Quantum random walks on congested lattices and the effect of dephasing

Keith R. Motes1, Alexei Gilchrist1,∗ & Peter P. Rohde1,2,∗

We consider quantum random walks on congested lattices and contrast them to classical random walks. Congestion is modelled on lattices that contain static defects which reverse the walker’s direction. We implement a dephasing process after each step which allows us to smoothly interpolate between classical and quantum random walks as well as study the effect of dephasing on the quantum walk. Our key results show that a quantum walker escapes a finite boundary dramatically faster than a classical walker and that this advantage remains in the presence of heavily congested lattices.

Quantum information processing1 promises many interesting technologies that are not available today. Perhaps most interesting is the promise for quantum computation, whereby quantum algorithms can be implemented that outperform their classical counterparts. The best known example is Shor’s factoring algorithm2, which can factor numbers exponentially faster than the best known classical factoring algorithm. Other examples include Grover’s database search algorithm3 and various graph theoretic algorithms4–6.

One route to implementing quantum information processing tasks is via quantum random walks7–10 whereby a particle, such as a photon, ‘hops’ between the vertices in a lattice. In this paper the effects of a congested, or obstructed, lattice on a quantum random walk (QRW) are studied and compared to a classical random walk (CRW). Congestion can be thought of as traffic and the walker is like a car trying to avoid the traffic. The quantum walkers also suffer a dephasing process as they propagate. This study provides insight into how random errors in the lattice and dephasing affect the dynamics of random walks and the robustness of certain quantum features.

In our model, congestion refers to where the lattice through which the walker propagates has defects. These random defects are like blocked streets that the walker encounters and has to back out of during the next step. These defects are stationary during the evolution of the random walk, though we average over many such random lattices. Dephasing occurs when the state decoheres and is implemented via a dephasing channel acting after each step. In the limit of full dephasing the QRW becomes a CRW, so that dephasing also allows us to interpolate between the classical and quantum regimes. For an experimental demonstration of dephasing in a QRW see Broome et al.11, and for related theoretical work on QRWs with phase damping see Lockhart et al.12.

For characterising the resulting probability distributions for QRWs and CRWs we use variance and ‘escape probability’, that is the probability that the walker escapes a finite region of the lattice, or more picturesquely, the probability that the walker ‘beats the traffic’.

Quantum Random Walks

A QRW describes the evolution of a quantum particle through a given topological structure represented as a d dimensional lattice. In a CRW, the walker probabilistically follows edges through a lattice to step to an adjacent vertex. Physically, the walker can be a wide range of quantum particles, though of particular interest is the photon as photons are readily produced, manipulated and measured using off-the-shelf components in the laboratory. Photons have found widespread use in quantum information processing, most notably linear optics quantum computing (LOQC)13. These technologies provide the topological structure for implementing a QRW. They also allow for multi-photon QRWs14, which increases the dimensionality of the walk. For a further review on QRWs see refs 7–10, and see refs 15–23 for the numerous optical demonstrations of elementary QRWs that have been performed.

Quantum random walk formalism

To illustrate our QRW formalism we present the details for a one-dimensional discrete QRW on an unbounded lattice without any defects. The state of a one-dimensional QRW at any given time has the form,

$$|\Psi\rangle = \sum_{x,c} \gamma_{x,c} |x, c\rangle,$$

where $x \in [-t_{\text{max}}, t_{\text{max}}]$ represents the position of the particle; $t_{\text{max}}$ represents the total number of time steps and the size of the lattice, $c \in \{-1, 1\}$ is the coin value that tells the walker whether to evolve to the left ($c = -1$) or right ($c = 1$), and $\gamma_{x,c}$ is the probability amplitude for a given position and coin value. The dimension of the lattice is $2t_{\text{max}} + 1$. Since there are two coin values for each position, the probability that the walker is at position $x$ is given by,

$$p(x) = |\gamma_{x,-1}\rangle^2 + |\gamma_{x,1}\rangle^2.$$

The one-dimensional walker begins at some specified input state $|\Psi(0)\rangle = |x_0, c_0\rangle$ before it begins to evolve at time $t = 0$, where $x_0$ and $c_0$ are the starting position and coin values respectively. The state then evolves for a finite number of time steps. The evolution is described by two operators: the coin $\hat{C}$ and step $\hat{S}$ operators,

$$\hat{C}|x, \pm1\rangle = (|x, 1\rangle \pm |x, -1\rangle)/\sqrt{2},$$

$$\hat{S}|x, c\rangle = |x + c, c\rangle.$$

The coin operator takes a state and maps it to a superposition of new states using the Hadamard coin,

$$H = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 & 1 \\ 1 & -1 \end{pmatrix},$$

exploiting both possible degrees of freedom in the coin while maintaining the same position. Next, the step operator $\hat{S}$ moves the walker to an adjacent position according to the value of $c$. $\hat{C}$ and $\hat{S}$ act on the state at every time step and thus the evolution of the system after $t$ steps is given by,

$$|\Psi(t)\rangle = (\hat{S} \cdot \hat{C})^t |\Psi(0)\rangle.$$

If the walker begins at the origin or on an even lattice position then, as the walker evolves, it lies on odd positions for odd time steps and on even positions for even time steps. Thus, as the walker evolves, the allowed locations for the walker oscillate between even and odd sites.

It is straightforward to generalise equation (1) to multiple dimensions by expanding the Hilbert space. For example, a two-dimensional walk would have the form,

$$|\Psi(2)\rangle = \sum_{x,y,c_1,c_2} \gamma_{x,y,c_1,c_2} |x, y, c_1, c_2\rangle,$$

where $x \in [-t_{\text{max}}, t_{\text{max}}]$ and $y \in [-t_{\text{max}}, t_{\text{max}}]$ denote the two spatial dimensions, $c_1, c_2 \in \{-1, 1\}$ indicates for the walker to move left or right, and $c_1, c_2 \in \{-1, 1\}$ indicates for the walker to move down or up, and the superscript represents the dimension. The dimension of the two-dimensional system is $(2t_{\text{max}} + 1)^2$. The coin and step operator can be generalised by taking a tensor product for each respective dimension, or alternately a coin could be employed which entangles the two dimensions. In the case of a spatially separable two-dimensional coin one obtains $\hat{C}^{(2)} = \hat{C}_x \otimes \hat{C}_y$ and $\hat{S}^{(2)} = \hat{S}_x \otimes \hat{S}_y$. Likewise, the Hadamard coin for two dimensions becomes $H \otimes H$.

After the system evolves, a measurement is made on either the position or the coin degree of freedom yielding the output probability distribution. With this probability distribution various metrics can be defined to characterise the evolution of the system, which we define next.

Random Walk Metrics

The two common metrics that we use to quantify a QRW are the variance $\sigma^2$ and the escape probability $p_{\text{esc}}$. All simulations done in this paper have the initial condition that the walker begins at the origin $|\Psi(0)\rangle = |0, 0, 1, 1\rangle$. Also, all statistics are averaged over one hundred simulations unless the walk was deterministic in which case only one simulation was needed. Although the sample space is exponential in size, averaging over an exponential number of simulations is not feasible; however, one hundred simulations is sufficient for our work because it produces stable statistics that converge to fixed values and it smooths out the oscillations between data points.

Variance

The variance $\sigma^2$ is a measure of how much the walker has spread out during its evolution. It is defined as,

$$\sigma^2 = \frac{1}{n} \sum_{i=1}^{n} (p_i - \mu)^2,$$

where $p_i$ is the probability distribution of the walker, $n = 2t_{\text{max}} + 1$ is the number of lattice sites, and $\mu = \sum_{i=1}^{n} p_i$ is the mean of the distribution. For calculating the variance in two-dimensions we take the variance of the marginal probability distribution where the probability distribution becomes $p_i = \sum_{j=1}^{n} p_{ij}$ and $p_{ij}$ is the
two-dimensional probability distribution. Figure 1a illustrates the variance versus time for both a QRW and a CRW on a two-dimensional square lattice of size $t_{\text{max}} = 20$. The QRW demonstrates a quadratic rate of spreading across the lattice while the CRW demonstrates a linear rate of spreading. This quadratic spreading is one of the distinguishing features of a QRW compared to the CRW. It forms the basis of some QRW algorithms such as the QRW search algorithm, which is quadratically faster than the corresponding classical algorithm. For simulations of the variance we don’t impose boundary conditions because the walker never reaches the boundary.

**Escape Probability**

The escape probability $P_{\text{esc}}$ is a measure of how much of the walker’s amplitude leaks outside of a certain region in the lattice. To calculate $P_{\text{esc}}$, a boundary must first be defined which depends on the size of the lattice. For the square two-dimensional lattice we let the walker begin in the state $\Psi(0) = 010_0$, and let the escape boundary be two vertical lines at $x = \pm x_b$, where $t_b$ is the distance the escape boundary is from the origin $(x = y = 0)$.

To calculate the escape probability on this square lattice we use,

$$ P_{\text{esc}} = \sum_{x} \sum_{y} p^{(2)}(x, y), $$

where $p^{(2)}(x, y) = |\gamma_{x,y,1,1}|^2 + |\gamma_{x,y,1,-1}|^2 + |\gamma_{x,y,-1,1}|^2 + |\gamma_{x,y,-1,-1}|^2$ is the two-dimensional version of equation (2).

Figure 1b illustrates $P_{\text{esc}}$ versus $t$ for both a QRW and a CRW on a square lattice of size $t_{\text{max}} = 100$ with a boundary given by $t_b = 10$. Here the QRW exhibits a dramatic jump in escape probability compared to the CRW. This is due to both the faster rate of spreading of the QRW, and to the QRW having larger amplitudes at the tails of its distribution. This dramatic jump is a key feature pointed out in this work that demonstrates an advantage that QRWs have over CRWs.

For all escape probability simulations the walker is allowed to walk back into the unescaped region which subtracts from the probability that the walker has escaped. This, in conjunction with the fact that the walker occupies alternating even and odd positions as the walker evolves, explains the oscillatory nature of the escape probability.

The two metrics, $\sigma^2$ and $P_{\text{esc}}$, are closely related. If the walker has a large spread in its distribution then the probability of escape is significantly larger for any given time after escaping than in the CRW.
Lattice Congestion

Lattice congestion is a model of defects in a medium. For the QRW and CRW the medium is the walkers’ lattice and the defects are modelled as blocked pathways where the walker has to enter the pathway to realise it is blocked and then reverse out on the next step. This model is closely related to percolation theory\(^{24}\) which models defects as missing lattice nodes. For a detailed introduction on percolation theory see\(^{25,26}\). Percolation is generally modelled on a \(d\) dimensional lattice with a given geometry such as a square, triangle or honeycomb. Regardless of geometry, the lattice consists of two components: sites and bonds. A site is a point on the lattice and a bond is the connection between the sites. These components give two strategies for introducing the random fluctuations that define percolation theory: site percolations and bond percolations. In site percolation the lattice sites exist with probability \(P \in [0, 1]\) and when a site does not exist it is a defect in the lattice. In bond percolation the positions in a lattice are fixed while the bonds between the positions exist with probability \(p\). The model in this paper is a variant of site percolation whereby the walker can occupy any site, but with probability \(1 - p\) will find an obstruction and reverse direction upon hitting the respective site.

Percolation theory has an associated scaling hypothesis that predicts critical values, such as percolation thresholds\(^{27}\), which we do not reproduce in this manuscript due to our small lattice sizes. Instead we observe the behavior of QRWs on congested lattices and compare them to CRWs. However, we expect the same percolation characteristics such as percolation thresholds to exist in the underlying lattice that the walkers are exploring. For a two-dimensional square lattice with site percolations that most closely resemble the lattice used in this paper, the percolation threshold is \(p_c \approx 0.638\). Values of \(p\) higher than this threshold produce long-range connectedness in the lattice. We make the comparison to percolation in this work because our spatial defects are equivalent to the defects in percolation theory; however, we do not observe the critical values that percolation theory predicts so we call it congestion to avoid confusion.

To generate a lattice with spatial defects a matrix of coin operators is constructed. The matrix is the same size as the lattice and each position in the matrix corresponds to a spatial position on the lattice. The coin operator corresponding to a given position then determines the behaviour of the walker. The coin operators are defined as either a Hadamard coin, equation (4), if the site is present, or a bit-flip coin,

\[
X = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix},
\]

if the site contains a defect. For the two-dimensional case the bit-flip coin becomes \(X \otimes X\).

As the quantum or classical walker evolves it will walk into these defects that signify congested points on the lattice. Upon reaching a defect the walker reverses direction, thus slowing the walker’s rate of spread. In this manuscript we define \(p\) as the probability that the site is not a defect; therefore, the probability that a site is a defect is \(1 - p\).

CRW on a congested lattice

The lattices we are considering contain randomly distributed defects, or points of congestion that impede the walker’s progress. Questions such as what is the probability that there is an open path from one side of the lattice to the other, are answered by percolation theory. There are many known applications for percolation theory\(^{29}\). A common example is asking whether a liquid can flow through a porous material. If enough pores (or sites) exist then the liquid can make it through. Another example is whether or not an electric current can flow through some medium where conductive sites are spread throughout some insulator. If enough conductive sites are present then a path will exist through the medium.

Within the congested lattice we examine the spread of random walkers. Defects have the effect of reducing the rate of spread of the walker, or stopping it entirely if the lattice is so congested that there is no escape possible from the region the walker finds itself in. Figure 2a shows the variance \(\sigma^2\) of a CRW versus time \(t\) in the presence of varying values of congestion \(1 - p\) on a lattice of size \(t_{max} = 75\). As the congestion increases the classical walker becomes trapped. In each case the variance preserves the linear dependence as is expected in a CRW.

In Fig. 2b the escape probability \(P_{esc}\) of a CRW is shown versus time \(t\) in the presence of varying values of congestion \(1 - p\) on a lattice of size \(t_{max} = 75\) and escape boundary \(t_b = 10\). \(P_{esc}\) decreases as congestion is increased but remains linear modulo the oscillations being averaged out. Again there is a threshold where in terms of \(P_{esc}\) the walker stops escaping the boundary and the lattice becomes insulating.

QRW on a congested lattice

Classically, the state can only move in one direction at a time while quantum mechanically the state spreads in a superposition of every direction simultaneously. As with a classical walker, the quantum walker escapes the bounded region more often if there are less defects. The significance of the quantum walker is both the quadratic spreading behaviour and the resulting probability distribution having more weight in the tails. For a review of work done on QRWs with percolation see\(^{30}\) for asymptotic results and analytic solutions. See\(^{31,32}\) for quantum tunneling effects on a one-dimensional QRW and, for a two-dimensional lattice, average distance measures and the order of quadratic scaling. This manuscript is unique from these two for several reasons. First, properties of a QRW on congested lattices with the \(\alpha^2\) and \(P_{esc}\) metrics were not studied in the previous two. Second, we compare QRWs to CRWs and observe whether QRWs maintain their advantages over CRWs on congested lattices. Third, we tune the random walks on congested lattices between being fully quantum and fully classical using a dephasing process, described later in this manuscript, which acts as an error model.

Figure 3a shows the variance \(\sigma^2\) versus time \(t\) for a QRW with varying values of congestion \(1 - p\) for \(t_{max} = 75\). As congestion increases the variance of the walker decreases; however, it retains its quadratic (i.e. ballistic)
spreading albeit with a different quadratic coefficient. This property shows that QRWs remain advantageous over CRWs even in the presence of lattice defects.

Figure 3b shows the escape probability $P_{\text{esc}}$ versus time $t$ for varying values of congestion probability $1 - p$ on a lattice of size $t_{\text{max}} = 75$. For $P = 1$ there is no congestion present and the $P_{\text{esc}}$ metric experiences a sudden jump from $t = 10$ to $t = 11$. This is because the QRW has most of its amplitude in its tails as it evolves. When $P$ decreases and the lattice becomes more and more congested the sudden jump is still present at the same value of $t$ but with a much smaller amplitude. This shows that QRWs retain their advantage over CRWs in the presence of congestion.
CRWs in the presence of heavy congestion. Note that the percolation threshold is around $P \approx 0.6$, below which we expect that on average there is no clear route across the graph.

**Varying escape boundary**

In the previous simulations involving escape probability the escape boundary was set to be near the initialised position of the walker. The next topic we consider on a congested lattice is how the escape probability on a congested lattice changes as $t_b$ varies. Consider Fig. 4 which shows $P_{\text{esc}}$ as a function of $t_b$ with varying values of congestion $P$ for the CRW (a) and the QRW (b). Both walkers evolve for $t_{\text{max}} = 50$ time steps and $P_{\text{esc}}$ is calculated at $t = t_{\text{max}}$. In both the CRW and QRW $P_{\text{esc}}$ reduces with increased congestion and when $t_b$ is farther from the walkers initial position. What is interesting is that the QRW maintains a significantly larger $P_{\text{esc}}$ than the CRW as the escape boundary moves away.

**Dephasing**

Next, we consider what happens to a QRW subject to dephasing. Dephasing represents decoherence caused by the environment which can be related to measurement errors caused by thermal fluctuations, white noise, photons interfering with the quantum walker, etc. To explore this we first introduce a model of dephasing and characterise it with our two metrics: variance and escape probability.

Consider a QRW where after each step, each state in the basis has probability $p_d$ of acquiring a $\pi$ phase flip. We can model this process as choosing to apply one of a set $\{F_j\}$ of unitary matrices covering all the combinations of $\pm 1$ on the diagonal. If $F_j$ has $s$ $1$s on the diagonal we choose it with probability $p_d^s (1-p_d)^{m-s}$.

The probability of a particular sequence will be the product of the probabilities of the $F_j$ appearing in the sequence since they are independently chosen at each step. If $\rho_{\text{seq}}$ is the final pure density matrix appearing with probability $p_{\text{seq}}$, then in general the final state of the system is described by,

$$\rho = \sum_{\text{seq}} p_{\text{seq}} \rho_{\text{seq}}.$$

That is, for any POVM element $E$ we have,

$$\sum_{\text{seq}} p_{\text{seq}} \text{Tr}\{E \rho_{\text{seq}}\} = \text{Tr}\{E \rho\}.$$

We algorithmically implement dephasing by randomly flipping the signs of individual kets in the walker’s superposition state with probability $p_d$, and average the results of any measurement at the end of a large number of runs. This in effect samples from the distribution represented by $\rho$ and is automatically weighted by the probability of a given sequence.

That this whole process represents dephasing is not immediately obvious. To see it, we first rewrite $\rho$ as the vector $|\rho\rangle$ using the $\text{vec}$ operation which simply stacks its columns on top of each other. Using the identity

---

**Figure 4.** The escape probability $P_{\text{esc}}$ versus a varying escape boundary $t_b$ for several values of congestion $1-P$ for the CRW (a) and the QRW (b). The walker evolves for $t_{\text{max}} = 50$ time steps. The QRW maintains a significantly larger $P_{\text{esc}}$ as the boundary moves away from the initial starting position than the CRW. In both cases $P_{\text{esc}}$ goes to zero as the boundary approaches the end of the lattice.
\[ |ABC \rangle = C^T \otimes A |B \rangle \]

for any three square matrices \( A, B, \) and \( C; \) then grouping the terms that turn up, we can write,

\[ |\rho \rangle = \cdots \sum_k \delta_k U \sum_j D_j U \sum_i p_i D_i U |\psi_0 \rangle, \]

(12)

where \( D_j = F_j^* \otimes F_j = F_j^{*2}, \) \( U \) represents the step and coin operations, and \( |\psi_0 \rangle \) is the vectorised initial density matrix. This shows that after each step we apply the process described by the dynamical matrix,

\[ D = \sum_j p_j F_j^{*2}. \]

(13)

The matrices \( F_j \) are diagonal so we write the diagonal as a vector denoted by \( |j \rangle \), so that the diagonal of \( F_j^{*2} \) is \( |j \rangle \langle j| \). Since \( |j \rangle \) has only real entries we can rearrange it into the matrix \( |j \rangle \langle j| \). We can do a similar arrangement with \( D \) so that,

\[ |d \rangle \langle d| = \sum_j p_j |j \rangle \langle j|. \]

(14)

It’s worthwhile pausing and noting what this matrix represents. From equation (12) we can see that the diagonal of \( D \) multiplies the elements of the vectorised \( |\rho \rangle \). Hence when we arrange the values into a matrix, the entries of \( |d \rangle \langle d| \) multiply the corresponding entries in \( \rho \).

The first thing to note is that this matrix is symmetric. We will denote the entries of \( |j \rangle \) by \( f_j \) and drop the reference \( j \) for clarity. The diagonals of \( |j \rangle \langle j| \) are of the form \( f_j^2 = 1 \) and since \( \sum_j p_j = 1 \) the diagonal of \( |d \rangle \langle d| \) is unity and the process does not change the amplitudes of the states. The off-diagonals are of the form \( f_j f_s \), where \( r = s \) and their sum over \( j \) has the value,

\[ (1 - p_d)^2 + p_d^2 - 2(1 - p_d)p_d = (1 - 2p_d)^2. \]

(15)

The terms on the left are the probabilities that both \( f_j \) and \( f_s \) are positive, both negative, or one of each respectively. Each of these terms is multiplied by the binomial sum of the probabilities of all the combinations of \( \pm 1 \) on all the other elements of \( |j \rangle \) and not \( r \) or \( s \), which evaluates to 1. Note that this result holds for any dimension. In summary, the map that is performed by \( D \) multiplies every off-diagonal element of \( \rho \) by \((1 - 2p_d)^2 \). This is a dephasing map.

If \( p_d = 0 \) none of the signs are flipped, and if \( p_d = 1 \) all of the signs are flipped. Since the QRW is invariant under a global phase flip, these two extremes reproduce an ideal QRW. When \( 0 < p_d < 1 \) dephasing is introduced into the system. A value of \( p_d = 1/2 \) corresponds to complete dephasing which causes the walker to behave classically. The classical results in this paper were produced by using our QRW code with a value of \( p_d = 1/2 \). This was checked with purely classical code to verify that we are indeed obtaining a CRW.

If we imagine an inefficient measurement of the QRW at every step where it is projectively measured with probability \( p_m \), or otherwise left alone, this map would describe dephasing by a dynamical matrix which multiplies all the off-diagonal elements of \( \rho \) by \((1 - 2p_d)^2 \). So our dephasing process is equivalent to a measurement performed with a probability \( p_m \) or otherwise left alone, this map would describe dephasing by a dynamical matrix which multiplies all the off-diagonal elements of \( \rho \) by \( 1 - p_m \). So our dephasing process is equivalent to a measurement performed with a probability \( p_m = 4(1 - p_d)p_d \).

In this work, dephasing is a method for introducing quantum decoherence to the QRW. To illustrate the effect of dephasing in our model we plot the probability distribution at the final time \( t_{max} = 75 \) of various random walks in Fig. 5. In Fig. 5a the walk has no dephasing \( p_d = 0 \) and is thus completely deterministic. We see that this probability distribution has one main peak near the positive \( x \) and positive \( y \) direction, which is in the initialised direction of the coin, and is at the edge of the lattice. This is in contrast to what occurs when dephasing is introduced. Figure 5b shows the same evolution again but with a dephasing probability of \( p_d = 0.01 \). With this value of dephasing the distribution retains most of its quantum behaviour. Figure 5c shows the same evolution again but with a dephasing probability of \( p_d = 0.03 \). With this value of dephasing the probability distribution loses much of its quantum behaviour and begins behaving like a CRW. Finally in Fig. 5d we show the same evolution but with \( p_d = 0.5 \) and obtain the probability distribution of a CRW.

We notice that with sufficiently strong dephasing the probability distribution becomes localized around the origin so that the QRW behaves like a CRW distribution. Note that the corresponding value of \( p_d \) that collapses the QRW to a CRW depends on \( t_{max} \). As \( t_{max} \) increases the underlying lattice has more sites where dephasing can occur and thus a smaller \( p_d \) will cause the corresponding collapse. By incrementing \( p_d \) we can smoothly interpolate between QRWs and CRWs, which is a key feature of this work.

### Congestion & Dephasing Combined

Next we combine congestion and dephasing and examine the joint effects. Figure 6a shows the variance obtained at the final time step of the QRW as a function of the congestion probability \( 1 - p \) for varying values of the dephasing probability \( p_d \) on a two-dimensional square lattice of size given by \( t_{max} = 75 \). A monotonic decrease is observed in the variance for a given \( p \) as \( p_d \) is increased and a quadratic rate of spreading is maintained for small values of \( p_d \). Figure 6b shows \( p_m \) with boundary \( t_b = 10 \) as a function of congestion probability \( 1 - p \) for varying values of dephasing probabilities \( p_d \) on a two-dimensional square lattice defined by \( t_{max} = 75 \). When \( p_d = 0 \) the
Figure 5. The QRW probability distribution shown at the final time step over a two-dimensional square lattice defined by $t_{\text{max}} = 75$ with no defects present. (a) The QRW with no dephasing $p_d = 0$ always yields a deterministic probability distribution with ballistic spreading. (b) The same QRW but with a dephasing probability of $p_d = 0.01$. It has a similar probability distribution but begins approaching classical statistics. (c) The same QRW again but with a dephasing probability of $p_d = 0.03$. Here the probability distribution becomes centred around the origin which begins to look much like the statistics of a CRW. (d) The same QRW again but with a dephasing probability of $p_d = 0.5$. This is maximal dephasing and the walk becomes identical to a CRW.

Figure 6. The variance $\sigma^2$ and escape probability $P_{\text{esc}}$ obtained at the final time step plotted against the congestion probability $1 - p$ for varying values of the dephasing probability $p_d$ on a square two-dimensional lattice of size given by $t_{\text{max}} = 75$. (a) The propagation of the walker decreases monotonically with the congestion rate for increasing values of dephasing $p_d$. A quadratic behavior remains for small values of $p_d$. (b) The escape boundary is at $t_{\text{esc}} = 10$. With decreasing $p_d$ the quantum walker has a larger chance to escape the boundary. As $p_d$ increases the QRW enters the classical regime and quantum advantages are lost.
walk is fully quantum so more of the probability distribution escapes the boundary. When dephasing is increased process errors are introduced, reducing $p_{\text{esc}}$ for any given value of $p$.

**Discussion**

Quantum random walks are a promising route towards quantum information processing, exhibiting many unique features compared to the classical random walk. In the classical context, walks on percolated lattices (i.e. lattices containing congestion) have been well studied. We have considered the analogous situation in the quantum context. We defined a mapping between quantum and classical walks, via the coin operator, to allow for a direct comparison of the two. Then we introduced a model for adding static defects to the underlying lattice via the introduction of bit-flip coins. These defects inhibit the spread of the classical and quantum walker, reducing the escape probability and variance metrics. We found that as a quantum random walk evolves it will suddenly and dramatically escape a finite boundary. It maintains this property even in the presence of congestion.

We also introduce a dephasing error model. Dephasing errors are errors caused by the environment on the quantum walker as it evolves. In the limit of large dephasing the quantum random walk spatially localises and behaves like a classical random walk. The spread of the walker is sensitive to small amounts of dephasing in our dephasing model and becomes more sensitive as the size of the lattice increases.

We also studied the effects of spatial defects and dephasing together on the propagation of the walker and found a monotonic decrease is observed in the variance and escape probability for a given congestion probability as the dephasing probability is increased. Our results indicate that a quantum walker on a lattice with defects and dephasing still exhibit a quadratic rate of spreading. Thus, as the quadratic spread of quantum walks is one of the key features that make them applicable to quantum information processing applications, such as the quantum search algorithm, quantum walks on congested lattices remain advantageous over classical random walks.

**Acknowledgements**

We thank Matthew Broome for helpful discussions. K.R.M. and A.G. acknowledges the Australian Research Council Centre of Excellence for Engineered Quantum Systems (Project number CE110001013). P.P.R. acknowledges support from Lockheed Martin.
Author Contributions
P.P.R. and A.G. contributed equally to this work. K.R.M., P.P.R., and A.G. participated in interpreting and analyzing the data. K.R.M. performed all simulations, prepared all graphics, wrote the initial draft and following drafts. P.P.R. and A.G. both supervised this work and contributed in writing further drafts of this manuscript.
