**Abstract**

Amyotrophic lateral sclerosis (ALS) is a fatal neurodegenerative disease characterized by the progressive loss of motor neurons. We previously showed that the expression of dynactin 1, an axon motor protein regulating retrograde transport, is markedly reduced in spinal motor neurons of sporadic ALS patients, although the mechanisms by which decreased dynactin 1 levels cause neurodegeneration have yet to be elucidated. The accumulation of autophagosomes in degenerated motor neurons is another key pathological feature of sporadic ALS. Since autophagosomes are cargo of dynein/dynactin complexes and play a crucial role in the turnover of several organelles and proteins, we hypothesized that the quantitative loss of dynactin 1 disrupts the transport of autophagosomes and induces the degeneration of motor neuron. In the present study, we generated a *Caenorhabditis elegans* model in which the expression of DNC-1, the homolog of dynactin 1, is specifically knocked down in motor neurons. This model exhibited severe motor defects together with axonal and neuronal degeneration. We also observed impaired movement and increased number of autophagosomes in the degenerated neurons. Furthermore, the combination of rapamycin, an activator of autophagy, and trichostatin which facilitates axonal transport dramatically ameliorated the motor phenotype and axonal degeneration of this model. Thus, our results suggest that decreased expression of dynactin 1 induces motor neuron degeneration and that the transport of autophagosomes is a novel and substantial therapeutic target for motor neuron degeneration.

**Introduction**

Autophagy is one of the major cellular systems that regulate protein degradation and organelle turnover in physiological and pathological conditions [1], and it is an essential quality control system for proteins in post-mitotic neurons that need to eliminate abnormal proteins and organelles for their proper function and survival [2,3]. It is well known that the dysregulation of autophagy causes neurodegeneration [4,5] and that the abnormal accumulation of autophagosomes is observed in several neurodegenerative diseases [6–9]. Particularly, intensified immunoreactivity for microtubule-associated protein 1 light chain 3 (LC3), which is a marker of autophagosome, is often observed in the spinal motor neurons of amyotrophic lateral sclerosis (ALS) patients [8,10]. Electron microscopy of the motor neurons of ALS patients shows an increased number of autophagosomes surrounded by a double-membrane that contain sequestered cytoplasmic organelles, e.g., mitochondria [8]. Although these observations suggest the possibility that autophagy is upregulated to protect neurons from increased amounts of aggregated proteins and/or damaged organelles, it is also possible that the accumulation of autophagosomes due to dysregulated autophagy leads to neurodegeneration.

One possible mechanism for the accumulation of autophagosomes in degenerated neurons is the disruption of the cellular transport system, given that autophagosomes are cargo that moves bidirectionally along microtubules, which is powered by the kinesin family of motor proteins and dynein/dynactin complexes [11,12]. We previously investigated the motor neuron-specific gene expression profile of sporadic ALS (SALS), which accounts for more than 90% of ALS, and found that the expression of dynactin 1, which is a key member of the dynactin family, is markedly decreased in the spinal motor neurons of SALS patients [9]. The decreased expression of dynactin 1 was also verified quantitatively using *in situ* hybridization analysis of tissues from SALS patients [13]. By contrast, the expression of other motor proteins including the kinesin family, which are responsible for anterograde transport and dyneins, which are responsible for retrograde transport was not significantly changed. Thus, we hypothesized that the decreased expression of dynactin 1 results in the disrupted transport of autophagosomes and thus attenuates the protective effects of autophagy against neurodegeneration.
Moreover, mutations of \textit{DCTN1}, the gene encoding dynactin 1, are linked to familial lower motor neuron disease [14]. Several mutant \textit{DCTN1} models exhibited motor dysfunction and pathological changes related to motor neuron disease [15,16]. As seen in the motor neurons of SALS patients, mutant \textit{DCTN1} mice exhibited a massive accumulation of membrane vesicles, including autophagosomes, in spinal motor neurons [16]. Although these findings suggest that impaired vesicular trafficking might cause the accumulation of vesicles, it remains unclear whether the transport of autophagosomes is actually impaired in the mutant \textit{DCTN1} mice or whether the accumulation of autophagosomes plays a causative role in the pathogenesis of motor neuron degeneration.

The aim of the present study was to clarify the biological link between the quantitative loss of dynactin 1 and the disruption of autophagy. In particular, we examined whether the decreased levels of dynactin 1 induce motor neuron degeneration by
hindering the transport of autophagosomes. To this end, we first examined the relationship between the decreased levels of dynactin 1, the accumulation of autophagosomes, and motor neuron degeneration in post-mortem tissues from SALS patients. Next, we created a Caenorhabditis elegans (C. elegans) model of the motor neuron-specific knockdown (KD) of dnc-1, the C. elegans homolog of human DCTN1, using small hairpin RNA (shRNA), and investigated whether the depletion of dynactin 1 impairs the transport of autophagosomes and thereby induces motor neuron degeneration. Using this model, we also explored therapeutic strategies targeting the transport of autophagosomes.

Figure 2. Creation of the motor neuron-specific dnc-1-KD C. elegans model. (A) Fluorescent visualization of ventral cholinergic motor neurons and their neurites in transgenic C. elegans worms expressing acr2p::shRNA::gfp. (B) Representative immunohistochemical staining of GFP and in situ hybridization against dnc-1 in ventral cholinergic motor neurons and their neurites in the control(RNAi) and dnc-1(RNAi) worms. (C) The number of GFP-positive motor neurons (white arrows in B) was not significantly different between the control(RNAi) and dnc-1(RNAi) worms (n = 20 animals for each strain). (D) Conversely, the number of dnc-1 mRNA-positive neurons (black arrows in B) was remarkably decreased in the dnc-1(RNAi) worms (n = 20 animals for each strain). (E) Representative images of in situ hybridization for dnc-1 in the head neurons. Scale bars = 100 μm (A), 10 μm (B), and 20 μm (E). Statistical analyses were performed using Student’s t test (*p<0.0001). The error bars are S.E.M. doi:10.1371/journal.pone.0054511.g002
Figure 3. Motor dysfunction in the motor neuron-specific dnc-1-KD C. elegans model. (A) Stereoscopic microscopy showing the phenotypes of the control(RNAi) and dnc-1(RNAi) worms. (B, C) Survival curves of the transgenic worms (dnc-1(RNAi-1), n = 90; dnc-1(RNAi-2), n = 90; control(RNAi) n = 90; and wild-type n = 30). The same survival data of the control(RNAi) and wild-type worms were used in both graphs. Both dnc-1(RNAi) worms with different shRNA sequences (101, 2888) had significantly reduced life spans compared with the control(RNAi) worms (101: p = 0.005; 2888: p < 0.0001; log-rank test). (D) The number of body bends associated with forward movement in 3 min. (E) The number of thrashing movements in liquid medium in 30 s. (F, G) The tracks (F) and average speed of the worms (G) analyzed by video capture at day 4. Scale bars in F = 100 μm. The error bars are S.E.M. (n = 30, 30, 40, and 40 for dnc-1(RNAi-1), dnc-1(RNAi-2), control(RNAi), and wild-type, respectively, in D, E; and n = 6, 6, and 6 for dnc-1(RNAi-1), control(RNAi), and wild-type, respectively, in G). The statistical analyses in C, D, and F were performed by one-way ANOVA followed by the Bonferroni/Dunn post hoc test (*p < 0.001 and **p < 0.0001).
Materials and Methods

Protocols for the human samples

Ethics Statement. The collection of autopsied human tissues and their use for this study were approved by the Ethics Committee of Nagoya University Graduate School of Medicine, and written informed consent was obtained from the patients’ next-of-kin. Experimental procedures involving human subjects were conducted in conformance with the principles expressed in the Declaration of Helsinki.

Immunohistochemistry. Six micrometer-thick sections from paraffin-embedded spinal cord sections from autopsied patients were prepared as described previously [17]: four patients with sporadic ALS (64.5±9.3 years-old; M:F = 2:2) and four disease controls (73.5±5.4 years-old; M:F = 1:3). The four control patients were diagnosed with progressive supranuclear palsy, multiple system atrophy, diffuse lewy body disease, and Parkinson’s disease, respectively. The sections were first microwaved for 20 min in 50 mM citrate buffer, pH 6.0, then blocked with TNB blocking buffer (PerkinElmer, Hvidovre, Denmark) in Tris-

Figure 4. Morphological changes in ventral motor neurons. (A) Representative view of fluorescent GFP microscopic images of the ventral nerve cord in a control(RNAi) C. elegans. All of the motor neurons (white asterisks) were located in the ventral side of the worm. Axons from the motor neurons project within the ventral nerve cord or toward the dorsal side. (B–E) Representative view of the ventral nerve cord in the control(RNAi) worms (B, C) and dnc-1(RNAi) worms (D, E). The degenerated axons were defasciculated (arrows in D, E) and formed spheroids (arrowheads in D, E) in the dnc-1(RNAi) worms. Mild defasciculation was observed occasionally in the control(RNAi) worms (arrow in C). While the cell bodies of the motor neurons were regular and round in control(RNAi) and young adult dnc-1(RNAi) worms (white asterisks in B–D), abnormally shaped cell bodies (yellow asterisks in E) were observed only in the worms with severe axonal changes. (F) Semi-quantification of the abnormal morphological changes in the control(RNAi) and dnc-1(RNAi) worms. The percentage of worms with axonal defasciculation, axonal spheroids, or cell body degeneration on days 4, 7, and 10. (G) Population of dnc-1(RNAi) worms with and without cell body degeneration (black and gray boxes, respectively) on day 4. (H) Correlation between the axonal defasciculation index and locomotor function in the dnc-1(RNAi) worms. The axonal defasciculation index represents the degree of axonal defasciculation (its details are described in the Materials and Methods). Scale bars = 20 µm. The statistical analysis in F was performed using Fisher’s exact probability test (°p<0.05, °°p<0.001, and °°°p<0.0001) and Pearson’s correlation coefficient in H.

doi:10.1371/journal.pone.0054511.g004
buffered saline (pH 7.5) at room temperature for 30 min and incubated with a monoclonal antibody against LC3 (anti-LC3, 1:40000; Medical & Biological Laboratories, Co., Nagoya, Japan) or dynactin 1 (anti-dynactin 1 H300; 1:2000; Santa Cruz, Santa Cruz, CA, USA) overnight at 4°C. The subsequent procedures were carried out using the EnVision+Kit/HRP (DAB) (DAKO, Glostrup, Denmark) according to the manufacturer’s protocol.

**Quantitative assessment of immunohistochemistry.** To assess LC3 immunoreactivity in spinal motor neurons, we included 4 ALS patients and 4 disease controls, and prepared 5 independent specimens from each subject. We counted about 200 motor neurons in ALS patients and about 400 neurons in control patients. The intensity of immunohistochemistry signals was quantified using a BZ-8000 fluorescent microscope and its software (BZ-Analyzer; Keyence, Osaka, Japan). Signal intensity was expressed as the individual intracellular cytoplasmic signal level (arbitrary absorbance units/mm²) per motor neuron by subtracting the mean background levels of 3 regions of interest in each section. The ventral spinal horn was defined as the gray matter ventral to the line through the central spinal canal perpendicular to the ventral spinal sulcus. To investigate the correlation between dynactin 1 and LC3 in individual motor neurons we used consecutive transverse spinal cord sections.

**In situ hybridization.** In situ hybridization for human tissue was performed as described previously [13]. We provide the detailed information in Materials and Methods S1.

**Electron microscopy.** Electron microscopy was performed on samples from 2 sporadic ALS patients (71 years-old male and 62 years-old female) and 2 disease control patients (68 years old male with multiple system atrophy and 60 years-old male with multiple system atrophy). Epoxy resin-embedded specimens of spinal anterior horn were cut into 70-nm ultrathin sections. Ultrathin sections were contrasted by staining with uranyl acetate and lead citrate. Sections were viewed with a JEM-1400EX electron microscope (JEOL, Tokyo, Japan) at 80 kV.

**Protocols for C. elegans**

**Ethics statement.** All animal experiments were performed in accordance with the National Institute of Health Guide for the Care and Use of Laboratory Animals and were approved by the Nagoya University Animal Experiment Committee.

**Culture of C. elegans.** Standard methods were used to culture C. elegans on nematode growth medium (NGM) agar [18]. The animals were maintained at 20°C unless otherwise indicated. We provide the detailed information in Materials and Methods S1.

**Constructs and C. elegans Strains.** To generate transgenic C. elegans, plasmid DNA encoding acr2promotor::shRNA::gfp was injected into the gonads of young adult hermaphrodite N2 worms. We provide the detailed information for the shRNA vector and other co-injected proteins, i.e., SNB-1 and Lgg1, in Materials and Methods S1.

**Whole Mount in situ Hybridization.** Whole mount in situ hybridization of worms was performed as described previously [13,19]. We provide the detailed information in Materials and Methods S1.

**Phenotypic analysis of C. elegans.** A lifespan assay was performed as described previously [20], with some modifications. The Worms were allowed to lay eggs on a dish for 3–6 h to obtain synchronous progeny for the experiment. L4 worms were collected and transferred every 3 days to a fresh plate until the end of their reproductive life. The animals were scored as dead if they did not move when prodded with a platinum pick and did not show pharyngeal pumping.

A body bend assay, liquid thrashing assay, and video capture analysis were performed as locomotion assays. To examine the body bend frequency, exposed worms were transferred onto a fresh NGM plate and scored for the number of body bends.

![Figure 5. Ultrastructure of degenerating motor neurons.](image-url)
performed in 3 min. A body bend was defined as a change in the direction of the part of the worm corresponding to the posterior bulb of the pharynx along the y-axis, assuming that the worm was traveling along the x-axis. We also performed a liquid thrashing assay as described previously [21], with some modifications. Briefly, the worms were put on a 6-cm NGM-coated plate with 3 ml of M9 media. The worms were allowed to settle for 30 s, their movements were captured by video for 30 s, and the number of thrashing movements was counted. We also analyzed the speed of movement using a video capture system as described previously [22]. Briefly, fully matured, adult worms were transferred individually to agar plates with no food. The movement of each worm was observed for 5 min and recorded using video equipment (Olympus, Tokyo, Japan) with a sampling rate of 30 frames/s. A computer-controlled microscope stage was automatically moved to center the worms in the visual field using a custom image analysis algorithm within the microscope's software package (MetaMorph; Universal Imaging Corp., West Chester, PA, USA). The midlines of the recorded worms were extracted from each image. All strains were randomized and scored on the same day.

Figure 6. Defective axonal transport of synaptobrevin-1 in dnc-1(RNAi) C. elegans. (A, B) Expression patterns of DsRed-tagged synaptobrevin-1 (SNB-1) in the dorsal nerve cord. In the control(RNAi) worms, SNB-1 puncta (arrowheads) are regularly spaced with a uniform shape. In the dnc-1(RNAi) worms (B), they are irregularly spaced and abnormally accumulated (white bars) with occasional clumps. (C, D) Histograms of the distances between neighboring SNB-1 puncta. The average distance between puncta in the control(RNAi) (3.240±1.716 μm, n = 139) and dnc-1(RNAi) (3.855±2.764 μm, n = 104) worms was not significantly different (p = 0.996 by Student’s t test), but the peak of the control histogram was higher than that of the dnc-1(RNAi) histogram, proving that the localization of SNB1 was irregular. (E, F) Representative kymographs of SNB-1::DsRed in the ventral nerve cord from the control(RNAi) (E) and dnc-1(RNAi) (F) worms derived from time-lapse imaging. Vertical lines represent stationary/docked SNB-1 puncta and oblique lines (labeled with yellow arrowheads) represent the tracks of moving SNB-1 puncta. The slope of this track is an indicator of velocity. (G) The number of SNB-1 puncta within a single image of kymograph was not different between the control(RNAi) and the dnc-1(RNAi) worms. (H) The mean velocities of SNB-1 puncta. (I, J) The quantitative analysis of mobile puncta. The number of puncta which moved more than 2 μm was counted (I). The ratio of moving puncta was calculated by dividing the number of moving puncta by the total number of SNB-1 puncta (J). A total of 20 time laps images were analyzed from each strains in G–J. Scale bar (black) = 10 μm (B). Statistical analyses were performed using Student’s t test (*p<0.05, **p<0.001, ***p<0.0001). Error bars are S.E.M. doi:10.1371/journal.pone.0054511.g006
Preparation of starved worms for the dietary restriction assay. All worms were synchronized by egg preparation [23]. The eggs were incubated at 20°C for 48 h in liquid medium. After 48 h, newly hatched worms were washed 3 times with distilled water, transferred to S basal medium without OP50, and incubated for 24 h. Worms were then picked randomly and used for the liquid thrashing assay.

Drug treatment. The worms were synchronized by egg preparation and incubated at 20°C for 24 h in liquid medium. They were then treated with rapamycin (LC Laboratories, Woburn, MA, USA) dissolved in ethanol at a final concentration of 10 or 100 μM, 3-methyladenine (3-MA) (SIGMA) dissolved in DMSO at a final concentration of 1 or 10 mM, or trichostatin A (TSA) (Tokyo Chemical Industry, Co., Tokyo, Japan) dissolved in DMSO at a final concentration of 1, 10, or 100 μM and incubated in liquid medium for 48 h. For controls (0 μM), ethanol or DMSO was added. Worms were then picked randomly and used for the liquid thrashing assay or microscopic analysis.

Primary neuronal cell cultures of nematodes. Primary neuronal cell cultures were prepared as described previously [24], with some modifications. In the present study, in order to obtain larger number of gravid animals, we cultured the worms in liquid medium (S basal medium with concentrated OP50) as described previously [25]. After incubation in liquid medium for 3 days, we performed egg isolation using lysis buffer (0.5 M NaOH/1% NaClO). Then we removed eggshell by enzymatic digestion using chitinase (SIGMA) and isolated embryonic cells were plated onto peanut lectin-coated glass bottom dishes (IWAKI, Tokyo, Japan).

Microscopic analysis. The worms were anesthetized by placing them in an 8-μl drop of levamisole (2 mM) on solidified pads of 2% agarose laid on slides. After covering slips, the worms were examined under an LSM710 confocal microscope (Carl Zeiss Inc., Thornwood, NY, USA). The regularity of SNB-1::DsRed localization/spacing was evaluated by measuring the distance between two neighboring fluorescent puncta of SNB-1::DsRed using ImageJ 1.43 software (National Institutes of Health). The axonal defasciculation index was measured as follows. The ventral nerve cord was divided into compartments consisting of two neighboring motor neurons. We counted the number of compartments with axonal defasciculation and divided it by the total number of compartments.

In vivo analysis of autophagosome mobility was performed as follows. Lgg1::DsRed worms were plated on an agar pad and observed using confocal microscopy. The red puncta, which represent autophagosomes, were observed for 1 min. The number of autophagosomes that moved within 1 min was divided by the total number of autophagosomes observed.

In vitro transport assay and image analysis. Time-lapse images were acquired at room temperature using a 63× oil-immersion objective (N.A 1.4) for live-cultured neuron analysis at figure 7. Impaired transport and abnormal accumulation of autophagosomes in the axons of dnc-1(RNAi) motor neurons. (A, B) Representative time-lapse images of autophagosome (DsRed-tagged Lgg1) transport in an axon (GFP-tagged shRNA; green) of a primary cultured motor neuron from the control(RNAi) (A) and dnc-1(RNAi) (B) worms. The autophagosomes were transported smoothly along the axon (arrows) of the control(RNAi) motor neuron (A). The autophagosome (arrows) was transported anterogradely, but was trapped where the axon was slightly narrowed (arrowhead) (B). There were also autophagosomes that accumulated in the distal part of the axon (B, bar). (C) Histograms of Lgg1::DsRed velocity in the retrograde (white bars) and anterograde (black bars) directions in neurons from the control(RNAi) and dnc-1(RNAi) worms. (D) Histograms of Lgg1::DsRed run-length in the control(RNAi) and dnc-1(RNAi) neurons. (E, F) Mean velocity (E) and run-length (F) of autophagosomes (n = 70 vesicles for each strain) in control(RNAi) and dnc-1(RNAi) neurons. Scale bar = 5 μm (A and B). The statistical analyses in E and F were performed using the Mann-Whitney U test (*p<0.05 and **p<0.0001). The error bars are S.E.M.
Figure 8. Accumulation of autophagosomes and motor neuron degeneration in the dnc-1(RNAi) worms. (A, B) Representative kymographs of Lgg1::DsRed in the ventral nerve cord from the control(RNAi) (A) and dnc-1(RNAi) (B) worms derived from time-lapse images. Vertical lines represent stationary/docked Lgg1 puncta, while the oblique lines (labeled with arrowheads) represent the tracks of moving Lgg1 puncta. The slope of this track is an indicator of velocity. (C) The number of Lgg1 puncta within a single kymograph image. (D, E) Quantitative analyses of the mobility of puncta. The number of puncta that moved more than 2 μm was counted (D). The ratio of moving puncta was calculated by dividing the number of moving puncta by the total number of puncta (E). (F) The mean velocities of Lgg1 puncta. A total of 20 time-lapse images were analyzed for each strain in C–F. (G) The number of Lgg1 puncta was increased in the dnc-1(RNAi) worms compared with the control(RNAi) worms (n = 15 for each group). (H, I) Accumulation of autophagosomes in the dnc-1(RNAi) worms was correlated with the severity of axonal defasciculation (H) and locomotor function (I) (n = 20 for each analysis). (J–L) Ultrastructural images of ventral motor neurons from the dnc-1(RNAi) worms. Aberrant membranous vesicles including degenerated mitochondria were observed in the cytoplasm (J) and axons (K) (arrows). Autophagosome-like, double membrane vesicles (asterisk in L) were also found in the axons of the dnc-1(RNAi) worms (L). Scale bar = 500 nm (A–C) or 10 μm (D). Statistical analyses were performed using Student’s t test (*p < 0.05 and **p < 0.0001) and Pearson’s correlation coefficient in H and I. The error bars are S.E.M. doi:10.1371/journal.pone.0054511.g008
Figure 9. Dysfunction of autophagy causes axonal degeneration. (A) Treatment with 3-MA decreased the number of autophagosomes in the ventral nerve cord in a dose dependent manner (n = 15 for each group). (B–E) The effects of 3-MA on the locomotor function (C) and axonal morphology (B, D, and E) of the control(RNAi) worms. Treatment with 3-MA increased axonal defasciculation (arrows in B and the graph in D) and the number of axonal spheroids (arrowheads in B and the graph in E) (n = 15 for each group). (F–H) The effects of 3-MA on the locomotor function (F) and axonal morphology (G, H) of the dnc-1(RNAi) worms (n = 15 for each group). Scale bar = 10 μm. Statistical analyses were performed using Dunnett’s post hoc test (A) and Student’s t test (B, D, and E) (*p<0.05, **p<0.001, and ***p<0.0001). The error bars are S.E.M.

doi:10.1371/journal.pone.0054511.g009
Figure 10. Starvation stimulates the retrograde transport of autophagosomes and attenuates axonal degeneration in the dnc-1(RNAi) worms. (A) Effect of rapamycin and starvation on locomotor function in the control(RNAi) and dnc-1(RNAi) worms (n = 50 for each group). (B) Fluorescent microscopy showing the morphological changes in axons after starvation in the dnc-1(RNAi) worms. (C) The number of axonal spheroids per transverse axon section in the dnc-1(RNAi) worms with or without starvation. (n = 15 animals for each treatment). (D) Effect of rapamycin (100 μM) and starvation on autophagosome mobility in the dnc-1(RNAi) worms. (n = 15 animals for each treatment). (E, F) Effect of rapamycin (100 μM) and starvation on the mean velocity (E) and run-length (F) of autophagosomes (black bars: anterograde transport; white bars: retrograde transport) (n = 70).
vesicles for each treatment). (G, H) Histograms of Lgg1::DsRed velocity (F) and run-length (G) in the anterograde (black bars) and retrograde (white bars) direction in primary motor neurons from the dnc-1(RNAi) worms cultured with normal (control) and serum-free (starvation) medium. Scale bars = 5 μm. Statistical analyses were performed by one-way ANOVA followed by the Bonferroni/Dunn post hoc test (A) and Dunnett’s post hoc test (D). Student’s t test (C) and Mann-Whitney test (E, F) were used for two-group comparison (*p<0.05, **p<0.001, and ***p<0.0001). The error bars are S.E.M.

doi:10.1371/journal.pone.0054511.g010

1–2 frames/s. The images were analyzed using Zen2008 (Zeiss) software. The run-length of Lgg-1 in primary motor neurons was measured by drawing a line over moving fluorescent puncta using Zen2008. Motile puncta were counted only if they moved continuously in the same direction for more than 2 frames and if their displacement was at least 2 μm. Some runs were terminated by a pause or reversal. To ensure the accuracy of the run-length measurements, we excluded moving puncta at the beginning and end of the movie. The velocity of Lgg-1 movements was obtained from the total distance traveled divided by the duration of the run.

**In vivo transport assay and image analysis.** Time-lapse images were acquired at room temperature using a 63× objective (N.A. 1.4) for live-worm analysis at 1 frame/s. The images were analyzed using Image J 1.43 software (National Institutes of Health). First, individual tracks of SNB-1 or Lgg1 movement were analyzed using the Multiple Kymograph plug-in, as described previously [26]. The velocity of the moving vesicles was tracked manually and their instantaneous velocity was extracted. To calculate the ratio of moving versus total vesicles, the number of vesicles that moved more than 2 μm during each time lapse period was divided with the total number of particles in each acquisition.

**Electron microscopy of C. elegans.** A conventional two-step fixation method was performed as described previously [27]. We provide the detail information in Materials and Methods S1.

**Western Blot Analysis and Quantitative real-time PCR.** Western blot analyses and quantitative real-time PCR were performed as described previously [28,29]. We provide a detail description in Materials and Methods S1.

**Statistical analysis.** Statistical analyses were performed using StatView software version 5 (Hulinks, Tokyo, Japan). We used the Kaplan-Meier and log-rank test, Student’s t-test, Mann-Whitney U test, and one-way analysis of the variance (ANOVA) with the Bonferroni or Dunnett’s post-hoc test. Pearson’s correlation coefficient was used to assess the correlation of variables.

**Results**

Dysregulated dynactin 1 expression and autophagy in degenerated spinal motor neurons in SALS patients

The expression of the DCTN1 gene was markedly reduced in the spinal motor neurons of SALS patients, as reported previously [9,13] (Fig. 1A). Recent studies indicate that the dysregulation of autophagy in motor neurons is a pivotal event in ALS [8,10]; thus, we investigated the relationship between decreased dynactin 1 expression and autophagy in ALS. Immunohistochemistry using consecutive sections of autopsy human spinal cords revealed that LC3 immunoreactivity, a histological marker of autophagy, was increased in the motor neurons of SALS patients in which dynactin 1 expression was decreased (Fig. 1B). Conversely, there was no change in the immunoreactivity for dynactin 1 and LC3 in cerebellar Purkinje cells, which showed no degeneration (Fig. 1C). Quantitative analysis revealed that anti-LC3 immunoreactivity was significantly increased in the spinal motor neurons of SALS patients (p<0.0001) (Fig. 1D), and was inversely correlated with the decreased mRNA levels of DCTN1 (Fig. 1E) and cell size (Fig. 1F) in the motor neurons of SALS patients, indicating that the dysregulation of autophagy is associated with the decreased expression of dynactin 1 in SALS. Electron microscopy of sections from the SALS and control patients (Fig 1G, H) also revealed that there was an abundance of autophagic vacuoles, e.g., multilamellar bodies (arrowheads in Fig. 1I, K), autophagosome-like double membrane vesicles (arrows in Fig. 1K, J), and autolysosomes (asterisks in Fig. 1L) in the motor neurons of the SALS patients, which were scarcely observed in the control patients.

**Generation of the dnc-1-depleted C. elegans model**

To examine the relationship between the loss of dynactin 1, the accumulation of autophagosomes, and motor neuron degeneration, we created a dnc-1-KD C. elegans model by transfecting C. elegans with a plasmid expressing an shRNA and GFP under the control of the motor neuron-specific ace2 promoter (dnc-1(RNAi)). In the transgenic worms, GFP was expressed diffusely in ventral motor neurons (Fig. 2A). We confirmed the effect of RNA interference on the level of endogenous dnc-1 mRNA using whole mount in situ hybridization. In the control(RNAi) worms, dnc-1 expression was not altered by shRNA::GFP expression (Fig. 2B). Conversely, in the dnc-1(RNAi) worms, motor neurons expressing shRNA::GFP exhibited reduced or no expression of dnc-1 (Fig. 2B). As shown in Fig. 2C, approximately 22 neurons were GFP-positive both in the control(RNAi) and dnc-1(RNAi) worms. The number of dnc-1-positive motor neurons was decreased by approximately 20 (control(RNAi)) worms, 33.3±3.8; dnc-1(RNAi)) worms, 15.9±9.8, suggesting that dnc-1 was successfully knocked down in almost all the GFP-positive cells (Fig. 2C, D). Moreover, dnc-1 expression was not affected in the head sensory neurons of the dnc-1(RNAi) worms, confirming the specificity of the promoter (Fig. 2E). Taking these results into account, in the following experiments, we selected the dnc-1(RNAi) and control(RNAi) worms expressing GFP in more than 30 motor neurons to avoid the influence of knockdown efficiency on the experimental results.

**Motor dysfunction in motor neuron-specific dnc-1-KD C. elegans**

The dnc-1(RNAi) worms demonstrated uncoordinated locomotion (Fig. 3A), which is a phenotype observed in C. elegans mutant models of motor neuronal defects [30,31]. Maturation of the worms resulted in the progressive aggravation of their uncoordinated locomotion, characterized by partial paralysis, slowed movement, and coiling. The feeding plate of the dnc-1(RNAi) worms appeared to be stagnated, as they only ate the food around the feeding plate of the control worms. Motor neuron-specific dnc-1(KD) C. elegans exhibited reduced or no expression of dnc-1 (Fig. 2F). Approximately 22 neurons were GFP-positive both in the control(RNAi) and dnc-1(RNAi) worms. The number of dnc-1-positive motor neurons was decreased by approximately 20 (control(RNAi)) worms, 33.3±3.8; dnc-1(RNAi)) worms, 15.9±9.8, suggesting that dnc-1 was successfully knocked down in almost all the GFP-positive cells (Fig. 2C, D). Moreover, dnc-1 expression was not affected in the head sensory neurons of the dnc-1(RNAi) worms, confirming the specificity of the promoter (Fig. 2E). Taking these results into account, in the following experiments, we selected the dnc-1(RNAi) and control(RNAi) worms expressing GFP in more than 30 motor neurons to avoid the influence of knockdown efficiency on the experimental results.

The dnc-1(RNAi) worms exhibited reduced or no expression of dnc-1 in the transgenic worms, 35.3±9.8, and wild-type worms, 15.9±9.8, suggesting that dnc-1 was successfully knocked down in almost all the GFP-positive cells (Fig. 2C, D). Moreover, dnc-1 expression was not affected in the head sensory neurons of the dnc-1(RNAi) worms, confirming the specificity of the promoter (Fig. 2E). Taking these results into account, in the following experiments, we selected the dnc-1(RNAi) and control(RNAi) worms expressing GFP in more than 30 motor neurons to avoid the influence of knockdown efficiency on the experimental results.
The thrashing speed of the control (RNAi) worms was slightly decreased compared with the wild-type worms, possibly due to the toxicity of GFP, as previously reported [32] (Fig. 3E). Although the toxicity of GFP was much less than that of dnc-1 knockdown and not detectable in the bending assay, to exclude any effects of the fluorescent protein on our analysis, we compared...
the dnc-1(RNAi) worms with the control(RNAi) worms, both of which express GFP at similar levels, in all experiments. We also performed a video capture analysis to visualize the movement trace of each worm and measure its average speed (Fig. 3F, G). The movement speed was dramatically decreased in the dnc-1(RNAi) worms compared with the control(RNAi) worms at an early adult stage.

### Axonal degeneration is the early sign of neurodegeneration in the dnc-1(RNAi) worms

We then examined the morphological changes in the dnc-1(RNAi) worms using fluorescent microscopy. In normal worms, the ventral nerve cords were tightly fasciculated and the motor-neuron cell bodies (white asterisks in Fig. 4A) were round or ovoid. (Fig. 4B, C). By contrast, we found irregular shapes and defasciculation of the ventral nerve cord as well as axonal swellings, or spheroids, in the dnc-1(RNAi) worms at an early stage (Fig. 4D). At this early stage (4 days old), the cell bodies in the dnc-1(RNAi) worms seemed normal judging from their shape and structure (Fig. 4D). However, at a later adult stage (7 days old), axonal degeneration was exacerbated and morphological changes were also detected in the cell bodies (Fig. 4E). Axonal changes were occasionally observed in the control(RNAi) worms with aging, but they were less frequent and not as severe as in the dnc-1(RNAi) worms (Fig. 4C). Semi-quantification of the axonal and cell body changes showed that the axonal abnormalities were observed at day 4 and cell body deformation occurred at a later stage (Fig. 4F).

Although some neurons exhibited an abnormal cell body shape at day 4, this change was only observed in the worms with axonal defasciculation (Fig. 4G), indicating that axonal degeneration occurs prior to cell body degeneration. Moreover, we also found that the severity of axonal defasciculation (i.e., the axonal defasciculation index) was correlated with locomotor dysfunction in the dnc-1(RNAi) worms (Fig. 4H). To clarify the time-course of the neuronal changes due to dnc-1 depletion, we also examined the morphological change during the developmental stage. The act2p:shRNA:GFP is not detectable before larval stage L1 (Fig. S1A–C). Furthermore, even after GFP is expressed, there was no alteration in morphology or motor phenotype during the larval stage (from L1 to L4, post natal days 1 and 2) (Fig. S1C–E). It was only after the worms became adult that the axonal degeneration and motor deficit appeared. Taken together, these findings suggest that the depletion of dnc-1 induces the degeneration, rather than developmental defects, of motor neurons in C. elegans.

Further analysis via electron microscopy confirmed the axonal degeneration in the dnc-1(RNAi) worms (Fig. 5C–F). In the early degenerative stage, dnc-1(RNAi) worms first exhibited whorl-like inclusions in axons with only a few morphological changes in their cell bodies (Fig. 5C, D) compared with control(RNAi) worms (Fig. 5A, B). In the later degenerative stage, strikingly abundant whorl-like inclusions and vacuoles, corresponding to degeneration and swelling of axons [21], were observed in axons and cell bodies (Fig. 5E, F).

### Axonal transport defect in the dnc-1(RNAi) worms

Abnormalities in the localization and accumulation of synaptic vesicles were reported in a C. elegans model showing a defect in axonal transport [20]. To determine whether our dnc-1(RNAi) model exhibited defects in axonal transport, we used a fluorescently tagged synaptic vesicle marker composed of the C. elegans VAMP2/synaptobrevin protein fused to DsRed (SNB-1::DsRed), and examined the distribution of the dorsally located red puncta (Fig. 6A). In the dorsal nerve cord (the axons of the ventral motor neurons) of the control(RNAi) worms, SNB-1::DsRed puncta were regularly spaced, whereas the dnc-1(RNAi) worms exhibited a discontinuous and irregular distribution of the marker, including occasional clumps that may represent the accumulation of cargo vesicles (Fig. 6B). Histograms of the distances between neighboring SNB-1 puncta displayed a broader curve in the dnc-1(RNAi) worms than in the control(RNAi) worms, suggesting some defect in axonal transport caused by the knockdown of dnc-1 (Fig. 6C, D).

To demonstrate direct evidence of a defect in axonal transport in our transgenic worms, we monitored the movement of SNB-1 puncta by acquiring a series of time-lapse images. The resulting kymographs showed that puncta in the dnc-1 KD worms were markedly static compared with those in the controls, confirming the disruption of axonal transport following the reduction of dnc-1 in C. elegans (Fig. 6E, F, Movies S1, S2). To quantify the movement of SNB-1, we analyzed 20 kymographs from each strain. While there was no significant difference in the number of SNB-1 puncta between the control(RNAi) and dnc-1(RNAi) worms (Fig. 6G), the number of moving puncta (moving more than 2 μm) (Fig. 6H) and the ratio of moving puncta to total puncta (Fig. 6I) were significantly decreased in the dnc-1(RNAi) worms compared to the control(RNAi) worms (p = 0.028 and p = 0.014, respectively). The velocity of SNB-1 transport in the dnc-1(RNAi) worms was significantly lower than in the control(RNAi) worms (p<0.0001, Fig. 6J).

### Impaired transport and accumulation of autophagosomes in the dnc-1(RNAi) worms

We next investigated the effects of dnc-1 depletion on autophagy in C. elegans. Autophagosomes are cargo that moves bidirectionally along microtubules, powered by the kinesin family of motor proteins and dynein/dynactin complexes [11,12]. Impaired autophagy has been observed in several neurodegenerative models, including the mutant DCTN1 mouse model [9,16,33,34]. However, little is known about the relationship between the decreased levels of dynactin 1 and the alteration of autophagy. To clarify the effect of quantitative loss of DNC-1/dynactin 1 in the transport of autophagosomes, we performed live-cell imaging analyses of autophagosome transport in the axons of primary cultured motor neurons from the dnc-1(RNAi) and control(RNAi) worms that co-expressed DsRed-tagged Lgg1/ATG8, which is associated with the autophagic membrane, in ventral motor neurons under the control of the act2 promoter (Mizushima et al. [35]). This marker of autophagosomes is expressed diffusely in the ventral motor neurons (Fig. S2A) and forms distinct puncta when autophagosomes are formed (Fig. S2B) [36]. In the control(RNAi) neurons, the fluorescent Lgg1 vesicles moved toward and away from the cell body, suggesting that these vesicles are powered by anterograde and retrograde motors (Fig. 7A, Movie S3). By contrast, in the dnc-1(RNAi) worms, the autophagosomes were easily trapped where the axon was tight or curved, or at spheroids (Fig. 7B, Movie S4).

This phenomenon was followed by the accumulation of autophagosomes distal to the trapped sites. Histograms showing the distribution of the velocity and distance of autophagosome movement demonstrated a significant loss of fast- and long-moving vesicles in the dnc-1(RNAi) cells compared with the control(RNAi) cells (Fig. 7C, D). The mean velocity and movement distance (run-length) were significantly decreased in the anterograde and retrograde directions in the dnc-1(RNAi) neurons (p<0.0001, = 0.0001; velocity of anterograde, retrograde movements, respectively, and p = 0.0045, <0.0001; run-length of anterograde, retrograde movements, respectively) (Fig. 7E, F).

Next, we performed kymograph analysis of Lgg1::DsRed using in vivo time-lapse images (Fig. 7A, B, Movie S5, S6). Although the total number of Lgg1 puncta was significantly increased...
(p<0.0001) (Fig. 8C), the number (Fig. 8D) and the ratio of moving puncta (Fig. 8E) were significantly decreased in the dnc-1(RNAi) worms compared with the control(RNAi) worms (p = 0.013 and p<0.0001, respectively). The velocity of Lgg1 movement was also significantly decreased in the dnc-1(RNAi) worms (p<0.0001) (Fig. 8F). These results indicated that the dnc-1 depletion resulted in the accumulation of untransported autophagosomes in the motor neurons.

We then investigated whether the accumulation of autophagosomes is related to the motor neuron degeneration. In the ventral nerve cord of the dnc-1(RNAi) worms, the number of Lgg1 puncta was significantly increased in comparison with the control(RNAi) worms (p = 0.019) (Fig. 8G), and the accumulation of autophagosomes was correlated with the axonal defasciculation index and locomotor function (Fig. 8H, I). We also explored the localization of Lgg1::DsRed in the distal ascending axon and observed Lgg1::DsRed accumulation in axonal spheroids (Fig. S2C), which is consistent with a previous report showing the abnormal accumulation of disorganized organelles and autophagosomes in axonal spheroids [37]. Electron microscopy showed that the accumulation of vesicular structures, including autophagosome-like vesicles and mitochondria, was observed in the proximal axons or cytoplasm of the dnc-1(RNAi) worms, although such accumulations were detected rarely in the axons of the control(RNAi) neurons (Fig. 8J-L).

We then treated the control(RNAi) worms with 3-MA, which inhibits the formation of autophagosomes (Fig. 9A). These worms showed the locomotory defects and axonal degeneration observed in the dnc-1(RNAi) worms, suggesting that the disrupted autophagy system is sufficient to cause the motor neuronal degeneration in this model (Fig. 9B-E). On the other hand, when we treated the dnc-1(RNAi) worms with 3-MA, worms did not exhibit a substantial change in the motor function or in the axonal integrity (Fig. 9F-H).

**Starvation dramatically attenuates the motor deficits in the dnc-1(RNAi) worms by facilitating the axonal transport of autophagosomes**

Autophagy is known to be activated by rapamycin, a specific inhibitor of the mTOR pathway [38]. Starvation is also a strong activator of autophagy; however, it also has other effects, e.g., activation of the mitogen-activated protein kinase (MAPK) pathway [39], stimulation of tubulin acetylation [40], and induction of sirtuin [41]. Both treatments have been used widely in many species, e.g., Drosophila, mouse, and C. elegans, to activate autophagy [42-44].

To study the effects of autophagy activators on axonal degeneration in C. elegans, we treated the control(RNAi) and dnc-1(RNAi) worms with rapamycin or starved them by food restriction, and investigated the changes in motor function via the liquid thrashing assay. Rapamycin and starvation are known to extend lifespan of C. elegans [42,45]. In the present study, we found that neither rapamycin nor starvation significantly altered the motor function of the control(RNAi) worms (Fig. 10A). In the dnc-1(RNAi) worms, rapamycin ameliorated the thrashing activity in a dose-dependent manner, although it showed only a limited effect even at the most effective dose (Fig. 10A). In contrast, starvation completely ameliorated the motor dysfunction of the dnc-1(RNAi) worms without affecting the efficiency of dnc-1 knockdown (Fig. 10A, Fig. S3A-C). The formation of axonal spheroids was also significantly suppressed by starvation (p = 0.001) (Fig. 10B, C). Given the differential effects of rapamycin and starvation, we hypothesized that starvation not only increases the formation of autophagosomes but also increases their mobility in axons. Indeed, the frequency of autophagosome movement was increased by food restriction (Fig. 10D). To further confirm this hypothesis, we cultured primary motor neurons from the dnc-1(RNAi) worms in serum-depleted medium, and quantified the mobility of autophagosomes by monitoring the movement of DsRed-tagged Lgg1 in axons. As we expected, starvation significantly increased the speed and run-length of moving Lgg1 puncta, especially the retrograde run-length, in the dnc-1(RNAi) worms (p<0.0001) (Fig. 10E, F). Conversely, neurons treated with rapamycin showed no detectable change in the transport of autophagosomes (Fig. 10E, F).

Histograms showing the distribution of the velocity and distance of autophagosome movement also demonstrated a significant increase of fast- and long-moving vesicles in the starved cells, especially in retrograde transport (Fig. 10G, H). For example, the percentage of vesicles that moved more than 8 μm retrogradely increased from 6.9% (dnc-1(RNAi) control) to 27.0% (dnc-1(RNAi) starvation), whereas the change was only from 12.7% to 19.7% in the anterograde direction (Fig. 10H).

Finally, we investigated how starvation stimulates the axonal transport of autophagosomes and assessed whether drugs that mimic the molecular mechanisms of starvation enhanced its effect. The acetylation of tubulin is known to stabilize microtubules and activate axonal transport by the subsequent recruitment of the molecular motors kinesin-1 and dynein/dynactin to microtubules [46,47]. Therefore, we assessed the acetylation state of alpha-tubulin in our cultured cell assay. Starvation increased the levels of acetylated tubulin, but this effect was not detected in cells treated with rapamycin (Fig. 11A, B). Moreover, real-time quantitative PCR demonstrated that starvation, but not rapamycin, significantly increased the mRNA levels of msc-17, an enzyme that acetylates tubulin in C. elegans [48] (Fig. 11C). Taken together, our results suggest the possibility that starvation mitigated axonal degeneration by activating autophagy and promoting the axonal transport of autophagosomes via the acetylation of tubulin in the dnc-1(RNAi) worms. To test this hypothesis, we examined the effects of TSA, an HDAC inhibitor that facilitates tubulin acetylation, on the phenotypes of the dnc-1(RNAi) worms. Although treatment with TSA did not exhibit substantial effects on the phenotype of the control(RNAi) worms (Fig. S4A-C), this treatment showed a significant effect on the locomotory function of the dnc-1(RNAi) worms in a dose-dependent manner, and attenuated the axonal degeneration without alteration of dnc-1 knockdown efficiency (Fig. 11D-F, Fig. S3A, B, and D). As expected, TSA increased the mobility of autophagosomes (Fig. 11G). Interestingly, treatment with 3-MA dampened the effect of TSA on locomotion (Fig. 11H). On the contrary, the worms treated with both TSA and 3-MA showed decreased transport of autophagosomes without defects in the transport of synaptobrevin (Fig. 11I, J). Furthermore, we also examined the effect of combination therapy with rapamycin and TSA. Although treatment with rapamycin or TSA alone had limited effects in comparison with control(RNAi) worms, the combination of rapamycin and TSA had greater effects such that locomotion was restored in the worms treated with these two drugs to the levels observed in the control(RNAi) worms (Fig. 11K).

**Discussion**

In the present study, we generated a novel C. elegans model that mimics the down-regulation of dynactin 1 observed in the motor neurons of SALS patients. Using this model, we investigated whether the quantitative loss of DNC-1/dynactin 1 causes motor neuron degeneration. Our results showed that the knockdown of dnc-1 caused progressive motor deficits in C. elegans, and the
pathological changes observed in this model shared several features with those seen in SALS patients, e.g., the axonal accumulation of membranous structures, such as mitochondria and autophagosomes, and motor neuron degeneration characterized by axonal degeneration including axonal spheroids. We also observed the disrupted transport of autophagosomes in the degenerated motor neurons of this model. Interestingly, our model exhibited adult-onset motor neuron degeneration even though the shRNA::gfp had already expressed in the larval stage. Given that the patients carrying mutant DCTN1 and SALS patients exhibit an adult-onset motor neuron degeneration, it is possible that developing motor neurons are resistant to the disruption of DNC-1/dynactin 1. However, differentiated motor neurons may be vulnerable to the detrimental effects of dynactin 1 depletion, since they require more efficient transport system to maintain axonal homeostasis than developing neurons. Together, these findings indicate that this dnc-1-KD C. elegans model is a powerful tool for understanding the relationship between the disrupted transport of autophagosomes, neurodegeneration, and motor phenotype.

The mechanism of autophagosome accumulation in motor neurons harboring a motor protein abnormality was shown directly by our analysis of autophagosomal transport; namely, the knockdown of dnc-1 decreased the transport of autophagosomes and shortened their run-length. Physiological cargoes typically use multiple motors, and their run-lengths are correlated with the number of coordinated motor proteins [49]. Our results showed that the knockdown of dnc-1 reduced the speed and distance of retrograde transport by approximately half. These results are consistent with previous in vitro studies of dynein showing that the run-length of retrograde motor complexes is reduced by approximately half in cells lacking dynactin 1 [49,50]. Our data indicated that the knockdown of dnc-1 also affected the anterograde transport of autophagosomes, which is consistent with previous reports showing that a defect in retrograde transport led to dysregulated movements in both directions [51,52].

The relationship between the decreased DNC-1/dynactin 1 levels, the increased number of autophagosomes, and axonal degeneration was confirmed by our observations that the dnc-1(RNAi) worms showed an abnormal accumulation of autophagosomes and that their locomotory defects and axonal degeneration were correlated with the accumulation of autophagosomes. Furthermore, the control(RNAi) worms treated with 3-MA, an inhibitor of autophagy, showed the same phenotype as the dnc-1(RNAi) worms, including defective locomotory function and degenerated axons. Taken together, our findings in the dnc-1(RNAi) C. elegans model provide direct evidence that the lack of DNC-1/dynactin 1 in dynein/dynactin motor complexes leads to slow, short-distance movements of autophagosomes, followed by their axonal accumulation, and neurodegeneration.

It is clinically important to determine whether the activation of autophagy could be an effective therapeutic strategy against neurodegenerative diseases, especially when the transport of autophagosomes is disrupted. In previous studies, the effects of rapamycin, which induces autophagosome formation [9], against other neurodegenerative diseases were controversial [53–55]. In the present study, rapamycin only slightly ameliorated the motor dysfunction of the dnc-1(RNAi) worms, although its effects were substantially enhanced by the addition of TSA which enhances the acetylation of tubulin. Given that tubulin acetylation was shown to stimulate axonal transport [47], our results suggest that combination therapy with rapamycin and TSA, attenuated the neurodegeneration and locomotory dysfunction of this model by facilitating the formation and axonal transport of autophagosomes.

Although it is still possible that the disrupted transport of other organelles such as mitochondria are also involved in the pathogenesis of motor neuron degeneration in the dnc-1(RNAi) worms, the observation that 3-MA, an inhibitor of autophagy, almost completely abrogated the benefit effects of TSA suggests a substantial role for autophagosomal transport in the functional maintenance of motor neurons. This view is further supported by the fact that the worms treated by both TSA and 3-MA showed the decreased transport of autophagosomes without defects in the transport of synaptobrevin.

In conclusion, we found that decreased levels of dynactin 1 in motor neurons induce neurodegeneration at least partially via the disruption of the axonal transport of autophagosomes. The therapeutic strategy we examined in this study could be expanded to other neurodegenerative disorders, since the accumulation of autophagosomes and disrupted axonal transport are common features of many neurodegenerative diseases. Future study is needed to explore the effectiveness and safety of the treatments that stimulate the transport of autophagosomes in the mammalian central nervous system.

Supporting Information

Figure S1 Expression pattern of shRNA::GFP and morphology of ventral motor neurons during embryonic and larval stage. (A, B) Representative confocal microscop image of shRNA::GFP expression during embryonic stages. GFP was not observed in the eggs even after delivery (asterisks in A, B). (C–E) GFP expression were observed in the ventral motor neurons (black arrows in C) from L1 (larval 1) stage of the worms. The ventral nerve axons (white arrows in D, E) did not exhibit abnormal changes such as axonal swellings or defasciculations during L1-L4. Scale bars = 20 μm (A–C), 100 μm (high magnification image in D, E), or 50 μm (high magnification in D, E). (TIF)

Figure S2 Expression pattern of the Lgg1::DsRed in the control(RNAi) worm and the dnc-1(RNAi) worm. (A, B) Representative fluorescent microscopic views of the Lgg1::DsRed in the ventral nerve cord of control(RNAi) worms (A) and dnc-1(RNAi) worms (B). The Lgg1 puncta (asterisks in B) was abundant in the dnc-1(RNAi) worms (B). (C) Co-localization of DsRed and GFP fluorescence in the axonal spheroids (arrows) indicating that the autophagosomes (asterisks) were accumulated in the axonal spheroids in the dnc-1(RNAi) worms. Scale bar = 10 μm (A–C). (TIF)

Figure S3 Pharmacological treatment or starvation did not alter the efficiency of the dnc-1 knock-down. (A–D) The representative image of GFP and in situ hybridization against dnc-1 of ventral cholinergic motor neurons in the control(RNAi) (A) and dnc-1(RNAi) (B, no treatment; C, treated with starvation; D, treated with TSA). Scale bars = 10 μm. (TIF)

Figure S4 Treatment with TSA did not alter the locomotor function or the axonal integrity of the control(RNAi) worms. (A) Effect of trichostatin A (TSA) on the locomotor function of the control(RNAi) worms (n = 35 for each group). (B, C) Effect of TSA (100 μM) on the axonal degeneration of the dnc-1(RNAi) worms (n = 15 for each group). Statistical analyses were performed using Student’s t test. (TIF)
