Received 29 December 2012; Accepted 20 May 2013

Abstract: To determine the process of cellulose degradation in mangrove estuaries of the South-Western Islands, Japan, the cellulase activity of sediments was examined at a total of 9 sites on Okinawa Main Island (the River Ge-sashi and Manko), Ishigaki Island (Nagura Gulf and River Miyara), and Iriomote Island (rivers Urauchi, Mare, Hinai, Shira and Maira). Zymographic analysis was used to record cellulase activity in all sediment samples and in the meio-benthos. A 27-kDa cellulase activity band was expressed by several animal groups examined in the meio-benthos, including Gammaridea, Turbellaria, Ostracoda, Oligochaeta, Nematoda, and Polychaeta. However, the mangrove whelk, Terebralia palustris, which is a widely distributed member of the macro-benthos in these areas except Okinawa Main Island, expressed cellulase activities at 29, 31, 49, and 56 kDa. Interestingly, 31-kDa cellulase activity levels were recorded both in sediments and in the feces of T. palustris. The results of this study indicate that various benthic animals contribute to cellulose degradation in mangrove sediments of estuaries in the Southwestern Japanese Islands.

Key words: benthos, cellulase, estuary, mangrove, South-Western Islands

Introduction

Mangroves represent unique ecological systems that exhibit extraordinarily high biological productivity. This is because the roots of mangrove trees function as refuges for larval fish, while mangrove litter is utilized as a carbon source for many estuarine organisms (Chong 2007). In Japan, mangrove estuaries are primarily located in the Southwestern Islands of Okinawa Prefecture and Amami Island in Kagoshima Prefecture; however, they can grow as far north as the River Aono (34°38′N) in Shizuoka Prefecture (Takeshita & Noguchi 1974). Vast areas of pristine mangrove estuaries are found on Iriomote Island, which is one of the southwestern islands of Okinawa Prefecture. Kandelia obovata, Bruguiera gymnorhiza, Rhizophora stylosa, Avicennia marina, Sonneratia alba. Rhizophora stylosa are the main species of mangrove tree growing there, restricted to islands south of Okinawa Main Island. Avicen-
(EC 3.2.1.91). Cellulose is degraded to glucose by these enzymes via two steps. In the first step, endo-β-1,4-glucanase and cellobiohydrolase degrade cellulose to cellulodextrin or cellobiose. In the second step, another enzyme, β-glucosidase (EC 3.2.1.21), further degrades the molecules into glucose (Watanabe & Tokuda 2010). Cellulases from bacteria (Olson et al. 2010), filamentous fungi (Trinci et al. 1994), basidiomycetes (Chow et al. 1994), myxomycetes (Ronsness 1968), and protozoa (Bera-Maillet et al. 2005) have been extensively studied. Furthermore, cellulase genes have been identified in termites (Watanabe et al. 1998) and nematodes (Smant et al. 1998, Kikuchi et al. 2005). The presence of such endogenous cellulases has also been reported in aquatic animals, such as the blue mussel (Xu et al. 2001), abalone (Suzuki et al. 2003), sea urchin (Nishida et al. 2007), and a brackish water clam (Sakamoto et al. 2007).

Occurrence of cellulase activities of *Telescopium telescopium* was reported by Alexander et al. (1979), who detected activity of laminarinase, fucoidanase, amilase, cellulase, xylanase, β-glucosidase and β-galactosidase in liquid extracts of the crystalline style. Cellulase activity was also found in the mangrove whelk *Terebralia palustris*, a species related to *Telescopium telescopium* distributed in the mangrove estuaries of Iriomote Island (Niiyama & Toyohara, 2011); and has also been found in the blood cockle *Anadara granosa*, estuarine mysids (*Mesopodopsis tenuipes, M. orientalis, Notacanthomysis hodgarni, Acanthomysis thailandica, Rhopalophthalmus orientalis*, and *R. egregius*) and Acetes shrimps (*Acetes sibogae, A. japonicus*, and *A. indicus*) collected from Matang Mangrove in Malaysia (Niiyama, Hanamura et al., 2012, Niiyama, Toyohara & Tanaka, 2012). These findings suggest the presence of a significant contribution of macrobenthos towards the degradation of cellulose in mangrove estuaries.

The meiobenthos (animals able to pass through a 1-mm-mesh sieve) includes a wide range of fauna: at least 22 phyla (Robert & Hjalmar 1988). Toyohara et al. (2012) first reported the possibility that the meiobenthos (including Turbellaria, Nematoda, and Oligochaeta) contributes to cellulose degradation in wetlands. Subsequently, Yamada and Toyohara (2012) reported the importance of the meiobenthos (including Oligochaeta and Ostracoda) for cellulose degradation in a Hokkaido wetland. Alongi surveyed the distribution of meiobenthos in Missionary Bay, Hinchinbrook Island (on the northeastern coast of Australia) and found that meiofaunal densities were highest in Austral autumn and winter and lowest in Austral spring and summer. (Alongi 1987). However, the function of the meiobenthos in the cellulose degradation of mangrove estuaries remains unresolved.

In the present study, cellulose activity in several mangrove estuaries in the southwestern islands of Japan to determine the process of cellulose degradation and understand how benthic animals contribute to this process. The results indicate that various benthic animals are involved in cellulose degradation of these mangrove estuary sediments.

### Materials and Methods

#### Materials

Sampling was performed from December 15 to 18, 2010, at nine sampling sites (Fig. 1): Okinawa main island (2 sites), Ishigaki Island (2 sites), and Iriomote Island (5 sites). Sediments were from nine mangrove estuaries (of the rivers Gesashi, 26°36’N 128°8’E; Manko, 26°11’N 127°30’E; Miyara, 24°21’N 124°12’E; Uruchi, 24°25’N 123°46’E; Mare, 24°25’N 123°46’E; Hmai, 123°81’N 24°39’E; Shira, 24°19’N 123°54’E; Maira; 24°18’N 123°54’E; and Nagura Gulf, 24°26’N 124°6’E: co-ordinates recorded with an eTrex Vista HCx hand-held GPS unit from Garmin, Olathe, Kansas, USA). Table 1 shows the dominant species of mangrove at each site.

On November 22, 2011, additional sediment samples were collected from the Mare and Hinai rivers. A further five *T. palustris* specimens were collected from the Mare river during the second period of sampling to assess the mechanism of cellulose degradation more precisely. At each sampling site, approximately 1 kg of sediment was collected from a depth of 5 cm, selecting a single sampling point devoid of plants. Fallen leaves of *Rhizophora stylosa* were collected at the Mare river. The collected sediment and fallen leaves samples were then transported at 4°C to the laboratory at Kyoto University and stored at 4 °C until analysis.

Two of the five live *T. palustris* transported to the laboratory in Kyoto were dissected to remove the midgut, which was then homogenized with three volumes of cold phosphate-buffered saline (PBS, containing 140 mM NaCl, 2.7 mM KCl, 8 mM Na2HPO4, and 1.5 mM KH2PO4, pH 7.4). The protein concentrations of the extracts were measured according to the method of Bradford (1976), using bovine serum albumin as the standard. The protein concentration of the extracts were then adjusted to 1 mg/mL and stored at −20°C until use. The other three *T. palustris* were kept alive at room temperature in the laboratory (approximately 20°C), to collect the feces for cellulase analysis. Unless otherwise specified, chemicals used were special reagent grade (Nacalai Tesque Inc.; Kyoto, Japan).

#### Isolation of meiobenthos

Live meiobenthic organisms were isolated from the sediments within 1 week of collection by recovery from the fraction small enough to pass through a 1-mm-mesh sieve, but too large to pass through one of 63-μm. Individual animals were isolated under a microscope (SZX12; Olympus, Tokyo, Japan). Organisms were identified to at least the Class level, according to Robert et al. (1988), except for nematodes. Arthropods were classified according to Joei & Gorge (2001). We used single individuals of each animal.
for qualitative cellulase assay.

**Qualitative analysis of cellulase activity**

Meiobenthic animals were individually isolated from the sediments using forceps under a light microscope, homogenized with cold 20 μL PBS and prepared for sodium dodecyl sulfate 7.5% polyacrylamide gel electrophoresis (SDS-PAGE) zymographic analysis. The length of the animals obtained ranged between 1 and 9 mm. A similar method was used to prepare the feces of *T. palustris* from a midgut extract, adjusted to 1 mg/mL, diluted 10 times with PBS and prepared for SDS-PAGE analysis.

Five volumes of sediment and 1 volume of 6× SDS sample buffer containing 0.6 M Tris–HCl (pH 6.8), 60% glycerol, 6% SDS, and 0.06% bromophenol blue were homogenized (HandySonic UR-20P; TOMY SEIKO, Tokyo, Japan), incubated at 4°C for 2 h with shaking, centrifuged at 8,000 × g for 5 min and the supernatant prepared for SDS-PAGE zymographic analysis.

Wood fragments of mangrove trees were removed from sediment using forceps. Approximately 0.5 g of mangrove residue, composed of wood fragments of mangrove trees or fallen leaves of *Rhizophora stylosa*, was rinsed thoroughly with tap water and diluted three times with distilled water, and then extracted using the same method as that used for the sediments. The protein concentration of the sediment extracts and mangrove residues was not detectable using the Bradford method.

**Zymographic analysis of cellulose** in the extracts prepared as above was performed using 7.5% or 10% SDS-PAGE gels containing 0.1% carboxymethylcellulose. After electrophoresis, the gels were soaked in 10 mM acetate buffer (pH 5.5) containing 0.1% Triton X-100 for 30 min to remove SDS, then transferred to 10 mM acetate buffer (pH 5.5) and incubated at 37°C overnight. Cellulase activity was detected as an unstained band in the gel after staining with 0.1% Congo Red and destaining with 1 M NaCl.
Results

Qualitative analysis of cellulases of meiobenthos and macrobenthos

The cellulase activities of macro- and meiobenthic animals was measured to detect which animals were involved in reducing sugar-releasing activity in the mangroves. All animals from all nine sites exhibited active cellulase bands under SDS-PAGE zymographic analysis (Figs. 2, 3). In 2010, it was noted that a large number of *T. palustris* in the Mare river are associated with sediment producing the most intensive cellulase activity seen in the zymographic analysis among the all sampling sites examined. Sediments from the Mare and Hinai rivers were therefore collected once again in 2011 to investigate any connection between this phenomenon and cellulases secreted in the feces of *T. palustris*. Meiobenthos was absent from the sediments, possibly because of exceptionally heavy rainfall 3 days before collection. Interestingly, however, new active bands were detected at 24, 49, 103, 132, and 260 kDa in these sediments (Fig. 3a, lane 1).

When we measured cellulase activities in the digestive organs of *T. palustris*, the midgut extract showed active bands at 29, 31, 49, and 56 kDa (Fig. 3a, lane 4). To determine whether midgut cellulases are secreted via the feces, we measured the fecal cellulase activity of *T. palustris* and found 29-, 31-, 56-, 62-, and 83-kDa active bands from zymographic analysis (Fig. 3a, lane 5).

Discussion

The occurrence of cellulase activities in various meiobenthic animals from the mangrove ecosystem sediments of the southwestern Japanese Islands suggests that these animals contribute to the cellulase activity found in the sediment itself (Fig. 2; cf. Toyohara et al. 2012, Yamada & Toyohara 2012). Interestingly, a common 27-kDa active band differed from the results of previous studies (Toyohara et al. 2012, Yamada & Toyohara 2012), suggesting a horizontal distribution of a gene encoding a 27-kDa cellulase among meiobenthic animals in this region. This will require genetic identification of the 27-kDa cellulase gene.

In the samples collected at the Mare river in 2010, the active cellulase band of sediment corresponded to that re-
corded for oligochaetes (Fig. 2b). This result suggests that oligochaetes may play a major role in the cellulose degradation of the Mare river sediments. However, it is difficult to determine whether cellulase activity was derived from enzymes encoded by genes on the chromosomes of benthic animals such as the brackish water clam, or from the enzymes of symbiotic microorganisms such as the shipworm (Tanimura et al. 2013). Further molecular biological studies are required to investigate this. In 2011, additional sediment samples collected from the Mare and Hinai rivers exhibited higher activity compared to sediments collected in 2010, despite collection during the season: winter (Fig. 4); the active bands for these years were also different (Figs. 2, and 3). Interestingly, meiobenthic animals were not detected in the sediments of the Mare and Hinai rivers in 2011, despite the assumption that they contributed to cellulose degradation based on the results obtained in 2010. These findings suggest that the meiobenthos fauna probably changed between 2010 and 2011. Hence, long-term studies are required to evaluate the biochemical mechanisms of cellulose degradation in these mangrove sediments.

Cellulases bound to plant residues in sediments are assumed to be important in cellulose degradation (Yamada & Toyohara 2012, Liu & Toyohara 2012). Hence, we measured the cellulase activity of residues from mangrove trees, including wood fragments and leaves. Cellulase active bands at 49, 103, 132, and 260 kDa were commonly detected in both the sediment and wood fragments collected from the Mare river in 2011 (Fig. 3a, lane 1, 2). In addition, active bands at 45 and 73 kDa were commonly observed in both the sediment and wood fragments collected from the Hinai river. These findings indicate that cellulase is adsorbed onto wood fragments in sediments, supporting the suggestions of previous studies (Yamada & Toyohara 2012, Liu & Toyohara 2012). Based on these results, mangrove fragments may bind cellulases preventing them from being washed out by water flow, which results in their functioning as bioreactors that efficiently degrade cellulose in sediments.

Large quantities of T. palustris inhabit the Mare river. In this study, a 31-kDa cellulase active band was recorded in the midgut extract and feces of this species. Hence, cellulases may be secreted from the body via the feces. Immunological identification is required to validate this possibility.

It is considered that the meiobenthos and macrobenthos have important functions in the sediments of the mangrove estuaries of the Mare and Urauchi rivers, suggesting that these animals are involved in cellulose breakdown occurring in the southwestern Japanese Islands. However, cellulases secreted from microorganisms including bacteria and fungi play important roles in the breakdown of mangrove fragments (Pointing et al. 1999, Gao et al. 2010). The possible implication of cellulases secreted in feces in addition to bacteria and fungi as a bioreactor in the breakdown process of cellulose in sediment was first demonstrated by Fig. 3 in the present paper. Liu & Toyohara (2012) reported that cellulases bound to sediment function as a bioreactor in the rivers of the warm temperate region of Japan. Further studies are required to validate the hypothesis of a bioreactor breakdown system in sediment that is independent of benthic animals.
