($G_{A_T}$) and calcium anomaly ($G_{Ca}$) techniques were highly correlated (Fig. 2; $R^2 = 0.98$, $p < 0.01$, $n = 34$). No significant difference was observed between rates measured by the two methods (see Table 4 for the 95% confidence intervals of the slope and intercept). The $^{45}$Ca method also provided rates very similar to those of the two previous approaches (Fig. 3; $G_{Ca}$ vs. $G_{13C}$ not shown), although the slope and the intercept of the geometric regression between $G_{A_T}$ and $G_{13C}$ were significantly different from 1 and 0, respectively. Finally, the only approach that did not provide similar rates to the others was the $^{13}$C incorporation technique. Calcification rates based on this method were systematically higher than those measured using the other three techniques (see Table 4), and rates were not always significantly related (e.g., $R^2 = 0.33$, $p > 0.05$, $n = 12$ for $G_{A_T}$ vs. $G_{13C}$; see Fig. 4; other relationships not shown).

### 4 Discussion

Under all experimental conditions (ambient pH vs. low pH, light vs. dark), significant consumption rates of $A_T$ and $Ca^{2+}$ as well as significant incorporation rates of $^{45}$Ca and $^{13}$C were observed in the zooxanthellate coral *Stylophora pistillata*. For all methods, calcification rates were lower in dark than in light conditions. Such trends are expected as it has long been established that calcification rates increase in zooxanthellate corals during periods in which photosynthesis is occurring (Yonge, 1931), a process known as light-enhanced calcification (e.g., Gattuso et al., 1999). Even under lowered pH conditions, at pH levels far below those predicted ($pH 4.5$), an extremely high rate of calcification (e.g., Gattuso et al., 1999), such as that observed in the zooxanthellate coral *Stylophora pistillata*.

to use the calcium anomaly technique when working in natural settings, assuming that Ca$^{2+}$ concentrations are measured with an analytical technique as precise as the one used in our study ($CV < 0.05\%$). Similarly, although corrections are possible when applying the alkalinity anomaly technique on organisms that significantly release nutrients (echinoderms, bivalves, etc.), the use of the calcium anomaly technique is highly recommended instead (Gazeau et al., 2015).

Calcification rate estimates based on changes of $A_T$ or Ca$^{2+}$ were highly correlated with estimates based on $^{45}$Ca incorporation in corals. These results are not consistent with those reported by Smith and Kinsey (1978), Tambutté et al. (1995), and Cohen et al. (2017). These studies revealed discrepancies between the alkalinity anomaly and the $^{45}$Ca incorporation techniques. Smith and Kinsey (1978) found that rates measured with the $^{45}$Ca method were higher than those measured using the alkalinity anomaly technique (significant $^{45}$Ca incorporation at $\Delta A_T = 0$). Results from both Tambutté et al. (1995) and Cohen et al. (2017) suggested the opposite with a decrease in $A_T$ consumption without any concomitant $^{45}$Ca incorporation. A number of reasons may explain these discrepancies. First, the present study is the first one comparing these techniques in the same incubations, in contrast to the other ones in which incubations for $A_T$ anomaly and $^{45}$Ca incorporation were performed over 2 consecutive days (due to radioactive contamination issues). Second, calcification expressed as absolute changes in $A_T$ during incubations, measured during our experiment, were at least 1 order of magnitude higher than measured during these studies (44 200 to 745 600 nmol vs. less than 4000 nmol in previ-
Figure 4. Calcification rates estimated based on the alkalinity anomaly technique \((G_{AT})\) as a function of calcification rates estimated based on \(^{13}\text{C}\) incorporation technique \((G_{13C})\). The dashed line represents the 1 : 1 relationship while the full line represents the model II regression relationship. Horizontal error bars represent standard errors (SE) associated with the estimation of \(G_{13C}\). Vertical error bars representing SE associated with the estimation of \(G_{AT}\) are too small to be visible. The corresponding dataset can be found in Table S1.

To the best of our knowledge, this is the first study comparing calcification rates measured using the \(^{13}\text{C}\) labeling technique to the more widely used alkalinity and calcium anomaly techniques. It shows that \(^{13}\text{C}\)-derived rates were systematically higher and much more variable (with large uncertainties) than the ones estimated using the two other techniques. As already mentioned, several studies have shown that most of the carbon precipitated in the skeleton comes from coral and its symbiotic zooxanthellae (e.g., Erez, 1978; Furla et al., 2000), leading to an underestimation of calcification rates based on labeled, radioactive carbon incorporation. As there is no reason for \(^{13}\text{C}\) to behave differently, our results appear inconsistent with a metabolic source of carbon.

As the nubbins were treated following the same protocol as for \(^{45}\text{Ca}\) incorporation measurements, it is unclear why much stronger \(^{13}\text{C}\) incorporation was obtained and why variability was so high. Before better insights into such discrepancies can be developed, we recommend to avoid this technique to estimate coral calcification rates.

Our study was designed to compare different techniques to estimate calcification rates and not to define the best experimental approach to study the effects of ocean acidification on coral species using these different approaches. As such, the chosen experimental protocol (e.g., incubation times) was not optimal and led, in some cases, to significant changes in the carbonate chemistry during incubations. However, our results provide some insights that we further discuss in the following section. Measuring and comparing calcification rates of organisms under varying pH conditions requires the careful choice of a volume and a time interval such that the precision of the calcification rate measurement is large enough to observe significant signals and that the change in carbonate chemistry parameters between the beginning and end of the incubation is small compared to the range of these parameters in the different treatments (Langdon et al., 2010). Table 5 illustrates the incubation time necessary to obtain measurable changes for each method (\(t_{\text{min}}\) considering the ratio between incubation volume and coral size chosen for our study. As the \(^{13}\text{C}\) incorporation method did not provide reliable rates, this technique was not considered in this analysis. The threshold for significant signals was set at 10-fold the analytical precision of the instruments (Langdon et al., 2010) for \(A_T\) and \(C_{\text{a}}^{2+}\) measurements (1.2 and 2.9 µmol kg\(^{-1}\), respectively) and above the detection limit of 15 CPM for \(^{45}\text{Ca}\) activity estimated. Maximum incubation times are more difficult to estimate. Langdon et al. (2010) and Riebesell et al. (2010) recommend considering incubation times short enough to maintain \(A_T\) and \(C_{\text{T}}\) within an acceptable range (\(\Delta A_T\) and \(\Delta C_T < 10\%\)). As it is more difficult to estimate what changes in pH are acceptable, we have arbitrarily considered a maximal change in pH of 0.06, corresponding to the lowest change in global surface ocean pH projected for 2100 (IPCC, 2014). Maximal incubation times, as presented in Table 5 \(t_{\text{max}}\), correspond then to incubation times that should not be exceeded in order to maintain acceptable conditions.
of the carbonate chemistry ($\Delta p_{\text{H}2}$ < 0.06 and $\Delta A_{\text{T}}$ < 10% and $\Delta C_{\text{a}}$ < 10%).

Under light and ambient pH conditions, even if the ratio between incubation volume and nubbin size is much higher than for previous similar studies (e.g., Cohen et al., 2017), all methods would allow a precise estimation of calcification rates over very short incubation times (~ 15 min to 1 h, depending on the method) while leading to moderate changes in carbonate chemistry. In the dark, and under ambient pH conditions, in the absence of pH increase due to photosynthesis, the decrease in pH due to respiration narrows the possible incubation period to 1.3 h. While this is still larger than the incubation time allowing us to obtain a significant signal with the alkalinity anomaly technique (~ 20 min), the other two methods necessitate longer incubation times to obtain precise estimates (> 1.5 h). At lower pH, under both light and dark conditions, and using open systems without a continuous pH regulation as in our study, it is obvious that all techniques are not well adapted to this experimental protocol. Indeed, as a consequence of lower calcification rates at lower pH and significant CO$_2$ degassing, incubation times necessary to obtain significant signals using these techniques are too large to maintain the carbonate parameters within an acceptable range. This is not insurmountable as a continuous regulation of pH using for instance pure CO$_2$ bubbling or incubations performed in a closed container (i.e., without contact with the atmosphere) would alleviate these problems.

In conclusion, the present study is the first one allowing a direct (i.e., during the same incubations) comparison of three methods used to estimate coral calcification rates, the calcium and alkalinity anomaly techniques and the $^{45}$Ca incorporation technique. These methods provided very consistent calcification rates of the coral *Stylophora pistillata* independently of the conditions set for the incubations (light vs. dark, ambient vs. low pH). Among these three methods, the alkalinity anomaly and the $^{45}$Ca incorporation techniques appear to be the most sensitive, allowing the quantification of coral calcification rates without significant changes in targeted environmental conditions. In contrast, the $^{13}$C incorporation technique did not provide reliable calcification rates and its use is not recommended until further investigations clarify the discrepancies. Finally, this study was restricted to a single coral species and used nubbins fully covered with tissues. Conducting similar comparison studies with other coral species as well as other major calcifying groups widely studied in the context of ocean acidification (e.g., coralline algae, mollusks) would be necessary for a better understanding of ocean acidification impacts on ecosystem services provided by calcifying organisms.

**Table 5. Incubation times ($t_{\text{min}}$, h) necessary to obtain significant signals using the three methods: the alkalinity anomaly technique ($A_{\text{T}}$), the calcium anomaly technique ($Ca^{2+}$), and the $^{45}$Ca incorporation techniques ($^{45}$Ca); see text for calculation procedures. $t_{\text{max}}$ (h) is the maximum incubation time to maintain carbonate chemistry within an acceptable range ($\Delta p_{\text{H}2} < 0.06$ and $\Delta A_{\text{T}} < 10\%$ and $\Delta C_{\text{a}} < 10\%$). The ratios between incubation volume ($V$, in milliliters) and the size of the nubbins ($S$, in centimeters), considered in our study for the different sets of incubations (ambient pH vs. low pH; light vs. dark), are also shown. $t_{\text{min}}$ values are noted in bold when higher than $t_{\text{max}}$.**

| Ratio $V:S$ | $t_{\text{min}}$ (h) | $t_{\text{max}}$ (h) |
|-------------|----------------------|----------------------|
|             | $A_{\text{T}}$ | $Ca^{2+}$ | $^{45}$Ca |
| Ambient pH – light | 77–95 | 0.26 | 1.00 | 0.6 | 4.7 |
| Ambient pH – dark | 59–69 | 0.33 | 2.10 | 1.5 | 1.3 |
| Lowered pH – light | 109–121 | 1.25 | 6.15 | 1.1 | 0.5 |
| Lowered pH – dark | 95–109 | 1.60 | 11.20 | 3.4 | 1.3 |
the Application of Nuclear and Isotopic Techniques” National Program PNUOLU/4-1/2 No. /2017 of the National Nuclear Agency (AENTA).

Review statement. This paper was edited by Lennart de Nooijer and reviewed by two anonymous referees.
