Abstract: Indirect detection signals from dark matter annihilation are studied in the positron channel. We discuss in detail the positron propagation inside the galactic medium: we present novel solutions of the diffusion and propagation equations and we focus on the determination of the astrophysical uncertainties which affect the positron dark matter signal. We show that, especially in the low energy tail of the positron spectra at Earth, the uncertainty is sizeable and we quantify the effect. Comparison of our predictions with current available and foreseen experimental data are derived.

Introduction

The quest for the identification of dark matter (DM), together with the comprehension of the nature of dark energy, is one of the most important and potentially far-reaching problems in the understanding of the physical world, and represents a matter of investigation where cosmology, astrophysics and particle physics converge together. It is therefore of utmost importance to address the problem of the identification of DM from many different points of view, which bring together research performed, from one side, in particle accelerators and on the other side in underground laboratories, in neutrino telescopes, in large-area surface detectors as well as in space. In this paper we attack the problem from the point of view of the indirect detection of DM through the search of its products of annihilation inside the galactic halo. We will specify our discussion on the positron signal, for which we intend to quantify the astrophysical uncertainties and derive the ensuing consequences for upcoming experiments. A more extended and detailed discussion of our analyses will be presented elsewhere \cite{3}.

The diffusion equation and its solution

The propagation of positrons in the galactic medium is governed by the transport equation:

$$-K(E)\nabla^2 \Psi(E) - \frac{\partial}{\partial E} \{b(E)\Psi(E)\} = Q(x, E),$$

where \(\Psi(E)\) is the positron number density per unit energy and \(Q(x, E)\) is the positron source term. The transport through the magnetic turbulences is described by the space independent diffusion coefficient \(K(x, E) = K_0 \epsilon^3\) where \(\epsilon = E/E_0\) and \(E_0 = 1\) GeV. Positrons lose energy through synchrotron radiation and inverse Compton scattering on the cosmic microwave background radiation and on the galactic starlight at a rate \(b(E) = E_0 \epsilon^2/\tau_E\) where \(\tau_E = 10^{16}\) s. The source term for positrons produced through DM annihilation is then:

$$Q(x, E) = \frac{\langle \sigma v \rangle}{m_\chi^2} f(E) \rho_\odot^2(x) = \kappa f(E) \rho_\odot^2(x),$$

where \(m_\chi\) is the mass of the DM particle and \(\langle \sigma v \rangle\) is the low–energy velocity–averaged DM annihilation cross–section. The positron spectrum \(f(E)\) produced in the annihilation process depends on the specific final states of the annihilation cross section. The DM density profile of the galactic
The positron injection energy $E_S$, for an observed energy of 10 GeV. The galactic halo profile is NFW [9] with a scale radius of 20 kpc. The curve labeled as MED corresponds to the choice of propagation parameters which best–fit the B/C ratio [7]. The MAX and MIN configurations correspond to the cases which were identified to produce the maximal and minimal DM antiproton fluxes [4], while the larger area denotes the full variation of the propagation parameters yet compatible with the B/C analysis [7].

The halo function $\tilde{I}$ is featured in Fig.1 as a function of the injection energy $E_S$ for a fixed value of the observed positron energy $E$ and assuming a NFW density profile [9]. In order to quantify the uncertainty related to the properties of the diffusion region, we have varied the astrophysical parameters which govern the diffusion process inside the range allowed by the B/C measurements [7]. Fig.1 shows that, for large injection energies as compared to the observed energy, the uncertainty on the halo function is sizeable, reaching a factor of two upwards and of 20 downwards at $E_S = 1$ TeV. Other DM profiles will be discussed in [3].

The positron signal

The solution of the diffusion equation allows us now to calculate the positron energy spectra at the Earth, and to determine the uncertainties on the fluxes. One example is given in Fig.2, where the positron flux for a DM particle which annihilates purely into a $\bar{\tau}\tau$ final state is shown. The annihilation cross section, here and in the following, is chosen to match the relic abundance for cold DM, as determined by the latest WMAP data [10], under the hypothesis of dominant $s$–wave annihilation for the DM candidate. The figure shows the band of allowed values for the positron signal in this channel: the uncertainty ranges from a factor of 5 at energies around 1 GeV down to a factor of 2 above 10 GeV.

A comparison with the HEAT data [2], in terms of the positron fraction, is given in Fig.3, for annihilation into a $W^+W^-$ final state by a 100 GeV DM particle. Due to the contribution of the background [8] (which we have reduced by 10%), the uncertainty on the predictions for the total flux is limited to a factor of the order of 20–30%. Clearly a complete understanding of the fluctuations of the
Figure 2: Positron fluxes for a 100 GeV DM particle which annihilates into a $\bar{\tau}\tau$ final state, as a function of the positron energy. The galactic halo profile is NFW [9] with a scale radius of 20 kpc. The upper, median and lower curves show the effect due to galactic propagation: the median curve refers to the best–fit set of propagation parameters [7], while the upper and lower curves delimit the uncertainty band on the theoretical determination of the flux.

Figure 3: Positron fraction $e^+/ (e^+ + e^-)$ as a function of the positron energy. The lower solid curve refers to the background estimate of Ref. [8], rescaled down by a factor 0.9. The upper, median and lower curves show the effect of including a signal component calculated for a 100 GeV DM particle which annihilates into a $W^+W^-$ final state and for a NFW halo profile [9] with a scale radius of 20 kpc. A boost factor of 32 is included. The median curve refers to the best–fit set of propagation parameters [7], while the upper and lower curves delimit the uncertainty band on the theoretical determination of the flux. The experimental points refer to the combined 1994, 1995 and 2000 HEAT results [2].

Conclusions

In this paper we have discussed the positron indirect detection signal of DM annihilation in the galactic halo, focussing our attention to the determination of the astrophysical uncertainties on the positron flux due to the positron propagation inside the galactic medium. We have shown that the uncertainties may be large: for a 100 GeV DM par-
Figure 4: Predictions for the positron fraction $e^+/(e^++e^-)$ as a function of the positron energy for the PAMELA flight and for a DM particles which annihilates directly into $e^+e^-$. The lower solid curve refers to background only [8]. The median curve refers to the best–fit prediction, while the upper and lower curves show the results for the extreme values of the propagation parameters. The error bars denote the predictions for a detector acceptance of 20.5 cm$^2$ sr [6] and a 3 years flight.
