The present status of the ANAIS experiment (Annual Modulation with NaI’s) is shown. ANAIS is intended to use more than 100 kg of NaI(Tl) in the Canfranc Underground Laboratory (Spain) searching for seasonal modulation effects in the WIMP signal; in a first stage, a prototype (one single 10.7 kg crystal) has been developed in order to obtain the best conditions regarding the energy threshold and the radioactive background in the low energy region as well as to check the stability of the environmental conditions. The first results corresponding to an exposure of 2069.85 kg day show an average background level of 1.2 counts/(keV kg day) from threshold ($E_{thr} \sim 4$ keV, even using one single photomultiplier) up to 10 keV.

1. INTRODUCTION

According to current robust evidences from supernovae and the CMB radiation, only $\sim 30\%$ of the density of the Universe must be due to matter and the rest should consist of unknown species of dark energy. In addition, most of the matter must be dark, non-baryonic and cold. Axions and Weakly Interacting Massive Particles, the so-called WIMPs, are the leading candidates to this type of dark matter. The lightest stable particles of supersymmetric theories, like the neutralino, describe a particular class of WIMPs.

Direct searches of WIMPs, which are supposedly filling the galactic halo, are based on the measurement of the nuclear recoil induced by the elastic scattering off target nuclei in a suitable detector [9]. This process is rare (interaction rates range from 10 to $10^{-5}$ c/(kg day)) and has an energy spectrum which decays almost exponentially from a few keV; therefore, ultra-low background conditions and very good energy thresholds are mandatory in the direct detection of WIMPs. But even in these conditions, the WIMP signal is entangled with the radioactive background; consequently, to confirm the existence of these particles it would be necessary to identify a distinctive signature such as the annual modulation of the counting rates due to the variation in the relative velocity between the Earth and the halo, produced by the movement of the Earth around the Sun [2]. The smallness of this effect ($< 10\%$) makes necessary to accumulate as much statistics as possible having a long time exposure and a large mass of target nuclei, requirement which may be fulfilled using NaI. The DAMA collaboration has reported an annual modulation effect [3] which singles out a region of WIMPs in the parametric space $\sigma - m_W$, partially excluded by other experiments (CDMS [4], EDELWEISS [5], IGEX [6] and ZEPLIN [7]).

2. THE PROTOTYPE OF ANAIS

ANAIS (Annual Modulation with NaI’s) is a large mass experiment intended to investigate the annual modulation effect in the signal of galactic WIMPs [8]. It will be installed in the Canfranc Underground Laboratory, located in an old railway tunnel in the Spanish Pyrenees with an overburden of 2450 m.w.e., using $\sim 100$ kg of NaI(Tl) as an improved scaled-up version of a previous experience [9]. Before setting-up the whole experiment, a prototype is being developed in Canfranc in an attempt to obtain the best energy threshold and lowest radioactive background in the low energy region, as well as to check the stability of
the environmental conditions which influence on the detector response.

In the ANAIS prototype, one out of the 14 NaI(Tl) detectors stored underground since 1988 has been used; it consists of an hexagonal 10.7 kg crystal encapsulated inside 0.5-mm-thick stainless steel and coupled to a photomultiplier (PMT) through a quartz window. Some components of the PMT have been removed because of their radioimpurities. The scintillator has been placed in a shielding consisting of 10 cm of archaeological lead (of less than 9 mBq/kg of $^{210}$Pb) followed by 20 cm of low activity lead, a sealed box in PVC (maintained at overpressure to prevent the intrusion of radon), 2-mm-thick cadmium sheets, and finally, 40 cm of polyethylene and tanks of borated water. An active muon-veto made of plastic scintillators is covering the set-up.

The data acquisition system, based on standard NIM and CAMAC electronics, has two different parts following the two output signals implemented from the PMT; the fast signal is recorded using a digital oscilloscope (500 time bins, 10 ns/bin) while the slow signal is routed through a linear amplifier and analog-to-digital converters controlled by a PC through parallel interfaces, to register the energy of events up to $\sim 1.7$ MeV.

2.1. Noise rejection

The noise in NaI detectors is mainly produced by thermoionic emission in photomultipliers. The different shape of the output signals from the PMT for scintillation and noise events makes feasible an efficient discrimination. Figure 1 shows a typical noise pulse and the theoretical shapes of noise and scintillation for a pulse having the same area. Typical parameters of the PMT pulses used in other NaI experiments to reject the noise are the mean amplitude [10], a ratio of area portions [11], etc. In the present work, the filtering of noise uses the squared deviation $d$ of the digitalized pulse $V_p$ from the well-known theoretical shape $V$ of a scintillation event of the same area:

$$d = 100 \times \frac{\sum_i (V(t_i) - V_p(t_i))^2}{\sum_i V_p(t_i)}$$  \hspace{1cm} (1)

$$V(t) = -\frac{QR}{\tau - \tau_s} \left( \exp\left(-t/\tau_s\right) - \exp\left(-t/\tau\right) \right)$$  \hspace{1cm} (2)

where $\tau = RC$ is the time constant of the RC circuit equivalent to the PMT, $\tau_s$ is the scintillation decay constant ($\sim 230$ ns for NaI(Tl)) and $Q$ is the total collected charge. To eliminate the noise, a safe cut at $3\sigma$ from the center of the gaussian distribution of this parameter for a population of $^{137}$Cs calibration events from 4 to 10 keV has been used. The effect of the noise rejection can be seen in Figure 2, where the raw spectrum and the spectrum after the elimination of noise are depicted up to 100 keV.

2.2. Radioactive background

By comparing the data recorded from December 2000 to October 2001 with Monte Carlo simulations, it was possible to identify the main sources of background in the region of interest. The $^{210}$Pb 46.5 keV line as well as a peak due to the escape of X-rays of I at $\sim 16$ keV seen in the spectrum (see Figure 2), may be caused by the presence of radioimpurities in the stainless steel can and/or in the PMT. The area of the 1460.8 keV peak is compatible with an activity of 15 mBq/kg from $^{40}$K in the NaI crystal; these contaminations produce an almost flat
background in the low energy region due to their beta emission. It is also worth noting that a comparison between the spectra recorded with and without the neutron shielding does not show noticeable differences.

A pulse shape analysis has been carried out in the low energy region with the purpose of investigating the possible appearance of the so-called "anomalous" or "bump" events found in other NaI experiments \cite{12,13}. No evidence of such anomaly has been discovered in the distributions for background events, neither following the method of the UKDMC (fitting integrated pulses to calculate the decay time constant) nor using other parameters (like the first momentum of the pulse).

2.3. Stability

In an experiment searching for a very small seasonal modulation, the stability of the conditions whose variation could mimic the effect we are looking for is essential. A monitoring system will be installed in ANAIS to control periodically, and even modify automatically, the environmental conditions in the laboratory. But using the data of the prototype, collected along almost 7000 hours, the stability of some parameters has been already checked.

The fluctuations of the ADC channels for peaks used to calibrate energy spectra are $\sim$1-1.5%, so the variations in the energy of events due to this effect are negligible compared to the energy resolution. The evolution in time of different counting rates (total, above 6 keV and above 100 keV) has been checked, since a modulation effect in the low energy region due to background (not to WIMPs) should be correlated with a modulation at higher energies. These rates are plotted as a function of time for the whole data collection in Figure 3. The gaussian distributions of the deviations of the rates from their mean values have a sigma of 1.75 for the rate above 6 keV, and 1.58 for the rate above 100 keV.

Since the scintillation light yield depends on temperature, a monitoring system (based on sensors and ADAM sensor-to-computer interfaces) has been tentatively developed to study the tem-
perature in the inner enceinte. Internal temperature does not depend neither on changes on the nitrogen gas flux injected inside the shielding nor on the periodical fluctuations of the temperature in the laboratory due to the air conditioning system. It is only sensitive to real changes outside the shielding. If a good stability of the external temperature is achieved, variations inside will be of only 0.03 Celsius degrees.

3. RESULTS

The results presented here correspond to an exposure of 2069.85 kg×day. As pointed out before, Figure 2 shows the raw spectrum and the spectrum after the noise rejection up to 100 keV. The energy threshold is of ∼4 keV and the background level registered from the threshold up to 10 keV is about 1.2 counts/(keV kg day).

We have used this region to derive the corresponding limits for the WIMP-nucleon cross sections. The galactic halo is supposed to be isotropic, isothermal and non-rotating, assuming a density of ρ=0.3 GeV/cm³, a Maxwellian velocity distribution with v_{rms}=270 km/s (with an upper cut corresponding to an escape velocity of 650 km/s) and a relative Earth-halo velocity of v_r=230 km/s. The Helm parameterization [14] is used for the coherent form factor, while the approximation from [15] is considered for the SD case. Spin factors (λ_pJ(J + 1)) 0.089 and 0.126 are assumed for Na and I respectively. Fig. 4 shows, in addition to the limits derived from the prototype results (solid lines), the estimates considering a flat background of 1 count/(keV kg day) from 2 to 8 keV after an exposure of 107 kg×y both for raw data (dotted lines) and assuming Pulse Shape Discrimination (PSD) techniques (dashed lines); rejection factors obtained on the average by other groups have been used [16]. The plots show the contour lines for each nucleus, Na and I, as well as the NaI case. That is shown both for SI scalar interactions (top) and SD WIMP-proton interactions (bottom). It should be noted that for SI interactions and using PSD techniques, ANAIS will be able to explore the region of WIMPs singled out by the possible annual modulation effect reported by the DAMA collaboration [3], even though it is not designed to be an exclusion experiment.

According to these first results, the next steps in the development of the prototype of ANAIS, currently underway, are the removal of the present PMT and the steel can so as to install, instead, two ultra-low background PMT and a 1-cm-thick teflon enclosure filled with special mineral oil, as in the NAIAD experiment [17]. A program of measurements to select high radiopurity materials has been carried out in Canfranc, using an ultra-low background Ge detector. The goals of these modifications are to reduce, as much as
possible, the various sources of background, to diminish the noise by using anticoincidence read-out (lowering so also the energy threshold) and to improve the collection of the scintillation light.

4. CONCLUSIONS

Summarizing, a prototype of the ANAIS experiment has been installed in the Canfranc Underground Laboratory. The noise rejection has lead to a \( \sim 4 \) keV threshold, even using a single PMT. The background in the low energy region is produced by \(^{210}\text{Pb}\) in the detector enclosure and/or the PMT and \(^{40}\text{K}\) in the NaI(Tl) crystal. The stability is being controlled and new improvements are being developed before setting-up the large-mass experiment.

ACKNOWLEDGEMENTS

The Canfranc Astroparticle Underground Laboratory is operated by the University of Zaragoza under contract No. FPA2001-2437. This research was funded by the Spanish Commission for Science and Technology (CICYT) and the Government of Aragón.
