ABSTRACT
We analyse the distribution and origin of OVI in the Circumgalactic Medium (CGM) of dark-matter haloes of $\sim 10^{12} \, M_\odot$ at $z \sim 1$ in the VELA cosmological zoom-in simulations. We find that the OVI in the inflowing cold streams is primarily photoionized, while in the bulk volume it is primarily collisionally ionized. The photoionized component dominates the observed column density at large impact parameters ($\gtrsim 0.3R_{\text{vir}}$), while the collisionally ionized component dominates closer in. We find that most of the collisional OVI, by mass, resides in the relatively thin boundaries of the photoionized streams. We discuss how the results are in agreement with analytic predictions of stream and boundary properties, and their compatibility with observations. This allows us to predict the profiles of OVI and other ions in future CGM observations and provides a toy model for interpreting them.

Key words: Circumgalactic Medium – photoionization equilibrium – cosmological simulation

1 INTRODUCTION
The analysis of the Circumgalactic Medium (CGM), the gas that resides outside galactic discs but still within or near its virial radius, has the potential of giving us valuable information about the past history of galaxy formation and also some hints of its future evolution (e.g. Tumlinson et al. 2017). The importance of studying the CGM in order to characterize the history of galaxy formation is clear: it has been shown conclusively that galaxies alone contain significantly fewer baryons than would be expected from the standard $\Lambda$CDM cosmology (the ‘missing baryon problem’). While a significant fraction of these baryons may have been ejected to the Intergalactic Medium (IGM) in the early stages of galaxy formation (Aguirre et al. 2001), or remained as warm-hot low-metallicity intergalactic gas throughout cosmic time (Shull et al. 2012), studies suggest that 10-100 percent of the cosmic baryon budget of the universe exists in the metal-rich CGM of galactic halos (Werk et al. 2014; Bordoloi et al. 2014). The CGM is thus certainly significant and possibly even dominant in baryonic matter. Further, by calculations of the total amount of metals produced in all stars, only about 20-25 percent remain in the stars, ISM gas, and dust (Peeples et al. 2014). Recent studies have been consistent with the idea that most of metals produced within stars and released by supernovae feedback or stellar winds reside in the metal-rich CGM (Tumlinson et al. 2011; Werk et al. 2013). The mechanisms collectively known as ‘feedback’ by which metals, mass, and energy are transported to the CGM, are not yet completely understood, and...
likely include contributions from several processes like stellar winds, supernova feedback, and interaction with winds from the central AGN. The interactions between these feedback mechanisms and their relative contributions, and their dependence on halo mass and redshift might be better constrained by studies of the kinematics and temperatures of the ions within the CGM.

The CGM properties are also relevant when studying the future evolution of galaxies. Current models of the $z \gtrsim 1$ CGM state that cold, relatively lower-metallicity gas inflows from the IGM feed star formation of central galaxies through narrow streams (Keres et al. 2005; Dekel & Birnboim 2006; Dekel et al. 2009; Ocvirk et al. 2008). An overview of the topic is found in Fox & Dav{Ä}l (2017), and references therein. Outside those streams, metal-enriched warm-hot gas ($10^{5.5} \leq T \leq 10^{9.5}$ K) mainly produced by stellar feedback from the central galaxy, and by the virial shock under specific conditions (White & Rees 1978; Birnboim & Dekel 2003; Fielding et al. 2017; Stern et al. 2020a), fills the rest of the CGM volume. Although widely accepted by the community, these models still suffer from large uncertainties due to the difficulty of observations and of comparing them with numerical simulations or analytic models. A more detailed review of this theoretical picture will also be presented in Section 5.1.

A useful parameter for the interpretation of existing and future data for those larger-scale phenomena is the ionization state of gas within the CGM, which as a rule is highly ionized (Werk et al. 2014). While the ionization level of the gas within the CGM can help to constrain the physical interpretation, analyzing the full volume of gas from a single or even several ion species is remarkably difficult (Tumlinson et al. 2017). This is because atoms can be ionized, in general, in two different ways. They can be photoionized (PI), meaning incoming photons from either the galaxy itself or the ultraviolet background light interact with an atom and strip it of electrons, or they can be collisionally ionized (CI), meaning thermalized interactions with nearby atoms will ‘knock off’ electrons, leaving the atoms in some distribution of ionization states (Osterbrock & Ferland 2006).

Broadly speaking, PI gas fractions are a function of density (as denser gas recombines more quickly, biasing gas towards lower ionization states) and CI gas fractions are a function of temperature (as hotter gas will have more kinetic energy per particle, biasing gas towards higher ionization states). Most studies tend to assume that only one of these mechanisms is in play at a time for a given patch of gas, with the rationalization that since denser gas tends also to be cooler, either mechanism will result in cold gas hosting low-ions (e.g. NII, MgII) and hot gas hosting high ions (e.g. NeVIII, MgX). Examples of assuming OVI is in PI-equilibrium include Stern et al. (2016) and assuming OVI is CI include Faerman et al. (2017). However, since OVI was detected in all star-forming galaxies in COS-Halos, such an assumption is very tenuous. In Roca-Fàbrega, S. et al. (2019) (hereafter RF19), it was found that in cosmological simulations of halos which reached roughly Milky-Way masses at $z \sim 1$, whether OVI is PI or CI depends strongly on redshift, mass, and position within the CGM, and ranged all the way from $\sim 100$ percent PI to $\sim 0$ percent PI over the course of their evolution. The main conclusions of RF19 were that OVI is more photoionized in the outer halo than the inner, and that galaxies transform from fully collisionally ionized to mostly photoionized at $z=2$, after which they diverge by mass, with larger galaxies becoming more collisionally ionized than smaller ones.

Recent detections of very high ionization states such as OVII and OVIII in nearby galaxies indicate that there is indeed a significant warm-hot component of the CGM, and it is a source of major controversy whether OVI should be considered to mostly be copartisan with that gas, whether it should be considered to be mostly cool and more closely connected to HI and low metal ion states, or whether both are relevant simultaneously. We will especially consider Stern et al. (2016) and Stern et al. (2018) (hereafter S16 and S18, respectively). In S16 a phenomenological model is proposed which explains the relations between low, intermediate, and high ionization states as a consequence of hierarchical PI densities, where smaller, denser spherical clouds containing low ions are embedded within larger, less dense clouds containing OVI. This model matched the observed absorption much better than an assumption of a single or small number of densities, and nearly as well as models with a separate gas phase for each ion, with many fewer parameters (see S16, Figure 6), S18, focusing especially on OVI, assumed this hierarchical density structure is global, with OVI residing in the outer halo and the low ions residing in the inner halo. They claimed that the majority of the OVI gas detected is located outside $\sim 0.6R_{200}$. This radial distance, which is defined as the approximate radius of the median OVI particle, is called $R_{OVI}$. In S18, both a ‘high-pressure’ (CI) and a ‘low-pressure’ (PI) scenario are presented which are consistent with the data. However, the PI scenario more naturally explains the observed $N_{HI}/N_{OVI}$ values of 1–3 seen at large impact parameters, and also alleviates the large energy input in the outer halo required by the CI scenario (see also Mathews & Prochaska 2017 and McQuinn & Werk 2018). It has also been suggested that the CGM might have both phases present at the same time in different regions, most recently in Wu et al. (2020).

Due to the low emission measure of the CGM, it is necessary to do most observations through absorption spectra. With the relatively low number of luminous background sources from which to observe CGM absorption lines, for many years only a few data points were available from each survey, from either quasar spectra (e.g. Rupke et al. 2005) or using background galaxies as sources (Steidel et al. 2010). In recent years with the release of the COS-Halos data from Hubble Space Telescope (Werk et al. 2013, 2014; Tumlinson et al. 2011; Prochaska et al. 2013), there has been an explosion of absorption line studies. This analysis can be used to detect relatively small column densities for different ions, including metal lines, giving insight into the temperature, density, and metallicity information of the gas. However, there are important limitations to this type of analysis. First and foremost, absorption-line studies require a relatively rare alignment between the background source and the foreground galaxy, and there are only a few examples where several lines pass through the same CGM in different places (Lehner et al. 2015) or strong gravitational lensing allows the same source to be seen in multiple locations throughout the CGM (Okoshi et al. 2019). This means many assumptions must be made in order to combine together the data even within an individual survey, such as assuming relatively sim-
ilar conditions of the CGM in all L\textsubscript{\textast}} galaxies, and that the CGM is spherically symmetric (or at least isotropic). The use and results of those assumptions are examined in (Werk et al. 2014; Mathews & Prochaska 2017; S16). Finally, the lack of visual imaging makes it very difficult to constrain the position of the detected gas along the line of sight, and it may well be at any distance greater than the impact parameter, or gas from different ions may even be in completely separate clouds.

Numerical simulations are thus playing an important role as tools for testing recent theoretical approaches that try to characterize the CGM properties and evolution (e.g. Shen et al. 2013; Faerman et al. 2017; Stern et al. 2018; Nelson et al. 2018; Roca-Fàbrega, S. et al. 2019; Stern et al. 2019, 2020a). Hydrodynamic simulations are commonly used to supplement analytical models regarding the CGM, as they can break the degeneracy between CI and PI gas. While most cosmological simulations have difficulty resolving the CGM due to the Lagrangian nature of the adaptive resolution, where the spatial resolution becomes very poor in the low density CGM/IGM (e.g. Nelson et al. 2016), several recent groups have implemented novel methods to significantly enhance the resolution in the CGM, obtaining results similar to COS-Halos and other observations (Hummels et al. 2019; Peeples et al. 2019; Suresh et al. 2019; van de Voort et al. 2019; Mandelker et al. 2019b; Corlies et al. 2020). In a broad sense, the CGM remains a useful testing ground for these simulations, as the ionization state of the gas will depend sensitively on the feedback mechanisms incorporated into the code. Several other hydrodynamic simulations have begun analyzing the OVI population in the CGM as well, including Suresh et al. (2017) and Corlies & Schiminovich (2016), generally finding that this ion exists in a multiphase medium, and replicating the bimodality between high column densities in star-forming galaxies and low column densities in quenched galaxies, first seen in Tumlinson et al. (2011).

In this work we analyse galaxies from the VELA simulation suite (Ceverino et al. 2014; Zolotov et al. 2015). These simulations are compared with observations in a number of papers (e.g. Ceverino et al. 2015; Tacchella et al. 2016a,b; Tomassetti et al. 2016; Mandelker et al. 2017; Huertas-Company et al. 2018; Dekel et al. 2020a,b), showing that many features of galaxy evolution traced by these simulations agree with observations, although the VELA simulated galaxies form stars somewhat earlier than observed galaxies. Using these simulations, we develop a model in which CGM gas is characterized by its relation to the aforementioned ‘cold accretion streams’, giving OVI a unique role where PI OVI gas acts as an indicator of these inflows. Much of the CI OVI gas turns out to lie in an interface layer between these inflowing cold streams and the bulk of the CGM.

This paper is organized as follows. In Section 2 we describe the simulation suite and our analysis methods. In Section 3 we explain how we robustly differentiate CI and PI gas for a variety of ions. Focusing on OVI, we analyse in Section 4 what this distinction shows us about the CGM and its structure. This is analyzed in 3D space in Section 4.1, in projections and sightlines in Section 4.2, and its dependence on redshift and galaxy mass in Section 4.3. In Section 4.4 we compare the implications of this model to the findings in S16 and S18. In Section 5 we present a physical model for the origin and properties of the different OVI phases in the CGM, relating these to cold streams interacting with the hot CGM. This is the first discussion of shear layer width around radiatively-cooling cold streams in galaxy halos. In Section 5.1 we summarize our current theoretical understanding of the evolution of cold streams in the CGM of massive high-z galaxies, as the streams interact with the ambient hot gaseous halo. In Section 5.2 we examine the properties of the different CGM phases identified in our simulations, in light of this theoretical framework. Finally, in Section 5.3 we use these insights to model the distribution of OVI and other ions in the CGM of massive z ∼ 1 galaxies. Our summary and conclusions are presented in Section 6.

2 DATA AND ANALYSIS TOOLS

2.1 VELA

The set of VELA simulations we used is a subsample of 6 galaxies from the full VELA suite (see Table 1 for details about the galaxies chosen). The entire VELA suite contains 35 haloes with virial masses (M\textsubscript{\textast}}\textsuperscript{1})\textsuperscript{1} between 2×10\textsuperscript{11}M\textsubscript{\odot} and 2×10\textsuperscript{12}M\textsubscript{\odot} at z = 1. The VELA suite was created using the ART code (Kravtsov et al. 1997; Kravtsov 2003; Ceverino & Klypin 2009), which uses an adaptive mesh with best resolution between 17 and 35 physical pc at all times. In the CGM, the resolution is significantly worse than this maximum, as expected. However, most of the mass within the virial radius is actually found to be in cells of resolution better than 2 kpc, as shown in figure 1. This is within an order of magnitude of several high-resolution CGM simulations of recent years (Peeples et al. 2019; Hummels et al. 2019; Suresh et al. 2019; van de Voort et al. 2019; Bennett & Sijacki 2020), although unlike VELA, those simulations required these high resolutions throughout the CGM. This gives the VELA simulations enough resolution for discussions of the CGM to be physically meaningful, at least with respect to higher ions such as OVI which should be less dependent on resolution effects than low ions which originate from small clouds. As we will see, the results agree qualitatively with current models. Besides gravity and hydrodynamics processes, subgrid models incorporate metal and molecular cooling, star formation, and supernova feedback (Ceverino & Klypin 2009; Ceverino et al. 2010, 2014). Star formation occurs only in cold, dense gas (n\textsubscript{H} > 1 cm\textsuperscript{-3} and T<10\textsuperscript{4} K). In addition to thermal-energy supernova feedback the simulations incorporate radiative feedback from stars, adding a non-thermal radiation pressure to the total gas pressure in regions where ionizing photons from massive stars are produced. Recently, the VELA simulations have been re-run with increased supernova feedback according to (Gentry et al. 2017), and this new feedback mechanism has led to improved stellar mass-halo mass relations as in Ceverino et al. (2020 in prep). We

\footnote{All virial quantities we show in this paper are taken from Mandelker et al. (2017) and correspondence with the authors. They are calculated according to the definition of virial radius from Bryan & Norman (1998). This gives some disagreement between the numbers listed here and in RF19, where the \textit{R}_{200} value was used instead. M\textsubscript{\ast}} only includes star particles within 10 kpc in order to ignore satellite galaxies within the halo.}
will compare the results of this paper to this newer version in future work. In the VELA simulations, the dark matter particles have masses of $8.3 \times 10^9 M_\odot$, while the average star particle has a mass of $10^3 M_\odot$. Further details about the VELA suite can be found in (Ceverino et al. 2014; Zolotov et al. 2015).

We chose to continue to use the same subsample of the VELA galaxies from RF19. In that work, they were chosen according to their virial masses and the final redshift the simulation reached. This means, we use all halos that have been simulated down to $z = 1$ which have a final mass greater than $10^{11.5} M_\odot$. This selection criteria derived from our desire to analyse the physical state of gas in galaxies near the ‘critical mass’ at which the volume-filling CGM phases show a transition from free-fall to pressure-support (Goerdt et al. 2015; Zolotov et al. 2015; Fielding et al. 2017; Stern et al. 2020b).

\begin{table}
\begin{tabular}{lcccc}
\hline

Semi-transparent lines represent individual results from the other selected VELA galaxies.}
\end{figure}

2.2 Analytical approach and analysis tools

In our analysis of the CGM ionization state, we will study both the photoionization and the collisional ionization mechanisms. We will simplify the problem by assuming that photoionization depends only on the metagalactic background light from Haardt & Madau (2012), and not from other location-dependent sources such as the central galaxy. This assumption is motivated by the evidence that local sources have a major effect mostly on the ionization state of the gas in the inner CGM $0.1 - 0.3 R_{vir}$, while gas outside this region receives a negligible fraction of the ionizing radiation from the galaxy (Sternberg et al. 2002; Sanderbeck et al. 2018).

In the VELA simulations photoionization or collisional ionization is not directly simulated. Two kinds of metallicity are explicitly recorded: metallicity from SNIa (iron peak elements) and SNII (alpha elements). In order to analyse the ionization fraction of different ions we will follow a similar approach as the one in RF19. First we will get the total mass and density of the different species (e.g. $n_{O}$, $n_{C}$) by multiplying total SNIa or SNII metal mass by their respective abundances. It is important to mention that although in RF19 we made the assumption that the Type II metals are entirely oxygen, and that Type Ia metals had no oxygen component, here we have relaxed this assumption by using a distribution of metals according to (Iwamoto et al. 1999). However, as nearly 90 percent of all Type II supernovae ejecta is oxygen by mass, the effect of this change was minimal. The second step was to use the CLOUDY software (Ferland et al. 1998, 2013) to assign the corresponding ionization fraction to each ion species, based on the gas temperature, density, and on the redshift. Finally, to access the total population of any ion species, we need to multiply this fraction (e.g. $f(O\text{VI})$) by the total amount of the individual nuclei of that species (e.g. $n_{O}$), that is $n_{O\text{VI}} = f(O\text{VI}) \cdot n_{O}$. This procedure was implemented in the simulation analysis package TRIDENT (Hummels et al. 2016), which is itself based in the more general $yt$ (Tork et al. 2011) simulation analysis suite. To add these ion number densities in post-processing requires an assumption of local ionization equilibrium within each cell at each timestep. Note that this does not imply that we assume the gas to be in thermal or dynamical equilibrium. The gas can still be experiencing net cooling, or net heating due to feedback processes from the central galaxy.

In order to emulate the absorption-line studies for direct comparison to observations, we create a large number of sightlines ($\sim 400$) through each CGM. The sightlines are defined via a startpoint and a midpoint. To choose the startpoint, we define a sphere at some maximum radius, outside of the simulation’s ‘zoom-in region’ (extending to $\sim 2R_{vir}$ from the center). This is for geometrical effect, and to make sure that no significant difference in path length appears between sightlines. It was confirmed by comparing results with all low-resolution ($>15$ kpc) cells removed and with them included that in no simulation did the gas outside the fiducial region have a significant impact on any results. We define this maximum radius $R$ to be at $6 R_{vir}$. We randomly choose one of a finite set of polar angles $\theta$ and a finite set of azimuthal angles $\phi$ according to a probability distribution scheme which distributes the startpoint uniformly across the surface of this sphere. The vector from the galaxy center to the startpoint is defined as normal to an ‘impact parameter’ plane. A midpoint is then selected from the plane at one of a discrete number of impact parameters, according to a probability distribution which gives a uniform point in the circle $r \leq 2 R_{vir}$. A slight bias is introduced to give $r = 0$ a non-zero chance of selection. However, this has a negligible effect on any results, and only affects our column densities for the few lines that go directly through the galaxy. This

MNURAS 000, 1–22 (2020)
line is extended past the midpoint by a factor of 2. A visualization of a sightline generated by this algorithm is shown in Figure 2.

This strategy is useful for several purposes. First, by choosing a finite set of sightlines, we can use the same statistical analysis methodology as used in observational studies. In particular, in Section 4.4, we can emulate the inverse-Abel transformation used in S18. Second, we save a significant amount of information within each sightline, allowing us to track correlations between ions within sightlines, and the state of gas within the sightlines (see Section 3), instead of losing it in continual averaging. We note especially that most studies of this kind average over impact parameters, denoted as white dots, and projected to twice that length. This is plotted over a projection of total gas density within the simulation, on the same snapshots and at the same angle as Figure 8.

3 COLLISIONAL AND PHOTO IONIZATION

In this section we present a physically motivated definition of ‘Collisionally Ionized’ and ‘Photoionized’ gas as distinct states which coexist throughout the CGM. We do this both specifically for OVI, as well as for all other ion species. We will refer to these states hereafter as CI and PI, respectively. We will also refer often to the following temperature states, which coexist throughout the CGM. We do this both specifically for OVI, as well as for all other ion species. We will refer to these states hereafter as CI and PI, respectively. We will also refer often to the following temperature states, which coexist throughout the CGM. We do this both specifically for OVI, as well as for all other ion species. We will refer to these states hereafter as CI and PI, respectively.

- Cold gas: $T < 10^{3.8}$K
- Cool gas: $10^{3.8}$K $< T < 10^{4.5}$K
- Warm-hot gas: $10^{4.5}$K $< T < 10^{6.3}$K
- Hot gas: $T > 10^{6.3}$K

In S18, the two states (CI and PI) were defined by the two peaks in the OVI fraction in temperature-density phase space, and a line was drawn to separate the two. This defined these as mutually exclusive, and let those two states be meaningfully analysed separately. However it was not clear how to classify gas far from these peaks, where the OVI fraction is nonnegligible but clearly depends sensitively on both temperature and density. We will present a different definition here, which agrees qualitatively with that definition and the procedure in RF19, but has some differences. We can define these two states (CI and PI) graphically, using the data from CLOUDY at redshift 1, assuming a uniform Haardt & Madau (2012) ionizing background. At a given temperature, the distribution of ions for a single atomic species is a function of density. At sufficiently high density, for each ion the ionization fraction either decreases to 0, converges to a stable nonzero fraction, or (for the neutral atom at low temperatures) increases to 1. At sufficiently low density, ionization fractions drop to 0 for all ions except for ‘fully ionized’ states. See Figure 3 for examples of both behaviors. There are three ‘characteristic’ shapes to these graphs:

- ‘fully CI’: flat after some high density, falls directly to 0 without any significant increase at low density (see red line in Figure 3). Clearly photoionization affects this state at low density, but the critical element is that photoionization only destroys this state, and does not create it. So we will claim this ion’s creation is density-independent, and therefore only depends on temperature, or in other words, is CI.
- ‘fully PI’: Does not stabilize at high density, but rather decays to 0 after reaching a maximum at some intermediate density (see grey line in Figure 3). Since the ionization fraction is always a strong function of density, this gas is PI.
- ‘transition’: Stabilizes at high density, but also contains a maximum which is higher than that stable fraction (see green and pink lines in Figure 3). We will define a transition point to be the density at which the ion fraction is exactly twice the stable CI fraction, and if the maximum is not this high, the ion is considered ‘fully CI’ because while there is a non negligible PI fraction, it is never dominant (see purple line in Figure 3).
So, for each temperature, each ion can be characterized as PI, CI, or it may have a transition point. Iterating over all temperatures from $T = 10^{5.5}$ K to $T = 10^{7.5}$ K in steps of 0.1 dex, we found that each species starts out as PI at low temperatures, has transition points for several consecutive increasing $T$ increments, each time decreasing the transition density $n$, and then becomes fully CI at sufficiently high temperatures. In Figure 4, we plot the transitions in $T−n$ space. Considering the above discussion, we extend the lines on the right to log $n = +\infty$ from the lowest-temperature transition, and on the left to log $n = -\infty$ from the highest-temperature transition. The two transition points from figure 3 are marked again with stars in figure 4. Note that in general ion species do not have the same number of transition points, and in fact OII (orange line in Figure 4) has none. This means it is ‘fully PI’ below T=10$^{4.2}$ K and ‘fully CI’ above. We speculate that with a higher resolution in $T$ space, a narrow temperature range around 10$^{4.2}$ K would be found where transition points exist for OII. It is also true that there are regions of $n−T$ space in which an ion will be classified as PI or CI by this definition even though that ion will have a fraction of approximately zero there. This naturally will have no effect on the distribution of the ion into the two states, as insignificant regions of the graph will have negligible contributions. We see that in this graph, low ions, which are from CI to PI, in or near cool gas, mid-range ions have transitions in the middle range of warm-hot gas, and high ions are CI only in hot gas and PI in warm-hot gas. We note that this implies that whether an ion should be considered ‘generally’ CI or PI throughout the CGM is a more complicated story than usually assumed in the literature. For example, it is accurate to say that low ions (MgII, SiIII, OII etc) only exist in cool or cold gas, but for them the CI-PI cutoff is also located within cool gas, so it would be inaccurate to say that those low-ion states are necessarily photoionized (see OII, orange, in Figure 4). A similar statement would be true about OVII and OVIII: they certainly can only exist within warm-hot/hot gas, but this does not imply they are entirely collisionally ionized. We can visualize the results of these definitions using a binary field in $yt$. We define a field $C_{LOVI}$ to be 1 if OVI is CI-dominated in that specific cell, 0 otherwise, and $PI_{LOVI}$ to be the opposite. Multiplying this field by the actual OVI density allows us to differentiate the two populations of OVI, and similar methods can be applied to other ions.

4 DISTRIBUTIONS OF PI AND CI OVI GAS

We now analyse the actual spatial distribution of OVI within the CGM of the VELA simulations. Unless otherwise noted, we will refer to the gas outside 0.1 $R_{vir}$ and within $R_{vir}$ as the CGM, though in fact, recent studies (Wilde et al. 2020) have shown that $R_{vir}$ is not really a ‘physical’ boundary to the CGM and probably underestimates the dynamical conditions of the CGM. However considering our decreased resolution outside the virial radius (Figure 1) and the fact many analytic models use $R_{vir}$ as a starting point (see below, Section 5.1), we will continue to use this definition. We focus

2 A full table for all ions mentioned in this paper, at redshifts from 1 to 4, is available online.

3 Images of all of the VELA galaxies at a variety of angles, as they would appear using HST, JWST, or other instruments, are available at https://archive.stsci.edu/prepds/vela/
so due to minor fluctuations moving them outside the plane of the slice. They are part of the same counterclockwise-spiraling dense streams visible in the projection of Figure 2. Overplotting the in-plane velocity, we see that within the hot gas are fast outflows with velocities $\sim 1000$ km s$^{-1}$. On this scale, the inflowing speed of the cool gas is not visible. As noted in RF19, the metallicity of these streams is substantially lower than the surrounding hot gas. However, the increased density in these regions more than makes up for their lower metallicity, so we expect them to be detectable in metals. In fact they are essentially traced out by OVI (see below). Finally, we see in the bottom right panel (Figure 5d) that none of these structures are reflected in the pressure diagram, and in fact pressure is almost spherically symmetric, with a maximum in the central galaxy. So, ‘overall’ the cool inflows are in approximate pressure equilibrium with the rest of the galaxy. However strong pressure variations are observed in locations with strong inflowing velocity. The correlation between pressure fluctuations and inflowing streams in these simulations should be taken as an object for further study in the future.

Focusing on OVI within the same slice, Figure 6a and 6b show the separation of the slice into PI cells (left) and CI cells (right) according to the definition in Section 3 (see green line in Figure 4). Since they are defined to be mutually exclusive, the filled cells in the left panel appear as
Figure 6. OVI properties within the same 2D slice of VELA07 shown in Figure 5. (a): OVI number density for only gas defined as PI. Overplotted is gas velocity within the cell, with respect to the galaxy center. Only cells which are classified as PI have their velocities shown here. The scale of the arrows in this graph is smaller than in Figure 5b. (b): OVI number density, for gas defined as CI. The two populations are defined to be mutually exclusive. (c): OVI number density restricted only to the interface and to within 0.1 - 1.0 \( R_{\text{vir}} \), where the interface is defined as CI cells within 2 kpc of a PI cloud. (d): ion fraction (fraction of oxygen nuclei ionized to OVI).

white space in the right panel, and vice versa. We see from this that CI gas fills the majority of the volume of this slice (more quantitative results, which do not depend on the specific snapshot and slice orientation, can be found in Table 2) and PI gas is found only inside the cool inflows. This follows from the temperature distribution since, as expected from Section 3 the PI-CI cutoff is nearly equivalent to a temperature cutoff. Also marked in the left plot is the velocity of the PI cells within the slice. Since the OVI ions are added to the simulation in post-processing, the velocity is the overall gas velocity in that region, not the separate velocity of only OVI. This shows that PI OVI clouds, and therefore also the streams shown in Figure 5 are generally inflowing and rotating, with a characteristic velocity of \( \sim 100 \) km s\(^{-1}\), significantly slower than the outflows. It is contained within filaments which become smaller in cross-section as they spiral towards the central galaxy.

Next we analyse the distribution of OVI by mass (instead of volume as in the previous paragraph) between the two states. It is clear from the top panels of Figure 6(a and b) that the OVI number density is higher in the PI clouds than in the CI bulk, but since the clouds fill only a small fraction of the CGM, it is not \textit{a priori} clear which phase would dominate in either sightlines or in the CGM overall. In RF19 it was found that this depended strongly on redshift and galaxy mass. All galaxies at high redshift were CI-dominated and become more PI-heavy with decreasing redshift, eventually diverging by mass, with larger galaxies approaching CI-domination again at low redshift, and smaller galaxies remaining PI-dominated to redshift 0. We find here (Ta-
ble 2, column 3) that the PI gas contains about 2/3 of the OVI mass, showing OVI is primarily found in the CGM in cooler, lower-metallicity gas, but that a nonnegligible fraction remains CI.

Before we can address which phase will dominate within sightlines, there is one other important feature of Figure 6. While the number density of the CI bulk is significantly lower than the PI clouds, within the CI slice (Figure 6b) there are small regions of high number density. These are present only along the edges of the PI clouds themselves. To get a more quantitative understanding of this ‘interface layer’, we used a KDTree algorithm to query each CI gas cell within 0.1–1.0 \( R_{\text{vir}} \) as to its nearest PI neighbor. We define the interface (for now, through see Section 5 for more details) as CI cells which had any PI neighbor within 2 kpc. In the bottom left panel, (Figure 6c) we show only the interface cells as defined above. These cells consist of \(~\sim\) 92 percent of the CI OVI mass within the virial radius, while occupying only \(~\sim\) 3.3 percent of the CI volume. Therefore, in addition to dividing the CGM into CI and PI components, we believe it is useful to further divide the CI gas into two phases: interface and bulk. An interface layer like the one shown in Figure 6 is often found surrounding cold dense gas flowing through a hot and diffuse medium (Gronke & Oh 2018, 2020; Ji et al. 2019; Li et al. 2019; Mandelker et al. 2020a; Fielding et al. 2020). In Section 5 we will present a model for the physical origin and properties of the interface layers found in our simulations.

The fraction of gas in each phase, calculated using both a 2 kpc and a 1 kpc boundary, is shown in Table 2. A complicating factor, which is outside the scope of this paper to address, is that within these boundary layers, gas is unlikely to be in ionization equilibrium (Begelman & Fabian 1990; Slavin et al. 1993; Kwak & Shelton 2010; Kwak et al. 2011; Oppenheimer et al. 2016) and so it is possible that the mass distribution of CI gas in the two phases will differ significantly from that presented here. In particular, it was found in Ji et al. (2019) that nonequilibrium ionization can increase the column densities of OVI by a factor of \(~\sim\) \((2 – 3)\) within turbulent interface layers.

In this simulation, outflowing warm gas is generally too hot to have a significant OVI contribution, making the bulk of the volume CI but negligible in OVI outside the inner halo \(\sim (0.3 R_{\text{vir}})\). We are not claiming that the total gas density in these warm-hot outflows is extremely low, but only their OVI number density. This could be due to a low value of any of the contributing factors of ion fraction, density, or metallicity. We find in these simulations that it is primarily the ion fraction which causes this bulk volume to be negligible in OVI, compared to both the interface and the cool streams (see Section 5.3). Outflows will never have low metallicity, as the outflows are driven by supernova winds. Additionally, as seen in Figure 5, the high density and low metallicity inside the streams mostly cancel one another. However, both of those effects are much smaller than the the ion fraction dependence (Figure 6d).

The distribution of OVI into the three categories within \(0.1 – 1.0 R_{\text{vir}}\) for each VELA simulation, and the ‘stacked’ results (the sum of the total values from each category) are shown in Table 2. Here we see that in each simulation, photoionized OVI consists of \(~\sim\) (40 – 90) percent of all OVI by mass, with an average of approximately 62 percent, and the CI gas is mostly concentrated within the interface. This parallels the findings of RF19, where it was found that cool gas dominates the CGM by mass, and warm-hot gas dominates the CGM by volume. Taking PI and CI OVI to be analogues of ‘cool’ and ‘warm-hot’ gas respectively, we see that OVI has a similar distribution. An interface of 1 kpc contains about two-thirds of CI gas, while a 2 kpc interface contains almost 90 percent of CI gas. From a volume perspective, the CI bulk occupies the vast majority (\(~\sim\) 90 percent) of the CGM, and this does not change appreciably when we consider a 2 kpc boundary layer instead of a 1 kpc boundary. There are effects which both underestimate and overestimate the amount of gas in these interfaces. In the outer parts of the CGM, the resolution is in fact worse than 1-2 kpc, and so even cells adjacent to PI clouds might not register as interface cells, underestimating that value. On the other hand, in the inner part of the CGM the resolution is much better and the 1-2 kpc cutoff might include some gas which is not dynamically ‘boundary layer gas’ (see Section 5).

### 4.2 OVI Within Sightlines

While we see in Table 2 that by mass, the majority of all OVI within the CGM is PI, the projection of OVI through sightlines will distort the distribution, biasing the observed OVI gas towards the outer halo compared to the impact parameter. This is because the impact parameter of gas is the minimal distance of gas along the sightline, and all gas interacted with will be at that distance or farther. We saw in RF19 that, regardless of galaxy mass and redshift, the outer halo was generally more PI than the inner halo, so we should expect the average sightline to be more PI than the gas distribution itself. However, the small volume filling factor could conceivably lead to a majority of sightlines not hitting any PI gas whatsoever.

We tested this in two ways. First, we used the random sightline procedure defined in Section 2.2. In each sightline, the total OVI column density is recorded, in addition to the

![](image)

**Figure 7.** The projection profile of several hundred sightlines per galaxy, randomly generated as described in Section 2.2. This is then disambiguated into total PI and CI profiles, as solid, dashed, and dotted lines, respectively. Each individual galaxy, with the same distinctive line styles, are shown in colors. Errorbars represent the 16th and 84th percentiles, with the median value indicated by the dot.
fraction in the CI and PI states. The sightline can then be broken down into a ‘total OVI column density’, a ‘CI OVI column density’ and a ‘PI OVI column density’. In Figure 7, sightlines are collected by impact parameter from all six galaxies at \( z = 1 \) and at each impact parameter, the median column density for each category is calculated. They are shown in black along with the 16th and 84th percentiles as error bars, with the total OVI in solid lines, the PI OVI in dashed lines, and the CI OVI in dotted lines (a slight offset in \( x \) between the lines is included for visualization, but the data is aligned in impact parameter). The individual galaxy medians are also included in lighter colors in the background, with the same format\(^4\). Data points for OVI from Werk et al. (2013) are included for order-of-magnitude reference, but it is important to note that that data is not directly comparable to the values from the VELA simulations, as the COS-Halos data is from significantly lower redshift than \( z = 1 \), which is the lowest redshift reached by these simulations. So, while the median OVI column density is approximately 0.5 dex lower than the observations, the redshift difference means that this does not necessarily represent a disagreement between the observations and the VELA simulations.

The main result of this study was that the sightlines become dominated by PI gas at impact parameters outside \( \sim 0.15 \text{R}_{\text{vir}} \). While CI gas is significant inside this radius, it falls off quickly to undetectable levels in the outer halo. The CI gas predictions of \( 10^{12} - 13 \) roughly agree with the OVI columns of Ji et al. (2019), who also found that CI OVI is found primarily in an interface layer, though unlike them we find that PI OVI is also significant in sightlines. It is also significant that the PI column density is approximately constant out to high impact parameters, only falling by approximately a factor of 2 at \( r_1 = \text{R}_{\text{vir}} \), while CI column density falls by a factor of almost 1000 within the same distance.

However, it is possible that the median values do not accurately convey the distribution, which due to the low filling factor of PI gas, could be very nonuniform. We also created using \( \Psi \) a projection through the full simulation volume. In Figure 8, we show the CI fraction of the gas along projected sightlines. This projection has the same horizontal (\( y \)) and vertical (\( z \)) coordinates as Figure 6, and the black circles continue to indicate 0.1 and 1.0 \( \text{R}_{\text{vir}} \). However, each pixel in this cell is the integral of all slices along the line, and this has the effect of making each pixel a sightline orthogonal to the image. So, a blue pixel in this image is 100 percent PI, a red pixel is 100 percent CI, and intermediate values are indicated by the color bar. We added to this image a black masking image which sets all pixels with a total OVI column density less than \( 10^{13} \text{cm}^{-2} \) to black, representing nondetections. This limit was chosen according to the presence of several systems with \( 10^{13} < N_{\text{OVI}} < 10^{13.5} \) found in the CASBaH survey Prochaska et al. (2019). If we were to adopt a threshold of \( 10^{13.5} \), the picture would broadly stay the same, though slightly more of the picture would be blacked out.

We see broadly the same phenomena in this image. In the inner halo (up to about \( 0.2 \text{R}_{\text{vir}} \)), OVI is uniformly CI (red). Then, with a fairly small transitional \( r_1 \) band (white) it switches to being nearly 100 percent PI (blue). We can see that while the detectable gas is PI outside some minimal radius, the covering fraction of all sightlines (defined here as the fraction with \( N_{\text{OVI}} > 10^{13} \)) is not 100 percent. Over all six selected VELA galaxies, the covering fraction remains \( \sim 70 \text{ per cent} \) out to \( r_1 = \text{R}_{\text{vir}} \).

So the situation is fairly complex. The volume (at least in these relatively large galaxies which are still star-forming) is overwhelmingly dominated by PI gas, but the density of OVI within this ‘bulk’ region is so low that it contributes almost nothing to the sightline’s OVI column density. This is shown by the projection fraction (Figure 8) being PI-dominated everywhere outside \( 0.3 \text{R}_{\text{vir}} \) whenever the projection isn’t empty. Since we have established that a strong majority of CI gas is in fact an interface layer on PI clouds, this result is unsurprising. Wherever there is a significant amount of CI OVI, a PI gas cloud must be nearby. While these clouds may be small, their 3D nature makes them dominant over the essentially 2D surfaces of CI gas in the interface regions.

\(^4\) Colors for individual galaxies in Figure 7 are the same as in Figure 10.

| VELA  | edge width | OVI PI mass % | OVI CI edge mass % | OVI CI bulk mass % | OVI PI vol % | OVI CI edge vol % | OVI CI bulk vol % | CI edge mass % |

| V22   | 2 kpc      | 80             | 18                | 2                | 4            | 2               | 94               | 90            |
| V29   | 2 kpc      | 97             | 2                 | 1                | 23           | 4               | 77               | 66            |
| Stacked | 2 kpc    | 62             | 33                | 5                | 10           | 4               | 86               | 87            |

Table 2. Distribution of CGM gas (within \( 0.1 - 1.0 \text{R}_{\text{vir}} \)) within the selected VELA snapshots at redshift \( z = 1 \). Columns 3, 4, and 5 are the mass distribution of OVI into PI gas, CI edge gas, and CI bulk gas (so they should sum to 100 percent, ignoring truncation errors). Columns 6, 7, and 8 are the volume distribution into the same categories. Column 9 is the percentage of CI gas by mass within the edge. The same analysis is repeated with an assumption of a 1 kpc edge and a 2 kpc edge.
Figure 8. Fraction of gas within a projected sightline which is collisionally ionized. Each pixel represents a sightline in the x direction, orthogonal to the plane of the image. A blue pixel intersects with only PI gas, a red pixel intersects only CI gas. As in Figure 6, the circles represent $0.1R_{\text{vir}}$ and $R_{\text{vir}}$. All pixels which have a overall OVI column density $< 10^{13}$ cm$^{-2}$ are blacked out, since OVI column densities $< 10^{13}$ cm$^{-2}$ are not observable with COS Prochaska et al. (2019).

Sightlines which only pass through the CI bulk region, and not through the interfaces, are visible here as the blacked out nondetections. These two images imply that almost all of the OVI which would be observed in absorption spectra is PI.

It remains an open question whether the CI-dominated region in the inner halo (0.1-0.3$R_{\text{vir}}$) follows from the same interface structure, or if the character of the CGM in this region is substantially different. The inner halo was found to be highly irregular and different from the outer halo in cosmological simulations similar to VELA in Danovich et al. (2015). This could mean that in this part of the CGM specifically, the model of CI OVI as primarily a skin on PI clouds breaks down. It is also possible that in this inner halo region, the fixed size (1 or 2 kpc) of the interface might be larger than strictly necessary, and could sample gas which is not dynamically connected to the PI gas it happens to be near. Within this region, there is a lot of warm-hot, metal-rich gas outflowing due to stellar feedback, and its effects on the overall dynamics of the gas distribution in Table 2 are substantial. However since sightlines will preferentially sample the outer halo, this should not change our overall conclusions.

4.3 Halo mass and redshift dependence

Now we will compare how the effects shown in Figure 7 change with mass and redshift. In RF19 the mass and redshift dependence of the ionization mechanism of OVI in the CGM was as follows (see RF19, figure 14). All galaxies start out with their OVI population entirely CI-dominated. This is a function of three effects: First, the low ionizing background at high ($z > 2.5$) redshift, second, the fact that at high redshift, the cold inflows are almost metal-free, and third, at higher redshift the streams are denser and more self-shielded (Mandelker et al. 2018, 2020b). The galaxies then experience a decrease in their CI fraction with time as the ionizing background becomes more significant and streams become less dense. As galaxies approach redshift zero, their OVI ionization mechanisms diverge according to their mass. Low-mass galaxies end up completely PI at late times, while high mass galaxies become mostly CI again, following the formation of a virial shock which heats up most of the CGM.

We can see some of the same effects in the time-series sightline projections (Figure 9). In this figure we repeat the procedure of Figure 7, including showing the profile of the median sightline with error bars representing the 40th and 60th percentiles, except binning the galaxies into mass bins of 0.5 dex at specific snapshots instead of combining all sightlines together into a single ‘overall’ curve. The smaller errorbars here compared to Figure 7 are to avoid overlapping lines. All data points are offset slightly in $r_{\text{L}}$ so the error bars are visible, but should be read as vertically aligned in the apparent groups. The substantial bias of impact parameter profiles towards outer-CGM gas, as discussed in Section 4.2, means PI gas still dominates for most redshifts and masses. However, the trend from RF19 is evident in the form of the decreasing ‘transition impact parameter’ where PI gas becomes dominant. At $z = 3$, we see that only the smallest galaxies (blue line) have such a transition, and the larger galaxies (orange and green lines) remain CI-dominated out to $r_{\text{L}} = R_{\text{vir}}$. Moving on to redshift 2, we see that both of the available mass bins have roughly the same crossing point at $\sim 0.6R_{\text{vir}}$, and CI dominates inside that impact parameter, PI dominates outside. At low redshift ($z = 1$), we see that this transition from CI to PI-dominated sightlines happens at $\sim 0.2R_{\text{vir}}$ as shown before. It is also worth noting that the CI gas seems to drop much more dramatically with impact parameter at redshift 1, and generally the OVI column density drops below $10^{13.5}$ cm$^{-2}$ at the outer halo for the first time.

We see that there is not a significant mass dependence of either the CI or the PI gas. Unlike in RF19, at $z = 3$ they diverge mostly for sightlines which pass through the galaxy, and at $z=1$ and $z=2$ there is little change in column density with mass between the available bins.

In this set of simulations, we are not studying any galaxies which have a smaller virial mass than $M_{\text{vir}} = 10^{11}M_\odot$. As presented in RF19, these small galaxies will allow inflows to reach all the way to the disc, which means that this model would suggest they are all PI. Studying whether this is generally true in smaller galaxies will be the subject of future work.

4.4 Comparison with Observations

Using a phenomenological analysis of the COS-Halos data, S16 proposed that cool and relatively low density clouds produce the observed OVI columns of $\lesssim 10^{14.5}$ cm$^{-2}$ and a comparable amount of neutral hydrogen ($N_{\text{HI}}/N_{\text{OVII}} \sim 3$), while higher density clouds embedded in or at smaller scales than the OVI clouds produce low ions and larger HI columns. This density structure suggests that sightlines with $N_{\text{HI}} \lesssim 10^{15.5}$ cm$^{-2}$ intersect the OVI clouds but not the low-ion clouds, and hence $N_{\text{HI}}$ and $N_{\text{OVII}}$ should be correlated in these
Figure 9. Evolution of OVI column densities with redshift and mass. Mass bins indicated in legend are in units of log $M_\odot$. The left panel is a snapshot of all galaxies at redshift 3, the center panel is the same at redshift 2, and the right is the same at redshift 1. Errorbars represent ± 10 percentiles.

Figure 10. Comparison of the HI vs OVI column densities of all of the sightlines through the different VELA simulations. The black curve shows the theoretical prediction from the phenomenological model presented in S16, fitted to the COS-halos data (Werk et al. (2013), blue).

sightlines, while sightlines with $N_{\text{HI}} \gg 10^{15}$ cm$^{-2}$ intersect both the OVI clouds and the low-ion clouds, and hence $N_{\text{OVI}}$ should be independent of $N_{\text{HI}}$. In Figure 10 we show that sightlines through the VELA simulations follow the same pattern. This indicates that the 'global' version of the S16 model, where OVI and $N_{\text{HI}} \sim 10^{15}$ columns originate from the outer halo and low-ions and $N_{\text{HI}} \gg 10^{15}$ columns originate from the inner halo, replicates the behavior in VELA.

It should be noted that simulated HI distributions in the CGM are resolution-dependent (Hummels et al. 2019), and so it is possible that $N_{\text{HI}}$ is not converged. This however should only have an effect at the highest $N_{\text{HI}}$, where the HI-OVI curve shown in Figure 10 has already flattened out. Also, we find that $N_{\text{OVI}}$ in the VELA simulations is a factor of ~3 lower than in COS-Halos, potentially due to the higher redshift of $z \sim 1$ analyzed in VELA relative to $z \sim 0.2$ in COS-Halos.

We can also check whether the sightlines allow us to infer correctly the 3D distribution of OVI. S18 showed that the column densities observed from COS could, under an assumption of spherical symmetry, be used to extrapolate the total OVI mass in the CGM as a cumulative function of radius. Assuming that all galactic CGMs from COS-Halos were broadly similar, one can use an inverse-Abel transformation on the column densities of OVI to predict the total mass of OVI in the CGM as a cumulative function of radius. In S18, the purpose of this was to make the argument that the median OVI ion’s radius, or $R_{\text{OVI}}$, actually exists outside half of the virial radius, and so is more emblematic of the outer CGM than the inner part, even in sightlines with impact parameters less than $R_{\text{OVI}}$. This makes the assumption, however, that the CGM is spherically symmetric. In Figure 7, we showed the median OVI column densities for a set of mock sightlines within the simulation. We will assume those median results are spherical and then apply the same inverse-Abel transformation algorithm to them as in S18. This can be compared to the real distribution of OVI gas. We find in Figure 11 that the inverse-Abel transform indeed approximately recovers the actual mass of OVI within the virial radius to within ~20 per cent. An interesting distinction between the two curves is rather their shape. We find that the deprojected curve appears to be concave down, so it would be overrepresented in the inner CGM and under-represented in the outer CGM, while the real OVI gas distribution is approximately linear out to the virial radius. Its different concavity (compare Figure 11, with S18, Figure 1, top) leads to our placing the (deprojected) $R_{\text{OVI}}$ closer to the
inner CGM than the actual $R_{\text{OVI}}$. This suggests then that in S18 itself, it is likely that the prediction for $R_{\text{OVI}}$ was an underestimate, because their deprojection was indeed concave down and we have shown that a linear radial profile in real space will lead to a concave-down profile in deprojection space. This means that most of the OVI in real observed sightlines might be near the edge of the virial radius, and there may even be a significant component in the IGM, if the virial radius is taken to be the boundary of the CGM.

In addition, our results that OVI traces cool inflows, combined with the Tumlinson et al. (2011) result that OVI is absent around quenched galaxies (albeit at lower redshift), may be evidence that the feedback mechanism which quenches galaxies also directly affects the cool inflows. We plan to study this effect in future work, using simulations which reach lower redshifts and higher masses.

5 PHYSICAL INTERPRETATION OF THE INTERFACE LAYER

There is existing literature regarding how the structure of galaxy formation is strongly regulated by inflows from the cosmic web into the galaxy through the CGM (e.g. Keres et al. 2005; Dekel & Birnboim 2006; Dekel et al. 2009; Fox & Dav{Á}l 2017, and references therein). We suggest that the metal distribution of the CGM might be governed by the same structures, and propose a three-phase model for future observers to fit absorption spectrum data to. A cartoon picture is shown in Figure 12. There are three regions of the CGM: the inside of the cool-inflow cones (hereafter the cold component, or cold streams), the outside (hereafter the hot component, or hot CGM), and the interface between these two components. The interaction between the inflowing cold streams and the ambient hot CGM induces Kelvin-Helmholtz instabilities (KHI) and thermal instabilities at the interface, causing hot gas to become entrained in the flow through a strongly cooling turbulent mixing layer of intermediate densities and temperatures (Mandelker et al. 2020a, hereafter M20a). We posit that the CI interface layer we find in our simulations represents precisely such a mixing layer. The general properties of radiatively cooling interface layers induced by shear flows were studied in Ji et al. (2019) and Fielding et al. (2020). The conditions of the cold streams and hot CGM, which set the boundary conditions for the interface region, as a function of halo mass, redshift, and position within the halo were studied in Mandelker et al. (2020b) (hereafter M20b), based on M20a. In this section, we combine the insights of these studies to explain the physical origin and the properties of the multiphase structure seen in our simulations. We begin in Section 5.1 by summarizing our current theoretical understanding of the evolution of cold streams in the CGM of massive high-$z$ galaxies, as they interact with the ambient hot gaseous halo. In Section 5.2 we examine the properties of the different CGM phases identified in our simulations, in light of this theoretical framework. Finally, in Section 5.3 we use these insights to model the distribution of OVI and other ions in the CGM of massive $z \sim 1$ galaxies.

5.1 Theoretical Framework

5.1.1 KHI in Radiatively Cooling Streams

Using analytical models and high-resolution idealized simulations, these have focused on pure hydrodynamics in the linear regime (Mandelker et al. 2016) and the non-linear regime in two dimensions (Padnos et al. 2018; Vossberg et al. 2019) and three dimensions (Mandelker et al. 2019a). Others have incorporated self-gravity (Aung et al. 2019), idealized MHD (Berkok & Pfrommer 2019), radiative cooling (M20a), and the gravitational potential of the host dark matter halo (M20b). We begin by summarizing the main findings of M20a regarding KHI in radiatively cooling streams. There, we considered a cylindrical stream with radius $R_s$, density $\rho_s$, and temperature $T_s$, flowing with velocity $V_s$ through a static background ($V_b = 0$) with density $\rho_b$ and temperature $T_b$.

$\rho_s \text{(OVI)} = \rho_b \left( V_s / V_b \right) \left( T_s / T_b \right)^{\frac{1}{2}}$
The stream and the background are assumed to be in pressure equilibrium, so \( \chi \equiv \rho_s / \rho_b = T_b / T_s \), where we have neglected differences in the mean molecular weight in the stream and the background. The Mach number of the flow with respect to the sound speed \( c_b \) in the background is \( M_b \equiv V_s / c_b \).

The shear between the stream and the background induces KHI, which leads to a turbulent mixing region forming at the stream-background interface. The characteristic density and temperature in this region are (Begelman & Fabian 1990; Gronke & Oh 2018)

\[
\rho_{\text{mix}} \sim (\rho_b \rho_s)^{1/2} = \chi^{-1/2} \rho_s, \quad (1)
\]

\[
T_{\text{mix}} \sim (T_b T_s)^{1/2} = \chi^{1/2} T_s. \quad (2)
\]

In the absence of radiative cooling, the shear region engulfs the entire stream in a timescale

\[
t_{\text{shear}} = \frac{R_s}{\alpha V_s}. \quad (3)
\]

where \( \alpha \sim (0.05 - 0.1) \) is a dimensionless parameter that depends on the ratio of stream speed to the sum of sound speeds in the stream and background, \( M_{\text{crit}} \equiv V_s / (c_s + c_b) \) (Padnos et al. 2018; Mandelker et al. 2019a). When radiative cooling is considered, the non-linear evolution is determined by the ratio of \( t_{\text{shear}} \) to the cooling time in the mixing region,

\[
t_{\text{cool, mix}} = \frac{k_B T_{\text{mix}}}{(\gamma - 1) \rho_s N(T_{\text{mix}})}, \quad (4)
\]

with \( \gamma = 5/3 \) the adiabatic index of the gas, \( k_B \) Boltzmann’s constant, \( n_{\text{mix}} \) the particle number density in the mixing region, and \( N(T_{\text{mix}}) \) the cooling function evaluated at \( T_{\text{mix}} \). If \( t_{\text{shear}} < t_{\text{cool, mix}} \), then KHI proceeds similarly to the non-radiative case, shedding the stream on a timescale of \( t_{\text{shear}} \) (Mandelker et al. 2019a). However, if \( t_{\text{cool, mix}} < t_{\text{shear}} \), hot gas in the mixing region cools, condenses, and becomes entrained in the stream (M20a). In this case, KHI does not destroy the stream. Rather, it remains cold, dense and collimated until it reaches the central galaxy. Similar behaviour is found in studies of spherical clouds (Gronke & Oh 2018, 2020; Li et al. 2020), and planar shear layers (Ji et al. 2019; Fielding et al. 2020).

Streams with \( t_{\text{cool, mix}} < t_{\text{shear}} \) grow in mass by entraining gas from the hot CGM as they travel towards the central galaxy. The stream mass-per-unit-length (hereafter line-mass) as a function of time is well approximated by (M20a)

\[
m(t) = m_0 \left( 1 + \frac{t}{t_{\text{ent}}} \right), \quad (5)
\]

where \( m_0 = \pi R_s^2 \rho_b \) is the initial stream line-mass, and the entrainment timescale is

\[
t_{\text{ent}} = \frac{\chi}{2} \left( \frac{t_{\text{cool}}}{t_{\text{sc}}} \right)^{1/4} t_{\text{sc}}, \quad (6)
\]

with \( t_{\text{sc}} = 2 R_s / c_s \) the stream sound crossing time, and \( t_{\text{cool}} \) the minimal cooling time of material in the mixing layer, which in practice has a distribution of densities and temperatures rather than being a single phase described by eqs. (1)-(2). If the stream is initially in thermal equilibrium with the UV background, the minimal cooling time occurs approximately at \( T = 1.5 T_\odot \), but any temperature in the range \( 0.1 - 2 T_\odot \) works equally well (M20a). The density is given by assuming pressure equilibrium. This mass entrainment causes the stream to decelerate, due to momentum conservation. A large fraction of the kinetic and thermal energy dissipated by the stream-CGM interaction is emitted in Lyα, which may explain the extended Lyα blobs observed around massive high-z galaxies (Goerdt et al. 2010, M20b).

### 5.1.2 Stream Evolution in Dark Matter Halos

In order to address the evolution of streams in dark matter halos, M20b, following earlier attempts (Dekel & Birnboim 2006; Dekel et al. 2009), developed an analytical model for the properties of streams as a function of halo mass and redshift. We here focus on \( 0.1 \lesssim \chi \lesssim 1 \) (Table 1), and refer readers to M20b for more general expressions. Near the halo edge, at \( R_{\text{vir}} \), the streams are assumed to be in approximate thermal equilibrium with the UV background, yielding temperatures of \( T_{\text{cool}} \sim 2 \times 10^4 \text{K} \). The temperature in the hot CGM is assumed to be of order the virial temperature,

\[
T_{\text{hot}} \sim T_{\text{vir}} \approx 10^6 \text{ K} M_{12}^{2/3} (1 + z)^{1/2}, \quad (7)
\]

with \( M_{12} = M_{\text{vir}} / 10^{12} M_\odot \) and \( (1 + z)_2 = (1 + z)/2 \). The stream and the hot CGM are assumed to be in approximate hydrostatic equilibrium. Accounting for order-unity uncertainties in the above quantities, the density contrast between the stream and the hot CGM is predicted to be in the range \( \chi \sim 20 - 200 \), with a typical value of \( \sim 70 \).

The density of the hot gas is constrained by the dark matter halo density in the halo outskirts, the Universal baryon fraction, and the fraction of baryonic matter in the hot CGM component, which has constraints from observations and cosmological simulations. Together with the \( \chi \) values quoted above, this gives the density in streams as they enter \( R_{\text{vir}} \). This is predicted to be \( n_b \sim (3 \times 10^{-4} - 0.01) \text{ cm}^{-3} \), with a typical value of \( 10^{-2} \text{ cm}^{-3} \).

In M20b, the stream is assumed to enter the halo on a radial orbit, with a velocity comparable to the virial velocity,

\[
V_{\text{vir}} \approx 163 \text{ km s}^{-1} M_{12}^{1/3} (1 + z_2^{1/2}). \quad (8)
\]

The mass flux entering the halo along the stream is given by the total baryonic mass flux entering the halo, and the fraction of this mass flux found along streams, where one dominant stream typically carries \( \sim \) half the inflow, while three streams carry \( \gtrsim 90\% \) (Danovich et al. 2012). The stream density, velocity, and mass flux can together be used to constrain the stream radius. This is predicted to be \( R_s / R_{\text{vir}} \sim (0.03 - 0.5) \), with a typical value of \( \sim 0.2 \), and where the virial radius is given by

\[
R_{\text{vir}} \approx 150 \text{ kpc} M_{12}^{1/3} (1 + z_2^{1/2}). \quad (9)
\]

Inserting the above constraints for the stream and hot CGM properties into eqs. (1)-(4) leads to the conclusion that \( t_{\text{cool, mix}} < t_{\text{shear}} \) in virtually all cases, even if the streams are nearly metal-free (M20b). Streams are thus expected to survive until they reach the central galaxy, and grow in mass along the way.
Within the halo, at $0.1 < r/R_{\text{vir}} < 1$, M20b assumed both the stream and the background to be isothermal, and to have a density profile described by a power law,

$$\rho \propto r^{-\beta},$$

with $x \equiv r/R_{\text{vir}}$ and $1 < \beta < 3$. The stream and halo thus maintain pressure equilibrium at each halocentric radius, with a constant density contrast. The stream is assumed to be flowing towards the halo centre, growing narrower along the way. The stream radius at halocentric radius $r$ is

$$a = R_h \left( \frac{m(r)}{m_0} \right)^{1/2} x^{\beta/2},$$

with $m(r)$ the stream line-mass at halocentric radius $r$, $m_0$ the line-mass at $R_{\text{vir}}$, and $R_h$ the stream radius at $R_{\text{vir}}$. In general, $m(r) > m_0$ due to the mass entrainment discussed above. However, in practice, the line mass of streams on radial orbits in $10^{12} M_\odot$ halos at $z \sim 1$ grows by only $\sim (5 - 40)$ percent by the time the stream reaches $0.1 R_{\text{vir}}$ (M20b). We can thus approximate $a \propto x^{\beta/2}$. In this case, it is straightforward to show that the cumulative volume occupied by the stream interior to a halocentric radius $r$ is

$$\text{Vol}_a(r) = \frac{\pi R_{\text{vir}}^3}{\beta + 1} \left( \frac{R_h}{R_{\text{vir}}} \right)^2 \left( \frac{r}{R_{\text{vir}}} \right)^{\beta+1}.$$ (12)

M20b assumed that the mass entrainment rates derived by M20a (eqs. 5-6) could be applied locally at each halocentric radius. When doing so, they used the scaling $t_{\text{cool}} \propto n^{-1} \propto r^0$ and $t_{\text{sc}} \propto a \propto x^{\beta/2} \mu^{1/2}$, with $\mu \equiv m(r)/m_0$.

They then derived equations of motion for the stream within the halo, where the deceleration induced by mass entrainment counteracts the acceleration due to the halo potential well. These equations were solved simultaneously for the radial velocity and the line-mass of streams as a function of halocentric radius. For $10^{12} M_\odot$ halos at $z \sim 1$, the line-mass at $0.1 R_{\text{vir}}$ was found to be $\sim (5 - 40)$ percent larger than at $R_{\text{vir}}$, while the radial velocity was $\sim (75 - 98)$ percent of the free-fall velocity.

### 5.1.3 Turbulent Mixing Layer Thickness

Several recent studies have examined the detailed physics behind the growth of turbulent mixing layers and the flux of mass, momentum, and energy through them (Padnos et al. 2018; Ji et al. 2019; Fielding et al. 2020). Using idealized numerical simulations and analytical modeling, these works considered a simple planar shear layer between two semi-infinite domains, without (Padnos et al. 2018) and with (Ji et al. 2019; Fielding et al. 2020) radiative cooling. While this is different than the cylindrical geometry we have thus far considered, the physics of shear layer growth are expected to be similar in the two cases.

By equating the timescale for shear-driven turbulence to bring hot gas into the mixing layer with the minimal cooling time of gas in the mixing layer, Fielding et al. (2020) obtain an expression for the mixing layer thickness, $\delta$, (see their
They find that $V_{\text{peak}}$, the maximum velocity in each radial bin. Solid (dashed) lines represent outflowing (inflowing) gas. Right: Mass-per-unit-length (line-mass) within each state.

\begin{equation}
\frac{\delta}{R_0} = \left( \frac{t_{\text{cool}} V_{s}}{V_{\text{vir}}} \right)^{3/2} \left( \frac{V_{\text{urb}} V_{s}}{V_{\text{vir}}} \right)^{3/2} \chi^{3/4}.
\end{equation}

They find that $V_{\text{urb}} \sim (0.1 - 0.2)V_{s}$ independent of other parameters, such as the density contrast. A similar result was found for the turbulent velocities in mixing layers around cylindrical streams in the absence of radiative cooling (Mandelker et al. 2019a). In the context of the M20b model described above, if we assume that eq. (13) can be applied locally at every halocentric radius, this implies that $\delta/\alpha \propto (a^3 r/\mu)^{3/4}$, where $r = (V_{\text{urb}} V_{s})/V_{\text{vir}}$ is the stream velocity at radius $r$ normalized by its velocity at $R_{\text{vir}}$, squared. In practice, for $10^{12} M_\odot$ halos at $z \sim 1$, $\delta/\alpha \sim (0.01 - 0.1)$ throughout the halo. For $R_a \sim 0.25 R_{\text{vir}} \sim 40$ kpc, this implies $\delta \sim 0.4 - 4$ kpc near the outer halo, and slightly narrower towards the halo centre. This is comparable to our assumed values of $\delta \sim (1 - 2)$ kpc for defining the CI interface gas in the CGM of our simulations, and can serve as a post-facto justification of this ad-hoc choice.

The simulations of Ji et al. (2019) have different resolution, initial perturbation spectrum, and cooling curve than those of Fielding et al. (2020). They also explore a different range of parameter space, and differ in their analysis methods. All these lead them to propose a different expression for the mixing layer thickness, based on their simulations. The main difference in their modeling is that they assume that pressure fluctuations induced by rapid cooling are what drive the turbulence in the mixing region, rather than the shear velocity. They suggest the following expression for the interface thickness (see their equation 27)

\begin{equation}
\delta \sim 750 \text{pc} \left( \frac{\Lambda(T_{\text{mix}})}{10^{-22.3} \text{erg s}^{-1}} \frac{n_s}{3 \times 10^{-4} \text{cm}^{-3}} \frac{T_k}{3 \times 10^4 \text{K}} \right)^{-1/2},
\end{equation}

where we have normalized the cooling rate, density, and temperature by typical values found in our simulations (see Section 5.2). In the context of the M20b model described above, where the stream is isothermal with density and radius following eqs. (10)-(11), this implies $\delta/\alpha \propto \mu^{-1/2}$, which is nearly constant throughout the halo. This is comparable to our assumed interface thickness of $\sim (1 - 2)$ kpc in the outer halo, but predicts a narrower interface layer closer to the halo centre, where the stream becomes narrower as well.

Importantly, even if the mixing layer thickness itself is unresolved, the mass entrainment rate and the associated stream deceleration and energy dissipation, are found to be converged at relatively low spatial resolution of $\sim 30$ cells per stream diameter, which is the scale of the largest turbulent eddies (M20a; see also Ji et al. 2019; Gronke & Oh 2020; Fielding et al. 2020). This is comparable to what is achieved in the VELA simulations.

5.2 Comparison to Simulation Results

We now analyze the overall properties of the three identified states of gas in the VELA simulations. Each cell is assigned to one of the states (PI, CI-interface, or CI-bulk). PI gas is defined as in Section 3. The ‘interface CI’ gas cells are defined via the following two criteria (besides being CI), (1), they are within 2 kpc of a PI cell, as described in 4.1, and (2), they have an OVI number density above $10^{-13}$ cm$^{-3}$, to allow the interface to become smaller than 2 kpc as the
The relatively low value for the density in this case results from the fact that in this particular galaxy, the hot CGM contains only ~ 10 percent of the baryonic mass within $R_{\text{vir}}$, rather than towards the halo centre roughly as $r^{-2.3}$. This is much steeper than the density profile in the CI bulk, which scales as $r^{-1.5}$ outside of ~ $0.4R_{\text{vir}}$, and has an even shallower slope at smaller radii. The steeper increase of the PI gas density towards the halo centre compared to the CI bulk, allows the two phases to maintain approximate, though not perfect, pressure equilibrium throughout the halo despite the decrease (increase) in the temperature of PI (CI bulk) gas towards the halo centre (see also Figure 5d). At $R_{\text{vir}}$, the PI gas is ~ 85 times denser than the CI bulk, consistent with the predicted density contrast between cold streams and the hot CGM (M20b). The CI interface also maintains approximate pressure equilibrium with the PI gas and the CI bulk throughout the halo, with density and temperature values roughly the geometric mean between those two phases, as expected for turbulent mixing zones (eqs. 1-2).

The volume occupied by the PI gas interior to radius $r$ scales as $r^{2.54}$, in agreement with eq. (12) given the slope of the CI bulk density profile. Assuming that the total volume of the PI gas is composed of $n$ streams, we can infer the typical stream radius by equating the right-hand-side of eq. (12) with $V_0/n$, where $V_0 = 1.5 \times 10^6 \text{kpc}^3$ is the total volume of PI gas at $R_{\text{vir}}$ shown in Figure 13. The result is $R_{\text{PI}}/R_{\text{vir}} \sim 0.25$, 0.30, and 0.40 for $n = 3, 2$, and 1 respectively. Most massive high-$z$ galaxies are predicted to be fed by 3 streams (Dekel et al. 2009; Danovich et al. 2012), with a single ‘dominant’ stream containing most of the mass and volume. Visual inspection of VELA07 at $z = 1$ reveals that $n = 2$ is likely the best value (see Figure 2, and the top-right and bottom-right of Figure 5a). We also note that if the stream is not radial, but rather spirals around the central galaxy, as in Figure 2, the total stream volume will be larger than inferred from eq. (12), and this can also be included by an effective $n > 1$ for a single stream. Regardless, the inferred values of $R_{\text{PI}}/R_{\text{vir}}$ for $n = (1 - 3)$ are consistent with expectations (M20b).

These results for the temperature, density, and volume of the three CGM phases lead us to conclude that we can associate the PI gas with cold streams, the CI bulk gas with a background hot halo, and the CI interface gas with a turbulent mixing layer forming between the two as a result of KHI (M20a). While we have focused our discussion on VELA07, the other galaxies examined in this work exhibit very similar properties, and are all consistent with this association. We

### Table 3. Properties of the cold streams and the hot CGM at the halo virial radius, as inferred from our model, in the six VELA simulations examined in this work. From left to right we list the VELA index, the ratio of hot CGM temperature to the halo virial temperature, the density ratio between the cold stream and hot CGM, the volume density in the cold streams, the ratio of stream radius to halo virial radius assuming one stream in the halo, the average of stream radius to halo virial radius assuming three streams, the ratio of stream velocity to the halo virial velocity, the ratio of stream radial velocity to total velocity, the metallicity in the cold streams, and the metallicity in the hot CGM. The range of these parameters found in the simulations is consistent with the predictions of M20b.

| VELA | $T_{\text{hot}}/T_{\text{vir}}$ | $\rho_{\text{hot}}/\rho_{\text{vir}}$ | $n_\text{s}$ [$10^{14} \text{cm}^{-3}$] | $R_{\text{s}}/R_{\text{vir}}$ ($n_\text{s} = 1$) | $R_{\text{s}}/R_{\text{vir}}$ ($n_\text{s} = 3$) | $V_{\text{tot}}/V_{\text{vir}}$ | $V_{\text{rad}}/V_{\text{tot}}$ | $Z_{\text{PI}}/Z_{\odot}$ | $Z_{\text{hot}}/Z_{\odot}$ |

| average | 1.97          | 36             | 2.7            | 0.43           | 0.25           | 0.93           | 0.46           | 0.06           | 0.33           |
list their properties in Table 3, all of which are consistent with the predictions of M20b. To further solidify this point, we now examine the profiles of velocity and line-mass of the PI gas, and compare to predictions for the evolution of cold streams flowing through a hot CGM (M20b).

The left-hand panel of Figure 14 shows radial profiles of the total velocity magnitude for the three CGM components. The PI and CI interface gas both have velocities of $\sim V_{\text{vir}}$ at $R_{\text{vir}}$. While the velocity at $r > 0.5R_{\text{vir}}$ is nearly constant, their velocity at $0.1R_{\text{vir}}$ is $\sim 1.6V_{\text{vir}}$, slightly less than the free fall velocity at this radius, which is $\sim 2.5V_{\text{vir}}$ assuming an NFW halo with a concentration parameter of $c \sim 10$. The CI bulk has velocities of order $2V_{\text{vir}}$ at $R_{\text{vir}}$, and increases by a similar factor between $R_{\text{vir}}$ and $0.1R_{\text{vir}}$. These super-virial velocities are due to strong winds (see Figure 5b), and are consistent with the super virial temperatures in this component seen in Figure 13.

In the middle panel of Figure 14 we show profiles of the radial component of the velocity normalized to the total velocity at that radius, for the three CGM phases. The CI bulk gas is outflowing almost purely radially from $0.1R_{\text{vir}}$ to $R_{\text{vir}}$. The PI gas, on the other hand, is inflowing from $R_{\text{vir}}$ to $0.1R_{\text{vir}}$, but with a significant tangential component. This is consistent with models for angular momentum transport from the cosmic web to growing galactic disks via cold streams (Danovich et al. 2015). These tangential orbits can be inferred from Figure 2, where a stream can be seen spiralling in towards the central galaxy. Such orbits were not considered by M20b, who only considered purely radial orbits for the streams. We therefore cannot strictly apply the predictions of their model to the stream dynamics within the halo. However, we expect that the model should work reasonably well in the region $r > 0.5R_{\text{vir}}$, where the orbit is mostly along a straight line before the final inspiral begins. The magnitude of the radial component of the CI interface gas velocity is comparable to that of the PI gas. However, this component experiences both net inflow and outflow intermittently, likely depending on the orientation of the inflow stream with respect to the outflowing bulk gas.

In the right-hand panel of Figure 14 we show the line-mass (mass-per-unit-length) of the three CGM components as a function of halo-centric radius. The line-mass of the PI gas increases by $\sim (5 - 10)$ percent from $R_{\text{vir}}$ to $0.4R_{\text{vir}}$, comparable to the predictions from the model of M20b. It then proceeds to increase rapidly, growing by more than a factor of 5 during the inspiral phase at $r < 0.4R_{\text{vir}}$. We also note that at all radii, the line-mass of the CI interface gas is $\sim 5$ percent of the line-mass of the photo-ionized gas. This implies that the mass flux of hot gas being entrained in the stream is proportional to the stream mass, which is indeed predicted to be the case (eq. 5). This strengthens our association of the PI gas and CI-interface gas with cold streams and the turbulent mixing layers that surround them, respectively.

5.3 Suggested ‘Inflowing Streams’ Model for OVI

Since both substantial components of OVI (PI gas, and CI interface gas) are closely linked to the physical phenomenon of inflowing cold streams, as discussed above, we suggest that OVI absorption sightlines in the CGM, and possibly metal absorption spectra more broadly, should be modeled as a three-phase structure following Figure 12. There are three phases to the CGM: Inside of the cool-inflow cones, their interface, and the outside bulk region. While we do not expect the exact temperatures or densities from the VELA simulations to be followed in the real Universe, considering the still relatively unconstrained feedback mechanisms, the structure given here could be used with detections of a variety of ions in a survey such as COS-Halos or CASB-H (Burchett et al. 2019; Prochaska et al. 2019) to fit these physical properties. These streams, which narrow as they approach the galaxy, can be characterized geometrically as ‘spiralising cones’, with a fit to their number $n$, their average cross-sectional radius $a(r)$, and their interface size $b(r)$. Internally, these streams would have a temperature, density, and metallicity which depends on $r$ as well. The properties of these streams will change with redshift, and so could explain some of the differences between the $z \sim 1$ data here and the lower-redshift COS-Halos results, including that the streams are expected to get wider as $z$ approaches 0 (Dekel et al. 2009).

Within each phase, we would suggest that each ion density should fit to a power law with radius, with some exceptions as we will describe. An example of this is shown in Figure 15. Here we see that the total oxygen within the streams, interface and bulk all increase as they approaches $r = 0$, reflecting the increase in both density and metallicity there. In the streams, this increased density ends up lowering the OVI ion fraction so much that the total density of OVI within streams remains nearly constant throughout the CGM. At the same time, the interface layer gas maintains a constant ion fraction as its density increases, since in CI this fraction is nearly density-independent. Therefore, its OVI density increases to become higher than that of the PI gas in the inner halo. Finally, the bulk gas has both a low oxygen density and a low OVI fraction, and is irrelevant throughout the halo. Combining this plot with the volume plot in the right panel of Figure 13 which showed that in the inner halo the interface tends to fill approximately the same volume as the stream it envelops, leads to the conclusions from this paper and RF19 that PI gas is more significant in the outer halo, and that sightlines mostly intersect PI gas outside of $0.3R_{\text{vir}}$ (see Section 4.2). The second threshold (besides the requirement to be within 2 kpc of a PI cell) of $n_{\text{OVI}} > 10^{-13}$ cm$^{-3}$ for interface gas is shown here to be not too high of a threshold, as the OVI number density for CI bulk gas is actually generally still higher than $10^{-13}$ cm$^{-3}$ and the interface is significantly higher, so its properties do not come primarily from selection bias. A higher threshold would decrease the cumulative volume in the interface, but otherwise would not significantly change its properties.

We briefly describe the procedure to fit other ions to this model here. Since the temperature change with radius in each phase is significantly less than the density change (Figure 13), we would begin by assuming constant temperatures for the bulk, interface, and stream, with characteristic values as determined by Begelman & Fabian (1990); Gronke & Oh (2018); M20a; M20b, and other alternatives. Given those temperatures, we determine using the procedure of Section 3 whether the ion will be PI, CI, or transitionary. If the ion is determined to be CI, its fraction (under the assumption of constant temperature) will be constant and its density will be therefore a constant times the phase density, unless this is lower than the critical CI density, in which
Figure 15. Radial profiles of OVI properties in the three OVI phases in the CGM of VELA07 at $z = 1$. Line colours are as in Figure 13. Left: Total oxygen number density, determined by total density, total metallicity, and overall oxygen abundance. Centre: OVI ion fraction within each phase. Right: OVI number density within each phase, which is in effect the product of the previous two panels.

Figure 16. Two different ions of lower and higher ionization than OVI. (a): CIV, (b): NeVIII. Note these images are of the same slice as Figure 6, but with a slightly lower dynamic range, reflecting carbon and neon’s lower abundances compared to oxygen. The same three phases, including the thin interfaces, are visible in these other ions.

case we will instead assume the CI contribution is zero (see Figure 8). If the ion is determined to be PI, its ionization fraction $f_{X_i}$ (i.e. the fraction of the $i$th state of atom $X$) can be simplified by assuming a broken power law, with a positive power in $f - n$ space below some density, an approximately flat region, and then a negative power in $f - n$ space above some density. This decomposition is justified by examining the PI ions in Figure 3, and images like it at other temperatures. If the breaks between these multiple power laws do not overlap with the density ranges within the three phases ($\approx 2$ dex, depending on which phase is under discussion), the ion number density itself will follow a power law:

$$n_{X_i} \propto Z \cdot \rho \cdot f_{X_i},$$

(15)

where $n_{X_i}$ is the number density of that ion state in that phase, $Z$ is the metallicity, and this equation will apply in any of the stream, interface, or bulk phases of the CGM. On the other hand, if the breaks between the power laws do overlap with the density ranges, the function will be much more complicated and probably cannot be well modeled. If the ion is at a ‘transitionary’ temperature, it can be modeled...
as a broken power law with four segments, adding an additional flat curve at high density. This does not change the procedure, except to increase the likelihood that the model will break down due to the additional power law break.

In this picture, OVI is unique in that its line of distinction between PI and CI mechanisms, as we defined in Section 3, happens to coincide with the temperature distinction between the streams and their interfaces. We have shown in Sections 5.1 and 5.2, by comparing the phases defined by the OVI ionization mechanisms to theoretical studies of cold streams and their properties, that these inflowing streams are identifiable with the regions of PI OVI. There is no reason to believe that other commonly-observed ions should have a meaningful CI boundary layer on the edge of PI clouds, or indeed that they are PI within the cold streams, and CI outside of them. We show two other ions in Figure 16 as an example, one of which (CIV) has a lower ionization energy than OVI while the other (NeVIII) has a higher ionization energy. CIV appears here to be even more negligible outside the cold streams, and within the streams falls off more strongly with radius (see the top right and bottom right clouds within the slice). The interface layers have lower CIV density (green, instead of blue), as opposed to comparable or higher OVI density. On the other hand, NeVIII is not localized to the streams at all, but rather has a higher density in the bulk material, and is highlighted in the interface layer in particular, which has a higher NeVIII density than either the bulk or the stream. The fact that the same streams and interface layers identified in OVI are also visible in NeVIII, though with totally different relative ion densities, is further evidence that the stream interface layers are a real phenomenon in the simulation, even though they were detected using the definition of the OVI CI-PI cut-off and not their other physical properties. This dependence is summarized in the following list, which shows how this model can lead to vastly different distributions throughout the CGM for similar (e.g. lithium-like, or containing three electrons) ions.

- For medium-ion states (e.g. CIV), we have $n_{\text{stream}} \gg n_{\text{interface}} \gg n_{\text{bulk}}$.
- For mid-to-high ion states (e.g. OVI), we have $n_{\text{stream}} \sim n_{\text{interface}} \gg n_{\text{bulk}}$.
- For high-ion states (e.g. NeVIII) we have $n_{\text{interface}} \gtrsim n_{\text{bulk}}$.

We do not here include a prediction for low ion states. While these could be fit to this model, they are likely subject to resolution limits (Hummels et al. 2019), so small clouds which are not produced in VELA could form a substantial contribution. The testable predictions of this model are that gas in mid-level ions reside in the inflows and can be detected all the way to the outer halo and beyond, while high ions (NeVIII) are significant throughout the bulk, and not strongly correlated to HI.

6 SUMMARY AND CONCLUSIONS

In this work we study properties of OVI in the CGM of $\sim 10^{12} M_\odot$ halos at $z \sim 1$ from the VELA simulations. We introduce a procedure for identifying all ions as photoionized or collisionally ionized, depending on the density, temperature, redshift, and assumed ionizing background, with negligible ‘overlap’. This causes low ions to convert from PI to CI at lower temperatures than high ions, resulting in large regions where some ions could be PI and others CI simultaneously. We run mock sightlines through the simulations and compare the results with data from observations, suggesting a toy model for use in future work.

The main results of our analysis can be summarized as follows:

- **Photoionized cool inflows**: PI OVI is found entirely within filamentary cool inflows from outside the CGM. While they fill only a tiny fraction of the CGM volume, most of the OVI in the CGM is located inside them.
- **Collisionally Ionized Interface Layer**: The cool inflows have a warm-hot thin interface layer, which is the primary source of CI OVI.
- **Low-density Collisionally Ionized Bulk**: The bulk of the OVI in the CGM by volume is CI. However this phase is too hot to have a significant OVI component at all, and is negligible in terms of total mass. This results in undetectably low column densities outside of the inner halo.
- **OVI sightlines are mostly PI in the outer halo of massive galaxies at $z \sim 1$**: Since sightlines naturally represent the outer halo more than the inner, the cool inflows structure above leads to OVI column densities being dominated by PI gas for all impact parameters outside $0.2 - 0.3 R_{\text{vir}}$.
- **Assumptions of spherical symmetry underestimate OVI median radius**: The non-spherical nature of the cool inflows’ model leads inverse Abel transformations (as in S18) to predict that the median OVI particle is located at around $0.6 R_{\text{vir}}$. However, this is an underestimate compared to the actual distribution of gas. Most OVI is therefore likely located very near, or beyond, the virial radius.
- **Inflows characterize the OVI structure of the CGM of massive galaxies at $z \sim 1$**: We propose a model in which metal absorbers are characterized by their number densities in three distinct phases: inside cool inflows, outside the inflows in the bulk CGM volume, and in an interface layer between these two phases. This geometrical structure is characterized by the characteristic radius of the inflowing stream (which is itself a function of halocentric radius), $a(r)$, and the thickness of the interface layer, $\delta$. This model appears consistent with analytical predictions about the gas distribution from the interaction between cold streams and the hot CGM (M20b).
- **OVI is unique in tracing both the stream and interface**: While the three-phase cool streams structure we describe here is a general prediction for observations of the CGM, OVI has a PI-CI cutoff which matches the difference between the stream and interface conditions.

Future work will apply the same framework for distinguishing PI and CI gas to other ions. We are especially interested in CIV and NeVIII, which are included in the Steidel et al. (2010); Bordoloi et al. (2014) and CASBAH (Burchett et al. 2019; Prochaska et al. 2019) surveys, among others, at redshifts $z \gtrsim 1$, so their actual column density values could be compared to those in VELA. This would let us further develop this three-density CGM model, $n_{\text{stream}}, n_{\text{interface}},$ and $n_{\text{bulk}}$. We will also follow the same idea in other simu-
lations that reach lower redshifts and different mass ranges, but which have good enough resolution to show these cool inflows in the CGM. Finally, a comparison with the new generation of the same VELA galaxies (Ceverino et al. in prep.) will allow us to directly compare the effects of increased feedback on the CGM with the same initial conditions.

ACKNOWLEDGEMENTS
