(Dated: February 7, 2014)

We investigate giant resonances of spherical nuclei on the basis of the Argonne V18 potential after unitary transformation within the Similarity Renormalization Group or the Unitary Correlation Operator Method supplemented by a phenomenological three-body contact interaction. Such Hamiltonians can provide a good description of ground-state energies and radii within Hartree-Fock plus low-order many-body perturbation theory. The standard Random Phase Approximation is applied here to calculate the isoscalar monopole, isovector dipole, and isoscalar quadrupole excitation modes of the $^{40}$Ca, $^{90}$Zr, and $^{208}$Pb nuclei. Thanks to the inclusion of the three-nucleon interaction and despite the minimal optimization effort, a reasonable agreement with experimental centroid energies of all three modes has been achieved.

I. INTRODUCTION

The most consistent starting point for nuclear structure theory are nuclear Hamiltonians derived from quantum chromodynamics (QCD) in the framework for chiral effective field theory containing two- and three-nucleon interactions [1,2]. Using these interactions we can employ unitary transformations, e.g. the Similarity Renormalization Group (SRG) or the Unitary Correlation Operator Method (UCOM), to pre-diagonalize the Hamiltonian and to improve the convergence behavior of various many-body approaches. Recently, this approach was applied successfully to light and medium-mass nuclei in the context of the No-Core Shell Model [3,4] and in Coupled-Cluster Theory and related methods [5,7].

The computational effort, however, limits the applicability of general three-nucleon interactions in the unitary transformation as well as in the application in many-body methods. Furthermore, to provide an appropriate starting point for the investigation of collective excitations in the framework of the Random Phase Approximation (RPA) the interaction has to reproduce experimental ground-state radii reasonably well—this has not yet been achieved on the basis of chiral two- plus three-nucleon interactions beyond the lightest nuclei. As a preparatory step towards the full inclusion of chiral two- and three-nucleon interactions, we follow a more pragmatic approach by using the unitarily transformed Argonne V18 potential [8] supplemented by a phenomenological three-body contact interaction. This allows us to investigate ground-state properties as well as collective excitations throughout the whole nuclear mass range up to $^{208}$Pb. In a previous paper the influence of phenomenological three-nucleon interactions on the description of ground-state nuclear properties was investigated [9] and a good simultaneous description of ground-state energies and radii was achieved. This was not possible with the pure two-body UCOM interaction employed in earlier studies [10]. We now examine whether dynamical properties, such as collective modes, show a similar quantitative improvement compared to previous work [11]. Therefore, in this Brief Report we apply the standard RPA to study collective excitations of closed-shell nuclei. We will show that the results obtained with the unitarily transformed Argonne V18 supplemented by a phenomenological three-body contact interaction agree within 20% with the results for traditional phenomenological potentials like the Gogny D1S interaction [12]. The characterization of these hybrid Hamiltonians in standard applications is mandatory to provide a well-defined footing for predictive calculations like the study of low-energy dipole transitions [13], and investigations in the framework of quasi-particle RPA (QRPA) [14].

After a presentation of the formalism in Sec. II we discuss briefly some ground-state properties of closed-shell nuclei across the whole nuclear chart on the basis of Hartree-Fock and many-body perturbation theory in Sec. III. In Sec. IV, we study the isoscalar monopole (ISM), isovector dipole (IVD), and isoscalar quadrupole (ISQ) excitation modes of three chosen nuclei, $^{40}$Ca, $^{90}$Zr, and $^{208}$Pb.

II. FORMALISM

The unitary correlation operator method (UCOM) and the similarity renormalization group (SRG) provide two different approaches for the generation of soft phase-shift equivalent two-body interactions. These two methods have already been discussed extensively (see [15] and refs. therein). Based on the Argonne V18 potential we will apply four different classes of unitarily transformed interactions in the following: UCOM(SRG), S-UCOM(SRG), SRG, and S-SRG which were introduced in [9]. These transformed two-body interactions are supplemented by a simple three-body contact interaction

$$V_{3N} = C_{3N} \delta^{(3)}(r_1 - r_2)\delta^{(3)}(r_1 - r_3)$$

(1)
with variable strength $C_{3N}$. The m-scheme matrix elements of the contact interaction can be evaluated on-the-fly, which is of great computational advantage. As single-particle basis the eigenstates of the harmonic oscillator are employed. For calculations beyond the mean-field level we have to introduce a regularization of the contact interaction which is achieved via a restriction of the total oscillator energy of the three-particle state: $(2n_1 + l_1) + (2n_2 + l_2) + (2n_3 + l_3) \leq E_{3\text{max}}$, where $n$ and $l$ are the principal and the angular momentum quantum numbers of the harmonic oscillator states, respectively [9].

### III. GROUND-STATE PROPERTIES

For a first characterization of the four different two- plus three-body interactions, the Hartree-Fock (HF) approximation and many-body perturbation theory are used to calculate ground-state energies and charge radii for selected closed-shell nuclei from $^4\text{He}$ to $^{208}\text{Pb}$. The formal inclusion of the three-body contact interaction in these two methods has been discussed in detail in Ref. [9]. The single-particle basis is truncated with respect to the principal oscillator quantum number $e = 2n + l$, which is restricted to $e \leq e_{\text{max}} = 14$ with an additional constraint for the orbital angular momentum quantum number $l \leq l_{\text{max}} = 10$. The oscillator parameter $a_{\text{HO}}$ is chosen for each nucleus separately such that the experimental charge radius is reproduced by a shell-model Slater determinant built from harmonic oscillator single-particle states. We have observed that for these values of $a_{\text{HO}}$ and for $e_{\text{max}} = 14$ the HF ground-state energies deviate by less than 1\% from their minimum with respect to $a_{\text{HO}}$ and that the mean square radius is stable against variations of $a_{\text{HO}}$. Thus the HF ground-state energy and mean-square radius are well converged with respect to $e_{\text{max}}$.

Figure 1 shows the ground-state energies per nucleon and charge radii for closed-shell nuclei across the whole nuclear chart. The three-body cut-off parameter is set to $E_{3\text{max}} = 20$ for all four interactions (cf. [9]). The strength of the three-body contact interaction is used to adjust the charge radii to the experimental values. As observed in Fig. 1 the strength $C_{3N}$ can be chosen such that the radii are well reproduced across the whole mass range by all four interactions. This is a remarkable result considering the simplistic structure of the three-body interaction. The optimal values for the three-body contact strengths are summarized in Table I together with the corresponding flow parameters.

The HF ground-state energies reproduce the systematics of the experimental values except for an almost constant shift, which is due to the missing effects of long-range correlations that cannot be described at the mean-field level. The influence of long-range correlations can be taken into account via second-order many-body perturbation theory [10]. Here, we apply perturbation theory only to the two-body part of the interaction (cf. [9]). The effect on charge radii is negligible, but for the ground-state energies the inclusion of the second-order perturbative corrections leads to a substantial improvement (open symbols in Fig. 1). The agreement with the experimental data is not yet perfect, i.e. the differences vary from 0.2 to 2.4 MeV per nucleon, but one has to keep in mind that the energy corrections are not yet fully converged with respect to the single-particle model space size. Furthermore, we only consider the second-order estimate and have no information about the influence of the third and higher orders [18, 19].

In case of the UCOM(SRG) interaction one observes that the energy corrections for some nuclei, mainly the heavier nickel isotopes and $^{100}\text{Sn}$, do not follow the general trend. The origin of this behavior is found in the corresponding HF single-particle spectra, where some level spacings are collapsed leading to divergent contributions to the perturbative corrections. Therefore, these data points are not shown here.

### IV. GIANT RESONANCES

For the investigation of collective excitations we apply the standard Random Phase Approximation (RPA) (cf. e.g. [11]). In the framework of the HF approximation and the standard RPA the three-body contact interaction is equivalent to the density-dependent two-body interaction [20–22]

$$V_{NN}[\varrho] = \frac{C_{3N}}{6} \left(1 + P_\tau \right) \frac{P_\tau}{2} \delta(3)(r_1 - r_2),$$

which is used for the implementation of the RPA for computational reasons. The only difference to the HF plus MBPT

| Interaction          | $C_{3N}$ [GeV fm$^3$] |
|----------------------|------------------------|
| UCOM(SRG)            | 0.16                   |
| S-UCOM(SRG)          | 0.10                   |
| SRG                  | 0.10                   |
| S-SRG                | 0.10                   |

**TABLE I: Optimal parameter sets for the different two- plus three-body interactions.**
calculations discussed in the previous section is the absence of the three-body cut-off $E_{3\text{max}}$ in the RPA. The HF calculations providing the basis for RPA are also performed using the density-dependent form of the three-body interaction without the cut-off. As the HF energies are independent of $E_{3\text{max}}$ the chosen implementation has no influence on the RPA results. Although we use density-dependent two-body interaction in RPA we will still refer to it as three-body contact interaction.

In the following, we investigate three excitation modes, namely isoscalar monopole (ISM), isovector dipole (IVD), and isoscalar quadrupole (ISQ) excitations, of $^{40}\text{Ca}$, $^{90}\text{Zr}$, and $^{208}\text{Pb}$. The different two- plus three-body interactions introduced in the previous sections are considered using the parameter sets listed in Table I. The single-particle basis is again truncated at $e_{\text{max}} = 14$.

As a first benchmark we consider the exhaustion of the classical sum rules. We validate our implementation by using the Gogny D1S interaction, whose momentum dependent terms are of zero range: the ISM and ISQ classical sum rules are then fulfilled within 1% or better. In case of the transformed AV18 interactions, the exhaustion of the classical ISM sum rule lies between 90.5% for $^{40}\text{Ca}$ calculated with the UCOM(SRG) interaction and 98.4% for $^{208}\text{Pb}$ calculated with the S-SRG interaction. The exhaustion of the ISQ sum rule lies between 98.4% for $^{208}\text{Pb}$ calculated with the SRG interaction and 102.9% for $^{40}\text{Ca}$ calculated with the UCOM(SRG) interaction. The deviations from the classical IS sum rules are mostly a consequence of the non-localities of the finite-range interactions used [23]. When including the three-body interaction we use a larger flow parameter in order to compensate for the additional repulsion. The larger flow parameter generates stronger non-localities in the transformed two-body interaction, which in turn influence the exhaustion of the classical sum rules. It is expected that the Thomas-Reiche-Kuhn sum rule for the IVD mode is significantly enhanced due to the non-localities of the applied interactions. Indeed, the smallest percentage that we found for the Thomas-Reiche-Kuhn sum rule was 168.3%, for $^{40}\text{Ca}$ based on the SRG interaction. Finally, we have found that the energy of the spurious dipole state never exceeds 20keV in the present cases.

In Figure 2 we compare the HF and RPA response functions for all three excitation modes calculated with the S-UCOM(SRG) interaction for $^{208}\text{Pb}$. The response functions are obtained via a convolution of the calculated discrete strength distribution with a Lorentzian function with a width of 2 MeV. The upper row shows the response functions obtained with the pure two-body S-UCOM(SRG) interaction using the flow parameter $\alpha = 0.04\text{ fm}^4$ while the response functions depicted in the lower row were obtained with the two-body S-UCOM(SRG) interaction plus the three-body contact interaction with $\alpha = 0.16\text{ fm}^4$ and $C_{1S} = 2.2\text{ GeV fm}^6$ (cf. Tab. I). The HF response is spread wide in case of both isoscalar modes while it is rather compressed for the isovector excitation. In comparison, the RPA response is compressed significantly and shifted to lower excitation energies in the isoscalar channels which leads to strongly collective excitation modes, the giant resonances. In case of the ISQ mode one observes the excitation of a low-lying $2^+$ state in addition to the giant resonance. The RPA response of the IVD excitation is shifted to higher excitation energies with respect to the HF response, i.e. the residual interaction is attractive in the IS channels and repulsive in the IV channel.

Comparing the HF response functions obtained with the pure two-body interaction with those resulting from the two-plus three-body interaction reveals that the inclusion of the three-body interaction leads to a compression of the response for all considered excitation modes. This compression can be understood by considering the HF single-particle spectra which are spread wide when calculated with a pure two-body interaction. The repulsion of the three-body interaction increases the level density and thus leads to a compression of the HF response.

The RPA response calculated with the two- plus three-body interaction is concentrated in a narrower resonance structure compared to the response functions obtained with the pure two-body interaction for all three excitation modes. Furthermore, the centroids are shifted to lower energies: the ISM centroid is shifted by 1 MeV while the IVD and ISQ centroids are moved by 3 MeV, respectively.

Figure 3 summarizes the response functions that were obtained with the four different two- plus three-body interactions for $^{40}\text{Ca}$, $^{90}\text{Zr}$, and $^{208}\text{Pb}$ including centroid energies extracted from experiment. All four interactions yield comparable results with only minor differences and are in reasonable agreement with the experimental centroids. The energies of the giant dipole and quadrupole resonances tend to be overestimated, but much less so than with the pure two-body UCOM interaction [11]. The systematic nature of these deviations hint at the role of higher-order configurations beyond RPA [32].

The results obtained with the S-UCOM(SRG) and the S-SRG interactions are very similar in all aspects confirming the similarities between these two interactions that were already observed earlier [9].

The centroid energies of the calculated response functions are compared to the experimental values and to calculations based on the Gogny D1S interaction in Table II. In most of the 36 cases the centroids are within 20% of the experimental value. The SRG interaction performs particularly well while

TABLE II: Centroid energies in MeV obtained for the (a) UCOM(SRG), (b) S-UCOM(SRG), (c) SRG, and (d) S-SRG interactions, compared to experimental values [24–29] and the (e) Gogny D1S interaction.
the largest deviations are observed for the UCOM(SRG). Our results are similar in quality with existing results using phenomenological energy density functionals, e.g. the Gogny D1S interaction listed in Table II. We note that the good overall agreement of the response with experiment is obtained despite the systematic deviation of the HF ground-state energy (without MBPT corrections) from the experimental binding energy. The same remarkable observation was made in [14]. It is well known that an excellent description of nuclear energies by phenomenological energy density functionals based on HF does not guarantee a good description of collective states within RPA. For example, they usually require a high nucleon effective mass, which leads to a strong underestimation of the IVD energy. Our present and previous results [14] consistently confirm that the HF or HF-Bogolyubov ground-state energy has little to do with the dynamical behavior of the system under study, as described by RPA or quasi-particle RPA. Instead it is more important to obtain a good description of the radii and the ground-state energies beyond the mean-field level, e.g. in many-body perturbation theory.

V. CONCLUSIONS

We have investigated the ISM, IVD, and ISQ giant resonances using unitarily transformed two-nucleon interactions supplemented by a simple phenomenological three-body contact interaction. For the three considered nuclei, $^{40}\text{Ca}$, $^{90}\text{Zr}$,
and $^{208}\text{Pb}$ we achieved a reasonable agreement with experimental centroid energies, where the SRG interaction yielded the smallest deviations. We have shown that a reasonable description of charge radii is important to obtain a good starting point for RPA calculations.

Following this benchmark, the hybrid interactions employed here can be applied for the quantitative description of other collective phenomena in closed and open-shell nuclei. Several follow-up studies are in progress. At the same time, our results represent an intermediate step towards a consistent inclusion of chiral two- plus three-nucleon interactions for the study of collective excitations. Apart from computational challenges, the systematic reproduction of ground-state radii will be a key issue when working with these Hamiltonians.
