(Dated: November 9, 2016)

We explore the space of scalar-tensor theories containing two non-conformal metrics, and find a discontinuity pointing to a “critical” cosmological solution. Due to the different maximal speeds of propagation for matter and gravity, the cosmological fluctuations start off inside the horizon even without inflation, and will more naturally have a thermal origin (since there is never vacuum domination). The critical model makes an unambiguous, non-tuned prediction for the spectral index of the scalar fluctuations: \( n_S = 0.96478(64) \). Considering also that no gravitational waves are produced, we have unveiled the most predictive model on offer. The model has a simple geometrical interpretation as a probe 3-brane embedded in an \( EAdS_2 \times E_3 \) geometry.

1. Introduction. In spite of its mathematical simplicity and observational triumphs, the Big Bang model of the Universe remains an unfinished work of art. Many of its late-time successes can be traced to the initial conditions postulated for its early stages, and these are put in hand, without justification, other than to retrofit the data. The main culprit for this shortcoming is the so-called horizon problem: the cosmological structures we observe today span scales that lay outside the ever-shrinking “horizons” of physical contact that plagued the early universe. This precludes a causal explanation for their initial conditions.

Several extensions of the Big Bang model have been proposed with the aim of opening up its horizons. An early bout of accelerated expansion \[ 4 \] , a contracting phase followed by a bounce \[ 4 \] , a loitering early stage \[ 5 \] , and a varying speed of light (VSL) \[ 6, 7 \] have all been considered. None of these proposals evades the criticism that retrofitting the data is still used to select in detail the primordial fluctuations that the model should produce. Once primordial causal contact is established, work can start on concrete physical mechanisms for spoiling perfect homogeneity (e.g. vacuum quantum fluctuations or thermal fluctuations). Typically it is found that one can produce a wide range of initial conditions including, but not circumscribed to those explaining the observations.

Specifically, the primordial density fluctuations can be characterised by an amplitude \( A_S \), measuring their intensity at a given scale, and a spectral index \( n_S \), measuring how the amplitude varies with scale. Observations \[ 8, 9 \] show that \( A_S = 2.142(49) \times 10^{-9} \) and \( n_S = 0.9667(40) \), signalling a very specific slightly red spectrum, i.e. one with enhanced amplitude for longer wavelengths. Whilst the observed \( A_S \) probably indicates nothing more than a hierarchy between two energy scales, one might have expected a theoretical forecast for \( n_S \). Yet, all theories effectively adjust their free parameters (e.g. the reheating temperature after inflation, or the number of e-foldings) to fit the observed \( n_S \), from within a range of possibilities. This is not to say that they entirely lack predictivity; indeed they do predict a plethora of conditions involving \( n_S \) and other observables (e.g. \( \Omega \)).

In this Letter, we revisit a class of VSL models \[ 11 \] in which there are two non-conformal metrics, one for matter and another for gravity, so that light and other massless matter particles travel faster than gravity. Conditions for the observational success of such models have been identified \[ 11, 12, 13 \] , considering both a vacuum and a thermal initial state. In common with other models, they do not bypass the criticism voiced above. However, in this Letter we uncover a remarkable result pertaining to thermal scenarios.

It is known that thermal VSL models require a fast phase transition in \( c \) so as to produce near-scale-invariant fluctuations; however, the scale-invariant limit (\( n_S = 1 \)) is unreachable. Closer inspection of the space of all possible theories reveals that this is due to a discontinuity, pointing to a special, critical solution that should be regarded as the preferential model for a phase transition in \( c \). Instead of \( n_S = 1 \), the thermal fluctuations in this model display a running \( n_S < 1 \). But what is truly notable is that the model has a single free parameter, so that the amplitude \( A_S \) fully fixes the value of \( n_S \) at the observationally relevant scales. The predicted value is within current constraints, but improved observations would unambiguously prove or rule out the theory. The model also has a simple geometrical interpretation as a probe 3-brane embedded in an \( EAdS_2 \times E_3 \) geometry.

2. The critical model. We start by reviewing the general framework of scalar-tensor bimetric theories. In these models there are two metrics (or frames): \( g_{\mu\nu} \) associated with the gravitational action (the Einstein frame), and \( \hat{g}_{\mu\nu} \), to which matter is minimally coupled (the matter frame). The action takes the general form:

\[
S = \frac{M_5^2}{2} \int d^4x \sqrt{-\hat{g}} R[\hat{g}_{\mu\nu}] + \int d^4x \sqrt{-g} \mathcal{L}_M(\Psi, \hat{g}_{\mu\nu}) + S_\phi
\]
where $M_P$ is the reduced Planck mass, and $S_\phi$ encodes the dynamics of the field $\phi$ relating the two metrics. If the metrics are conformally related we have a “varying-G” theory, such as Brans-Dicke theory. In “varying-c” theories, rather, the metrics are non-conformally related:

$$\hat{g}_{\mu\nu} = g_{\mu\nu} + B(\partial_\mu \phi)(\partial_\nu \phi),$$

so that the light cones spanned by massless matter particles and by gravitons do not coincide \cite{13, 14}. In general $B$ (also known as the warp factor, for reasons to be made obvious soon) is a function of $\phi$. If the speed of light is to be larger than that of gravity, then $B > 0$ (with signature $+\ldots-$).

It may seem that the number of theories of this type is endless, but this is not the case. The simplest non-trivial $S_\phi$ must consist of two generally non-constant cosmological terms, one in the matter frame and the other in the Einstein frame:

$$S_\phi = \int d^4x \sqrt{-\hat{g}}(-2\Lambda_m(\phi)) + \int d^4x \sqrt{-g}(-2\Lambda_g(\phi)) = 0 .$$

(2)

Furthermore, only one of the functions $\Lambda_m(\phi)$, $\Lambda_g(\phi)$ and $B(\phi)$ is independent \cite{17}. This has been known for a while; here we sketch the proof in two steps.

Firstly, let $\phi$ be canonically normalized in the generalized sense that it should exhibit a Klein-Gordon equation of motion in the matter frame when no matter is present. Then, its action should be a cosmological term in the matter frame, due to a simple calculation in variational calculus in the presence of two metrics (see \cite{13, 14}). Furthermore, if the field dynamics is to be driven by $2\Lambda_m$, regarded as a potential, we should have $2\Lambda_m(\phi) = -1/B(\phi)$. This fully fixes the first term of (2) in terms of $B$, and it is known \cite{14} that it amounts to postulating a DBI action in the Einstein frame:

$$S_\phi = \int d^4x \sqrt{-\hat{g}} \left( \frac{1}{B} \sqrt{1 + 2BX - V} \right) ,$$

(3)

with $X = \frac{1}{4}(\partial_\mu \phi)(\partial^\mu \phi)$ and $V = 2\Lambda_g$. This can be derived from simple properties of determinants, and will be important in seeking a geometrical interpretation for our critical model.

Secondly, of the two remaining free functions ($B$ and $V$) only one is free in the UV limit, which is the limit of interest to us. In the physical situation we are considering, the action (3) should more strictly be called anti-DBI, since the sign of $B$ is opposite to the usual one, so that the speed of light is larger, rather than smaller than that of gravity. Thus, the UV limit of the theory is achieved with $X \gg 1$ (instead of saturating at an upper bound, as is the case with the usual DBI theory), so that:

$$L_\phi \approx \sqrt{\frac{2X}{B}} - V + \mathcal{O}\left(\frac{1}{\sqrt{B^3X}}\right) .$$

(4)

This is nothing but the cuscuton model \cite{18, 19}, and indeed the speed of sound is infinite in this limit ($c_s \approx \sqrt{2BX} \to \infty$). The model has conformal (Weyl) symmetry \cite{20, 21}, so that any scale-factor $a(t)$ is a solution. This implies that spatial flatness is compulsory and fully fixes $V$ \cite{15, 20}. If $\rho$ and $p$ denote density and pressure, we have $\rho \approx V$ and $p + \rho \approx K$ \cite{18, 22}, where $K = \phi/\sqrt{B}$ is the kinetic energy. The (spatially flat) Friedmann and continuity equations are:

$$3M_P^2H^2 \approx V \quad \text{and} \quad \dot{V} + 3HK \approx 0 ,$$

(5)

where $H = \dot{a}/a$. These can be integrated as:

$$V(\phi) = \frac{3}{4M_P^2} \left( \int \frac{d\phi}{\sqrt{B(\phi)}} \right)^2 + \mathcal{O}\left(\frac{\epsilon V}{c_s^2}\right) ,$$

(6)

fixing $V$ as a function of $B$. Here $\epsilon = -\dot{H}/H^2 = \frac{3}{2}(1+w)$, where $w = p/\rho$, and $c_s$ is the speed of light in the matter frame. Although any $w$ is possible, it can be shown that $c_s^2 = \partial p/\partial \rho|_X \to \infty$, the next order corrections yield $w = p/\rho \to \infty$ for generic solutions \cite{23, 24}.

So far we have merely reviewed old results. Now we come to the crucial element of this Letter. It has been shown \cite{10, 12, 16} that thermal bimetric scenarios are close to scale-invariance whenever $B(\phi) \propto \phi^n$, with $n$ close to 2. Then, the potential $V$ is still a power-law, but its exponent is close to zero (cf. Eqn. (6)). The variation in $c_s$ is abrupt, but one still has constant $\epsilon_s = \dot{c_s}/(c_s H)$, with $\epsilon_s \to -\infty$ as $n \to 2$. The cosmological solutions are “scaling solutions”, i.e. they have constant $\epsilon$ and $\epsilon_s$, leading to thermal fluctuations with constant $n_S$, which can be tuned to be as close to 1 as wanted. Indeed

$$n_S - 1 = \frac{\epsilon + 1}{\epsilon_s + \epsilon - 1} ,$$

(7)

and although $n_S = 1$ is unreachable, any red spectrum as close to scale-invariance as required can be obtained by suitably tuning $B$.

It should be immediately obvious from Eqn. (6) the reason why the scale-invariant limit cannot be reached. Within the space of these theories, there is a discontinuity at $B \propto \phi^2$, because the potential fails to be a power-law. All the theories around it imply power-law potentials, but this “critical” theory stands out as an exception:

$$B_{\text{crit.}}(\phi) = B_0 \left( \frac{\phi}{M_P} \right)^2 ,$$

(8)

$$\Rightarrow V_{\text{crit.}}(\phi) = \frac{3}{4B_0} \ln^2\left( \frac{\phi}{M_P} \right) .$$

(9)

It marks a special, crucial boundary in the space of theories. The critical model is unique in that it cannot have a constant $\epsilon_s$, since $V$ is no longer a power-law. This induces natural deviations from scale-invariance, making its phenomenology remarkable, as we will show presently.
3. Geometrical interpretation. Before embarking upon the phenomenology of the critical model we reinforce its special status by uncovering an elegant geometrical interpretation. It is known that the DBI action can be derived from the induced metric on a probe 3-brane embedded in a higher dimensional geometry, with the $B$ function interpreted as a geometrical “warp” factor. For example, in the celebrated DBI action associated with the motion of a probe 3-brane in $AdS_5 \times S_5$ geometry, one finds $B \propto -\phi^{-4}$, with interesting cosmological implications [25, 26]. Likewise, $B(\phi) \propto \phi^2$ follows from embedding a 3-brane in the $EAdS_B$ geometry given by:

$$d\tau_s^2 = \frac{r^2}{R^2}dt^2 + \frac{R^2}{r^2}dr^2 - dx^2 - dy^2 - dz^2,$$

where $R$ is the radius of the Euclidean $AdS_2$. Ignoring the gravitational backreaction, the induced action on a uniform probe 3-brane at $r(t)$ is given by:

$$S_{3B} = T_3 \int d^3x \sqrt{\frac{r^2}{R^2} + \frac{R^2\dot{r}^2}{r^2}},$$

where $T_3$ is the brane tension (with mass units $M^4$). Field $\phi$ is a redefinition of $r$ that renders $\frac{R}{r}$ canonical in the IR limit, and a Taylor expansion shows that this is given by $r = 4R^2 T_3/\phi^2$. Straightforward algebra shows that this brings [11] to the anti-DBI form [3] with $B$ matching the critical model [8] and

$$B_0 = \left(\frac{M_P}{2RT_3}\right)^2.$$

Turning on gravity for the effective 4D geometry, the potential is fixed by Eq. [9], as a result of the conformal invariance of the theory in the UV [20, 21].

A crucial novelty here is that the extra dimension, $r$, is time-like rather than space-like, something also discussed in string theory literature [27]. While this may raise alarm about ghost instabilities for the bulk, the ghost degrees of freedom may be made arbitrarily heavy and thus decouple from the 4D low-energy effective field theory [24].

4. Density fluctuations. We now come to the core of this Letter, the evaluation of the thermally induced fluctuations for the critical solution. This can be done following well-known methods developed for theories with a varying speed of sound $c_s$ [14, 16, 22], since that is what our theory is in the Einstein frame. The second order action for the curvature fluctuation $\zeta$ is:

$$S_2 = \frac{1}{2} M_P^2 \int d^3x \, z^2 \left[ \zeta'' - c_s^2 (\nabla \zeta)^2 \right],$$

where $z = \frac{\sqrt{2}}{c_s^2} \eta$ and $\eta$ is conformal time. Therefore we have a standard quantum field theory in variable $v = M_P z \zeta$, subject to dynamical equation:

$$v'' + \left( c_s^2 k^2 - \frac{z''}{z} \right) v = 0,$$

where $k$ is the comoving wave-number. The central quantity to be computed is $c_s$, and this is given by [14, 18, 22]:

$$c_s = \sqrt{1 + 2BX} \approx \frac{2}{3} \epsilon B \rho \approx \frac{2}{3} \epsilon B \rho e^{\frac{\eta}{B}},$$

where the first identity is generic for (anti-)DBI models, in the second step we used $\frac{\dot{\epsilon}}{\epsilon} = \frac{\dot{B}}{B} \approx \frac{\dot{\rho}}{\rho}$ and $K \approx \sqrt{2X/B}$, and in the third we used Eqs. [8] and [9]. The fact that $V$ (and so $\rho$) is not a power-law in $\phi$, explains why the model has a $c_s$ which is not a power-law in $\alpha$ or $\rho$. Even if the background scales (constant $\epsilon$), the speed of sound does not, with a varying $c_s$ given by:

$$c_s = \frac{c_s}{c_s^2} = -2\epsilon \left( 1 + 2\sqrt{\frac{B \rho}{3}} \right).$$

Thus, $n_S$ is expected to run, a property that can be guessed from [7]. However that formula is incorrect for varying $c_s$, indeed many standard formulae in the literature [14, 16, 22] break down. A full derivation of $n_S$ can be found in the Supplementary Material [23] (SM) (in this version of our paper included in appendix). Here we present an approximate calculation, good enough to extract all the salient features.

As usual, Eq. (11) has two regimes, an acoustic one and a gravitational instability one, depending on which of its two terms in $v$ dominates. The two regimes are separated by the sound horizon scale, $k_h$, where these terms become of the same order:

$$c_s^2 k_h^2 \sim \frac{z''}{z} \approx \frac{(aH \epsilon_s)^2}{(aH \epsilon_s)'} \approx (aH \epsilon_s)^2,$$

and

$$\frac{c_s^2 k_h^2}{k^2} \sim \frac{z''}{z},$$

for simplicity, we have assumed a constant $\epsilon$, but in fact this is not necessary). The sound horizon scale therefore satisfies $c_s k_h \approx aH \epsilon_s$, and we note the extra factor of $\epsilon_s$ with regards to the usual formula. Matching the 2 types of solution is sufficient to derive to a good approximation the power spectrum frozen-in outside the horizon. For $k \gg k_h$ the solutions should be normalized as [14, 16, 22]:

$$v = \frac{e^{-i\int_{k_h}^{k} dk}}{\sqrt{2\epsilon k}},$$

whereas for $k \ll k_h$ the growing mode takes the form $v = F(k) z$. By means of simple algebra $F(k)$ can be found by matching the two expressions at $k \sim k_h$. The square of $F(k)$ is nothing but the frozen-in power spectrum of $\zeta$, up to a factor representing the expectation value of $2N + 1$, where $N$ is the number operator (note that upon quantization $v^2$ is multiplied by $\hat{a}^\dagger \hat{a} + \hat{a} \hat{a}^\dagger$, where $\hat{a}$ is an annihilation operator). For vacuum fluctuations, this factor is simply 1, whereas for a thermal
state it is twice the thermal occupation number of mode $k$ in the Rayleigh-Jeans limit. This is $2T_c/k$, where $T_c = Tc_\epsilon/\rho$ is a “conformal temperature” which remains constant during the varying-$c$ phase. The frozen-in dimensionless power spectrum of the thermally induced fluctuations is therefore:

$$P^\prime_\zeta(k) \equiv \frac{k^3}{2\pi^2} \langle |\zeta|^2 \rangle^\prime \approx \frac{1}{24\pi^2} \frac{\rho}{\epsilon s M_p^2} T_c,$$

where the right hand side is to be evaluated at horizon crossing (now $c_s k \approx aH\epsilon_s$). We stress the extra factors in $\epsilon_s$ found in Eq. (17) and (19), in relation to standard formulae. They are irrelevant if $\epsilon_s$ is a constant, but not in our case. Eq. (19) is valid up to factors of order one (fully restored in the SM [23]; see appendix).

Combining Eqs. (17) and (19) and using the chain rule we find for the spectral index:

$$n_S - 1 = \frac{d \ln P^\prime_\zeta}{d \ln k} = -\frac{1}{4} + 2\epsilon \left( \frac{B_0\rho}{\rho} \right)^\frac{3}{4} + O\left( \frac{1}{B_0\rho} \right),$$

where $\rho$ is the density when $k = k_h$. Thus, $n_S$ runs from very red, at the largest scales, to almost scale-invariant, at the smallest. However, as announced, the observed amplitude $A_S$ fixes where we are in this running flow. Note that the model has a single free parameter, the 4-volume scale $B_0$. Although Eq (19) seems to depend both on $B_0M_p^2$ and $B_0\rho$, the former can be eliminated by using $c_s k \approx aH\epsilon_s$, the Friedman equation, and some basic thermodynamics, to recast it in the descriptive form:

$$P^\prime_\zeta(k) \approx C(B_0 \rho)^{1+\epsilon} \exp \left( \frac{4\sqrt{3}B_0\rho}{\epsilon_s} \right)^{\epsilon/2},$$

where $C$ is a numerical constant. The left hand side can be evaluated from observations. For a given mode (say, $k = 0.05 \text{ Mpc}^{-1}$) the first factor is the observed amplitude ($P_c(k) = 2.142(49) \times 10^{-9}$, [8]), and the second is the dimensionless entropy inside the scale $k$ nowadays (with $y_0 = 3.91$ the effective number of relativistic degrees of freedom). As stated above (and in [23]), generically $\epsilon \rightarrow \infty$, so we can solve (20) to get $B_0\rho \approx 583.03(16)$, where the uncertainties are both observational and arise from the fact that the model is only reliable to $O(B_0\rho)$. Using (20) we thus obtain:

$$n_S = 0.96478(64),$$

well within the most stringent current observational constraints (viz. $n_S = 0.9667(40)$, cf. [8]). This is a remarkable result. But the model makes much further predictions. It produces no tensor modes (since the horizon problem is not solved for gravitons), and so singles out a point in the $(n_S, r)$ diagram, with $r = 0$. It also predicts (cf. Eqs. (17), (19) and (20)) the running of the spectral index to be:

$$\frac{dn_S}{d\ln k} = -\frac{3}{2} (n_s - 1)^2 \approx -1.8 \times 10^{-3},$$
for the level of primordial gravitational waves ($r = 0$), the running of $n_S$, and non-Gaussianity, we can conclude without prejudice that we have in hand a very predictive model indeed. The fact that its main prediction (for $n_S$) lies spot in the middle of the Planck results should not beguile us into a false sense of security. Improved observations will soon vindicate or disprove this model.

One may wonder about the status in our model of the other cosmological problems, such as the flatness, homogeneity and isotropy problems. Firstly, the view may be held that such historically motivating problems are now considered to be of lesser importance than explaining the structure of our Universe, or may even be misguided [28]. Nonetheless we remark that it is possible to solve them using the VSL mechanism before the phase transition (e.g. [7, 13]). In other scenarios it may also happen that their solution takes place in a different phase to structure formation. Furthermore, we find that at least the flatness problem can be solved, in a single package, during the phase transition. The conformal symmetry of the theory in the UV [20, 21] not only fixes the potential but requires exact flatness (Eqs. (5) lead to a contradiction in the presence of spatial curvature). A full investigation of these matters is deferred to [24].

Acknowledgments We would like to thank Robert Brandenberger, Keith Copsey, Giulia Gubitosi and Sarah Shandera for helpful discussions. APPENDIX: SUPPLEMENTAL MATERIAL

A. Cosmological Perturbation Theory

The FRW metric with scalar linear perturbations in the longitudinal gauge is given by:

$$ds^2 = a^2(\eta) \left[ (1 + 2\Phi) d\eta^2 - (1 - 2\Psi) d\mathbf{x} \cdot d\mathbf{x} \right].$$  (23)
Observational constraints on scalar adiabatic perturbations are often described in terms of the gauge-invariant Bardeen variable \[29\]:
\[
ζ = Ψ - \frac{H}{H} (HΦ + Ψ).
\] (24)

Following \[22\], we shall adopt the following quadratic action for the Bardeen variable:
\[
S = \frac{1}{2} M_P^2 \int d^3x \, \left[ ζ^2 - (\nabla ζ)^2 \right],
\] for acoustic waves of speed \(c_s\), where
\[
q ≡ \frac{a \sqrt{2} \nu}{\sqrt{c_s}},
\] (26)
\[
y ≡ \int \frac{c_s dt}{a} = \int c_s dt,\]
(27)
\[
\nu \equiv \frac{∂v}{∂y}, \quad \epsilon \equiv -\frac{H}{H^2},
\] (28)
\[
M_P ≡ (8\pi G_N)^{-1/2} = 2.435 \times 10^{18} \text{ GeV}.\]
(29)

We shall call \(y\) the tachyo-conformal time (which is also equal to the comoving sound horizon), and \(M_P\) is the reduced Planck mass.

We can change to the Mukhanov-Sasaki variable:
\[
v ≡ M_P q ζ,
\] (30)
which is canonically normalized:
\[
S = \frac{1}{2} \int d^3x \, \left[ v''^2 - (\nabla v)^2 \right],
\] leading to the mode functions that obey the field equation in the Fourier space:
\[
v'' + \left( k^2 - \frac{q''}{q} \right) v_k = 0.
\] (32)

If we have
\[
q = Q(-y)^{1/2-ν} \Rightarrow \frac{q''}{q} = \frac{ν^2 - 1/4}{y^2},
\] (33)
our mode equation becomes
\[
v'' + \left[ k^2 - \frac{ν^2 - 1/4}{y^2} \right] v_k = 0.
\] (34)

So far, we have only considered the classical equations for linear perturbations. Following the standard canonical quantization procedure, we can decompose the free quantum fields in the Heisenberg picture as:
\[
\hat{v}(x, y) = \int \frac{d^3k}{(2π)^3} \left[ v_k(y) \hat{a}_k e^{ikx} + v_k^*(y) \hat{a}_k^† e^{-ikx} \right],
\] (35)
where \(\hat{a}_k\) and \(\hat{a}_k^†\) are the creation and annihilation operators for particles (or phonons) of momentum \(k\) around a gaussian vacuum state \(\{0\}\), which, by definition, has zero particles.

The adiabatic vacuum state \(\{0\}_{ad}\) is defined by the condition that mode functions \(v_k(y)\) approach the positive frequency (flat space) limit, when \(y \to -∞\), which is also where adiabatic approximation in Eq. (34) becomes exact:
\[
v_k(y) \to \frac{\exp(-i ky)}{\sqrt{2k}}, \quad \text{when } y \to -∞,
\] (36)
while its subsequent evolution follows from exactly solving the mode equation (34). This ensures that the adiabatic vacuum coincides with the ground state of the Hamiltonian at infinite past.

It turns out that Eq. (34) with the initial condition \[33\] has an exact solution in terms of the Hankel function of the 2nd kind (or Bessel functions of 1st and 2nd kind):
\[
v_k(y) = \frac{\sqrt{\pi} y}{2} e^{-iγν} H^2(2)(ky),
\] (37)
where
\[
γν = \frac{π}{4}(2ν + 1).
\] (38)

The late-time power spectrum of \(ζ\) in a thermal state of temperature \(T_s\) is given by:
\[
\langle P_ζ(k) \rangle_T = \lim_{y \to -0} \frac{k^3}{2π^2 ν^2 Q^2 M_P^2} \langle |v_k|^2 \rangle_{T_s} [2\langle n_k \rangle_{T_s} + 1].
\] (39)

Here, the thermal particle occupation number is given by the Bose-Einstein distribution:
\[
\langle n_k \rangle_{T_s} = \frac{1}{\exp \left( \frac{kc}{aT_s} \right) - 1}
\] (40)
We can also use the asymptotic form of Hankel function for small arguments:
\[
|v_k|^2 = \frac{4ν^2 - 1}{π y^{2ν - 1} k^{2ν + 2}} + O(y^{2ν}).
\] (41)

Combining Eqs. (33) with \[39\] yields:
\[
\langle P_ζ(k) \rangle_T = \frac{Γ[ν]}{π^3 M_P^2 Q^2} \left[ \frac{2}{\exp \left( \frac{k c_s}{aT_s} \right) - 1 + 1} \right] (k/2)^{3-2ν}.
\] (42)
Notice that, in the Rayleigh-Jeans limit \(k c_s \ll aT\), we have \(\langle n_k \rangle_T \propto k^{-1}\), and thus the scalar spectral index is given by:
\[
n_s - 1 = 2 - 2ν ≈ 0 \Rightarrow ν ≈ 1.
\] (43)
Therefore, close to scale-invariance in the tachyonic phase, the power spectrum takes the form:
\[
\langle P_ζ(k) \rangle_T \approx \frac{T_s}{π^3 M_P^2 Q^2} \approx -\frac{T_c}{π^3 M_P^2} \frac{d q^2}{dy} = \left[ -\frac{d \ln(c_s/ε)}{d \ln a} + 2 \right] \frac{HT c}{2π^3 c M_P^2 a},
\] (44)
where we used the definitions of $q$ and $Q$ (Eq. 26 and 33), while $T_c \equiv a T/c_\gamma$. Furthermore, using the definition $\epsilon$ (Eq. 28), and for a rapidly decaying speed of sound $-\epsilon_s = -d\ln c_s/d\ln a \gg 1$, we can further simplify the expression for the power spectrum:

$$\langle P_c(k) \rangle_T \approx \frac{d \ln (c_s/\epsilon)}{dH^{-1}} \frac{T_c}{2\pi^3 M_p^2 a}.$$  \hspace{1cm} (45)

The comoving wavenumber at which the power spectrum freezes to this value is similarly given by:

$$k \approx |y|^{-1} = \frac{q^2}{Q^2} = -a \frac{d(\epsilon/c_s)}{dH^{-1}}.$$  \hspace{1cm} (46)

We now evaluate the thermal fluctuations for the critical solution discussed in the main text. The model has a single free parameter, the 4-volume scale $B_0$. Its speed of sound is:

$$c_s^2 \approx 2B \approx \frac{4}{9} c^2 B^2 \approx \frac{4}{9} c^2 (B_0 \rho)^2 \exp \left( 8 \sqrt{\frac{B_0 \rho}{3}} \right).$$  \hspace{1cm} (47)

Conservation of entropy relates temperature to expansion and acoustic history:

$$g_0 T_0^3 = g_a \left( \frac{T_a}{c_s} \right)^3 \Rightarrow T_c = T_s a_s = T_0 \left( \frac{g_0}{g_a} \right)^{1/3} \rho_{*},$$  \hspace{1cm} (48)

where

$$g_0 = 3.91, T_0 = 2.73 \text{ K} = 2.35 \times 10^{-4} \text{ eV},$$  \hspace{1cm} (49)

are the effective number of degrees of freedom today, and the CMB temperature respectively. $T_s$, $a_s$, and $g_0 \gtrsim 107$ are the temperature, scale factor, and the effective relativistic degrees of freedom at the end of the tachyacoustic phase, where $c_s^2 \ll \frac{1}{3}$, $\epsilon \ll 2 \Rightarrow 6B_0 \rho \approx 6B_0 \times \frac{5}{3}g_0 T_0^4 \approx 1$, using Eq. (47). Furthermore, Eq. (47) implies:

$$\frac{d \ln (c_s/\epsilon)}{dH} = -2 \left( 1 + 2 \sqrt{\frac{B_0 \rho}{3}} \right).$$  \hspace{1cm} (50)

Using Eq. (49) and Friedmann equation $3M_p^2 H^2 = \rho \propto a^{-2\epsilon}$ (assuming constant $\epsilon$) leads to an expression for the power spectrum:

$$P_c = \frac{d \ln (c_s/\epsilon)}{dH^{-1}} \frac{T_c}{2\pi^3 M_p^2 a}$$

$$= \frac{5^{1/4} b}{3^{1/2} \pi^{7/2}} g_0^{-1/4} \left( B_0 \rho \right)^{2/3} \left( 1 + 2 \sqrt{\frac{B_0 \rho}{3}} \right),$$  \hspace{1cm} (51)

and the sound horizon crossing wavenumber:

$$k = a \frac{d(\epsilon/c_s)}{dH^{-1}} = \frac{3^{1/2} \pi^{1/2}}{6^{1/2} 5^{1/4} g_0^{1/3} g_s^{-1/12} \times T_0 \left( 1 + 2 \sqrt{\frac{B_0 \rho}{3}} \right) \exp \left( -4 \sqrt{\frac{B_0 \rho}{3}} \right)}{(B_0 M_p^4)^{1/4} (B_0 \rho)^{2/3}},$$  \hspace{1cm} (52)

which can be combined to give:

$$P_c \approx \frac{5 \cdot 6^{2/3} (B_0 \rho)^{2+2/3}}{9 \pi^3 g_0} \frac{T_0^3}{T_0^3} \exp \left( 4 \sqrt{\frac{B_0 \rho}{3}} \right).$$  \hspace{1cm} (53)

Subsequently, for scalar spectral index we get:

$$n_S - 1 = \frac{d \ln P_c}{d \ln k} = -\frac{1 + 2(1+2\epsilon)}{3} \left( B_0 \rho \right)^{-1/2} + O(B_0 \rho)^{-3/2},$$  \hspace{1cm} (54)

while its running is given by:

$$\frac{d n_S}{d \ln k} = -\frac{3(1 + 2\epsilon)}{16 \epsilon B_0 \rho} + O(B_0 \rho)^{-3/2}.$$  \hspace{1cm} (55)

Up to here, we have provided results for general $\epsilon$. However, we shall argue below that $\epsilon \to \infty$ is the only expected consistent asymptotic behavior as we approach the critical mimetic model in the UV limit, and thus we shall focus our predictions to $\epsilon \to \infty$.

Planck 2015 TT,TE,EE+lowP+lensing+ext (1-sigma) Table 4 [3] gives:

$$P_c = (2.142 \pm 0.049) \times 10^{-9},$$  \hspace{1cm} (56)

at $k = 0.05 \text{ Mpc}^{-1} = 3.198 \times 10^{-31} \text{ eV}.$  \hspace{1cm} (57)

For these values, Eq. (53) can be solved iteratively to give:

$$B_0 \rho = \frac{\rho}{6 \epsilon_s} \approx 580 \text{ for } \epsilon = \infty,$$  \hspace{1cm} (58)

We see that the spectral index as $\epsilon \to \infty$ becomes:

$$n_S(\epsilon = \infty) \approx 0.96478(64).$$  \hspace{1cm} (59)

The theoretical uncertainty is estimated by difference between the first and second lines in Eq. (54), as the analytic model is only reliable to leading order in $(B_0 \rho)^{-1/2}$.

The prediction [50] is well within the observed range (Table 4 in [3]):

$$n_S = 0.9667 \pm 0.0040,$$  \hspace{1cm} (60)

Planck 2015 + lowP + lensing + ext.

For, $\epsilon \to \infty$ (and $g_s \approx 107$), we can further find the density and temperature at the end of the tachyacoustic phase:

$$\rho_s = \frac{1}{6B_0 M_p^4} = 9.0 \times 10^{-14},$$  \hspace{1cm} (61)

$$\Rightarrow T_s = 2.24 \times 10^{-4} M_p = 5.5 \times 10^{14} \text{ GeV}.$$  \hspace{1cm} (62)

Eqs. (26-55) also give the running for the scalar spectral index for $\epsilon \to \infty$:

$$\frac{d n_S}{d \ln k} = -\frac{3}{2} (n_S - 1)^2 = -1.8 \times 10^{-3},$$  \hspace{1cm} (63)

well within the allowed observational range of $(-6.5 \pm 7.6) \times 10^{-3}$ (Eq. 42 in [8]).
B. Approaching the UV limit, and $\epsilon \to \infty$

While we have used symmetry and consistency principles to construct the UV limit of the critical bimetric theory in the main text, the subleading UV behavior remains unconstrained, and is reflected by the freedom to choose $\epsilon$. Here, we carefully study this subleading behavior and prove that the only consistent choice is to have $\epsilon \to \infty$ as $c_s \to \infty$.

Equations (3), (8), and (9) in the main text provide the action for the critical UV tachyacoustic model. Let us write the sub-leading corrections to the Lagrangian (setting $M_P = 1$ for simplicity):

$$ S_\phi = \int d^4x \sqrt{-g} \left[ \frac{\sqrt{1 + B_0 \phi^2 (\partial \phi)^2}}{B_0 \phi^2} - 3 (\ln \phi) \frac{W(\phi)}{B_0^{3/2}} \right], $$

(64)

$$ \frac{B_0^{-3/2}}{\phi^{4} \phi^4 \ln \phi} \left\{ \dot{\phi} \phi \ln \phi + \dot{\phi}^2 \left[ 1 + 3 \ln \phi + (W(\phi) - W'(\phi) \phi \ln \phi) \phi \dot{\phi} \right] \right\} + \mathcal{O}(B_0^{-2}) = 0. $$

(65)

This equation is trivial at $\mathcal{O}(B_0^{-1})$, demonstrating the nature of the UV cuscuton limit which allows for arbitrary expansion (or field) history at this order. However, at $\mathcal{O}(B_0^{-3/2})$ we have dynamical field equations.

For $W(\phi)$ to be subdominant at early times, it should drop (or grow more slowly than $\ln^2 \phi$) at large $\phi$. If we assume a power-law asymptotic fall-off, i.e. $W(\phi) = W_0 \phi^{-n}$ with $n \geq 0$, Eq. (65) has a power-law asymptotic solution:

$$ \phi(t) = \left[ \frac{W_0}{(n-4)t} \right]^{\frac{1}{n-4}}. $$

(66)

where we have extracted the pre-factor $B_0^{-3/2}$ for $W(\phi)$, as subleading corrections are suppressed by powers of $B_0^{-1/2}$. Note that the kinetic term is fully fixed by the $EAdS_2 \times E_3$ symmetry in the no-gravity limit, and thus the subleading correction, $W(\phi)$, only appears in the potential. Now, combining Friedmann and homogenous field equations for this action, and expanding in powers of $B_0^{-1/2}$, we find:

$$ c_s \propto \phi \phi^4 \ln \phi \propto \phi^4 \ln t \propto \phi^4 (\ln t)^2 \propto \infty, $$

(67)

$$ \rho \propto H^2 \propto (\ln \phi)^2 \propto \left( \ln t^{-\frac{1}{n-4}} \right)^2 \propto \infty, $$

(68)

as $t \to 0$, implies $n > 6$.

Finally,

$$ \epsilon \equiv -\frac{\dot{H}}{H^2} \propto \frac{1}{t^2 \ln t^2} \propto \infty, \text{ as } t \to 0. $$

(69)

$Q.E.D.$
