South China tiger · *Panthera tigris amoyensis* · 16S rRNA gene · Fecal microflora

**Abstract**
Postnatal colonization and development of the gut microbiota is linked to health and growth. A comprehensive understanding of the postnatal compositional changes and development of the microbial community is helpful to understand the gut health and improve the survival rate of South China tiger cubs (*Panthera tigris amoyensis*). Fecal samples from three tiger cubs were collected on the day of birth in 2018 (June 17–21 [G0], July 18 [G1], July 31 [G2], and August 7 [G3]). The 16S rRNA genes of the fecal microflora were sequenced. Results showed that 38 phyla, 58 classes, 134 orders, 272 families, and 636 genera of bacteria from 3,059 operational taxonomic units were identified from 12 fecal samples. The diversity and abundance of species of group G0 were significantly higher (*p* < 0.05 or 0.01) than those of groups G2 and G3. The predominant phylum was Proteobacteria in groups G0 and G1 (38.85% and 48%, respectively) and Firmicutes in groups G2 and G3 (71.42% and 75.29%, respectively). At the phylum level, the abundance of Deinococcus-Thermus was significantly decreased in groups G1, G2, and G3 as compared to group G0 (*p* < 0.05), while that of Firmicutes was significantly increased in groups G2 and G3 (*p* < 0.05). At the genus level, the abundance of *Faecalibacterium*, *Ralstonia*, and unidentified *Rickettsiales* was significantly decreased in groups G1, G2, and G3 as compared to group G0 (*p* < 0.05), while that of *Pseudomonas* was significantly decreased in groups G2 and G3 (*p* < 0.05). The composition and structure of fecal microbiota of South China tiger cubs changed after birth.

Introduction

The South China tiger (*Panthera tigris amoyensis*), also known as the Xiamen or Amoy tiger, is the most threatened tiger subspecies [Qin and Nyhus, 2018]. Approximately 100 South China tigers have been raised in zoos or reserves [Jiang et al., 2016]. Under artificial feeding programs, due to low genetic diversity and inbreeding, the health and survival rate of tiger cubs are very poor [Chen et al., 2016]. Hence, increasing the survival rate is key to expand populations and prevent extinction.

The diversity and abundance of gut microbes are indicators of the health of both humans and animals [Alonso and Guarner, 2013; Lee and Hase, 2014; Long et al., 2018]. The gut microbiota plays a significant role in host metabolism and physiology [Nagpal and Yamashiro, 2015], which have been associated with health and growth [Feng et al., 2020]. Microbial colonization of the gastrointestinal tract begins in the early stages of life and the establishment of a complex and stable community is essential for optimal growth and development of the host [Marcolla et al., 2019]. The early establishment of the gut microbiota is influenced by environmental factors, as well as the mode of feed delivery, maternal diet, family structure, disease, and the use of medications [Nagpal and Yamashiro, 2015]. The microbes inhabiting the intestine are broadly divided into prokaryotes (bacteria and archaea), bacteriophages, viruses, and meiofauna, of which bacteria are the most abundant and comprise about 60% of the fecal mass [Andoh, 2016]. A previous study explored the impact of host intraspecies genetic variation, diet, and age on the intestinal microbiota of tiger cubs fed commercial milk in the Guangzhou Zoo [Jiang et al., 2020]. However, the effects of formulated milk on the intestinal microbiota of South China tiger cubs remained unclear.

Here, the succession of the fecal microbiota of tiger cubs was reported with the use of high-throughput sequencing technology to provide a foundation to further study the influence of formulated milk on the health and physiological regulation of tiger cubs.

Results

Quality Assessment of Sequencing Data

The results of data preprocessing statistics and quality control are shown in Table 1. An average of 84,416 raw reads and 80,111 clean reads were obtained for each sample. The quality of the sequencing data was 94.95% (online suppl. Table S3; for all online suppl. material, see www.karger.com/doi/10.1159/000518395). Sequences were clustered into operational taxonomic units (OTUs) based on a canonical clustering threshold of 97% identity [Stackebrandt and Goebel, 1994]. In this study, a total of 3,059 OTUs were acquired (Fig. 1 and online suppl. Table S4).

Alpha Diversity Analysis

Alpha diversity indices (Shannon, Simpson, Chao1, ACE, and Goods coverage) are shown in Table 1 and Figure 2. The Shannon and Simpson indices were used to measure species diversity. According to the Shannon and Simpson indices, there were significant differences in species diversity among groups G0, G2, and G3 (*p* < 0.01), as well as between groups G1 and G2 (*p* < 0.01). Meanwhile, according to the Shannon index, there were significant differences in the species diversity between groups G1 and G3 (*p* < 0.05). According to the Chao1 and ACE indices, the abundance of species was significantly higher in group G0 than groups G2 and G3. The coverage of all sample libraries was greater than 99.9%, indicating that the library size of this study was sufficient to represent the majority of bacteria.

Bacterial Diversity and Relative Abundance

In this study, a total of 38 phyla, 58 classes, 134 orders, 272 families, and 636 genera were identified in the fecal microbiota of the 12 fecal samples (online suppl. Table S2). In groups G0 and G1, the predominant...
phyla were Proteobacteria (38.85% and 48%), followed by Firmicutes (15.79% and 29.07%) and Cyanobacteria (21.47%) in group G0 and Actinobacteria (12.12%) in G1. The relative abundance of Firmicutes ranged from 15.79% (G0) to 29.07% (G1) and was the dominant phyla in groups G2 (71.42%) and G3 (75.29%) (Table 2 and Fig. 3). Unidentified Cyanobacteria (21.80%) and Sphingomonas (9.09%) were the main species in group G0, while unidentified Enterobacteriaceae and unidentified Clostridiales were dominant in group G1 (15.96% and 12.91%, respectively). In addition, Megamonas and Streptococcus were the dominant genera with relative abundances of 42.19% and 24.87% in group G2, and 45.41% and 15.31% in group G3, respectively.

### Beta Diversity Analysis
The fecal microbiome composition profiles of groups G0 and G1 were obviously separated from those of groups G2 and G3, as shown by the weighted UniFrac PCoA plot presented in Figure 4d. Hierarchical clustering UPGMA analysis showed that groups G0, G1, G2, and G3 were clearly individually clustered (Fig. 5).

### Significantly Altered Microbiota
The species differences at the phylum and genus levels among the four groups by t test analysis are shown in Figure 6. At the phylum level, as compared with group G0, the abundance of Deinococcus-Thermus was significantly decreased in groups G1, G2, and G3 (p < 0.05), while that of Firmicutes was significantly increased in groups G2 and G3 (p < 0.05). The abundance of Proteobacteria was significantly increased in group G2 (p < 0.05), while that of Fusobacteria was significantly decreased in groups G2 and G3 (p < 0.05). At the genus level, as compared with group G0, the abundances of Faecalibacterium, Ralstonia, and unidentified Rickettsiales were significantly decreased in groups G1, G2, and G3 (p < 0.05), while those of Pseudomonas were significantly decreased in groups G2 and G3 (p < 0.05). The abundance of Megamonas was significantly increased and that of unidentified Acidobacteria was significantly decreased in group G1 (p < 0.05).

### Discussion
The gut microbiota of both humans and animals develop after birth and the composition will impact health in later life [Rodriguez et al., 2015; Laforest-Lapointe and Arrieta, 2017; Tanaka and Nakayama, 2017]. In humans, Enterobacteriaceae and Staphylococcus are the dominant gut microbiota after birth, while in the gut of infants, Bifidobacterium and some lactic acid bacteria are the main constituents. After weaning, the adult-type

microorganisms Bacteroides, Prevotella, Ruminococcus, Clostridium, and Veillonella colonize the infant intestines. By about the age of 3 years, a typical adult-like gut microbiota is established [Tanaka and Nakayama, 2017]. Previous studies have described the gut and fecal microbiota of the tiger [He et al., 2018a, b, c; Karmacharya et al., 2019]. However, the members of the microbial community of the tiger after birth remain unclear. Hence, the aim of the present study was to analyze changes in bacterial diversity and abundance in the fecal contents of tiger cubs.

After birth, the dominate phyla in the feces of tiger cubs are Proteobacteria, Firmicutes, and Cyanobacteria. At about postnatal day 50, the dominate phyla are Firmicutes and Proteobacteria. Proteobacteria account for 38.85% of the microbes in the gut of newborn cubs. Dur-

Fig. 3. Fecal bacterial composition among the four groups at the phylum (a) and genus (b) levels. The top 10 bacterial phyla (a) and genera (b) chosen according to the results of species annotations were ranked by the relative abundance in each sample or group. The x axis and y axis represent the information of samples and relative abundance, respectively.
Colonization and Development of Tiger Cubs’ Fecal Microflora

During initial colonization of the neonatal gut, Proteobacteria, which are facultative anaerobes and promote colonization of obligate anaerobes in the intestinal niche, are soon replaced by Firmicutes and Bacteroidetes, which are obligate anaerobes that dominate the gut microbiota of healthy adults [Shin et al., 2015]. At about postnatal day 50, the abundance of Proteobacteria had decreased to 16.93%, while that of Firmicutes had increased to 75.29%. Firmicutes are the dominant phyla in the gut of healthy adults [Mariat et al., 2009]. The Firmicutes/Bacteroidetes ratio is commonly employed as a universal indicator of shifts in bacterial communities between infants and adults [Mariat et al., 2009; Zeineldin et al., 2018]. In the present study, the Firmicutes/Bacteroidetes ratio had increased with age due to the significant increase in the abundance of Firmicutes.

**Fig. 4.** NMDS (a), principal component analysis (b), and PCoA (c, d) of fecal bacterial community structures among the four groups. Different colors and shapes represent different groups. For PCoA, c and d were analyzed with weighted UniFrac distance and unweighted UniFrac distance, respectively.
At birth, unidentified Cyanobacteria and Sphingomonas were the main microbes in the gut of tiger cubs. The phylum Cyanobacteria consists of gram-negative species, which are inferred to be one of the earliest branching bacterial lineages and have been found in the human gut [Di Rienzi et al., 2013]. A previous study reported that the fecal metagenome of captive Amur tigers had a lower abundance of Cyanobacteria [He et al., 2018b]. In the present study, the abundance of Cyanobacteria had decreased with age. Sphingomonas, which are gram-negative opportunistic human pathogens, are the predominant bacteria in fecal samples of pigs and chickens [Chien et al., 2011]. The Sphingomonas in feces efficiently degrades macromolecular organic pollutants, such as phenanthrene, which has carcinogenic activities in animals and induces an allergic response in the skin [Wu et al., 2010]. Megamonas and Streptococcus became the dominant genera with age. Megamonas, which can utilize fructooligosaccharides, is a predominant member of the family Veillonellaceae that has a potential impact on gastrointestinal health [Beloshapka et al., 2013]. In the family Streptococcaceae, the genus Streptococcus consists of gram-positive cocci that are considered to have certain advantages in the health of both commercial and domestic pigs [Huang et al., 2020]. Overall, the abundance of microorganisms in the gut of tiger cubs decreases with age, as in humans and other animals [Nagpal and Yamashiro, 2015; Rodríguez et al., 2015]. In the present study, the abundances of Faecalibacterium, Ralstonia, unidentified Rickettsiales, and Pseudomonas had significantly decreased at about postnatal day 50.

In conclusion, the results of the present study revealed changes in microbial diversity and abundance in the gut...
Colonization and Development of Tiger Cubs’ Fecal Microflora

Fig. 6. Histogram of species differences at the phylum (a) and genus (b) levels among the four groups. The species differences at the phylum (a) and genus (b) levels in groups G0, G1, G2, and G3 were analyzed using the \( t \) test. In each histogram, the left shows the abundances of differential species and each bar in the graph represents the mean values of species with significant differences in abundance among the groups. The figure on the right shows the confidence degree of inter-group differences. The leftmost endpoint of each circle in the figure represents the lower limit of the 95% confidence interval of the mean difference, and the rightmost endpoint of the circle represents the upper limit of the 95% confidence interval of the mean difference. The center of the circle represents the difference in the mean. The group represented by the color of the circle has a high mean value. At the far right of the results is the \( p \) value of the inter-group significance test for differences.

(Figure continued on next page.)
### G0 vs G1

of tiger cubs after birth. Proteobacteria was the most predominant phylum in the gut of the South China tiger cubs at birth, which changed to Firmicutes at about postnatal day 50. Moreover, unidentified Cyanobacteria and Sphin-
gomonas were the most abundant species in the gut of the tiger cub at birth, which were replaced by Megamonas and Streptococcus. The diversity and abundance of species had decreased with age. At the phylum level, the abundance of Deinococcus-Thermus had significantly decreased. Notably, at the genus level, the abundances of Faecalibacterium, Ralstonia, unidentified Rickettsiales, and Pseudomonas had significantly decreased. These findings provide further insight into the influence of diet on the health and physiological regulation of tiger cubs.

Materials and Methods

Animals and Sample Collection

Three South China tiger cubs from different litters born nearly on the same day at Fujian Meihuashan South China Tiger Breeding Institute (Fujian, China) were raised under the same environmental and nutritional conditions (online suppl. Tables S1 and S2). These cubs were abandoned by their mothers and fed artificially. The newborn cubs were raised in incubators at a constant temperature of 28°C for 1 week. Afterward, the temperature was maintained at about 25°C with relative humidity of 55–65%. The incubators were cleaned and sanitized daily. After 3 weeks, the tiger cubs were moved into feeding chambers with similar environmental conditions as the incubators. During the artificial feeding period, the tiger cubs were in good health and defecated normally. The composition of formulated milk and feeding scheme are tal conditions as the incubators. During the artificial feeding pe-

DNA Extraction and 16S rRNA Gene Amplification

Total bacterial genomic DNA from fecal samples was extracted using the cetyl trimethylammonium bromide method as described by Tilson et al. [2004]. DNA concentration and purity were measured using a NanoDrop™ One spectrophotometer (Thermo Fisher Scientific, Waltham, MA, USA). Genomic DNA was diluted in sterile water to a concentration of 1 ng/µL. The V4 region of the 16S rRNA gene was amplified using the primer pair 528F (GGCCTGTTTCGACTTCCAA) and 768R (AATCCCRGAAATTTCACCTGTC). All PCR reactions were carried out in a 30-µL reaction volume consisting of 15 µL of Phuson® High-Fidelity PCR Master Mix (New England Biolabs, Ipswich, MA, USA), 0.2 µM forward and reverse primers, and 10 ng of template DNA. The thermal cycling conditions consisted of an initial denaturation step at 98°C for 1 min, followed by 30 cycles of denaturation at 98°C for 10 s, annealing at 50°C for 30 s, and elongation at 72°C for 30 s, with a final extension step at 72°C for 5 min.

The PCR products were mixed with the same volume of 1× loading buffer (containing SYBR green) and then separated by electrophoresis on a 2% agarose gel. The samples were pooled by mixing the PCR products at equidensity ratios and then purified with the GeneJET™ Gel Extraction Kit (Thermo Fisher Scientific).

Library Preparation and Sequencing

Sequence libraries were generated using the Ion Plus Fragment Library Kit 48 rns (Thermo Fisher Scientific) in accordance with the manufacturer’s instructions. The library quality was assessed with the use of a Qubit® 2.0 Fluorometer (Thermo Fisher Scientific). Then, the library was sequenced on an Ion S5™ XL platform and 400/600-base pair single-end reads were generated.

Data Analysis

Single-end reads were truncated by cutting off the barcodes and primer sequences. Quality filtering of the raw reads was performed under specific filtering conditions to obtain high-quality clean reads with the use of Cutadapt version 1.9.1 software [Martin, 2011]. The reads were compared to the reference Silva database [Quast et al., 2012] using the UCHIME algorithm [Edgar et al., 2011] to detect chimeras, which were then removed to obtain clean reads [Haas et al., 2011].

Sequence analysis was performed using Uparse version 7.0.1001 software [Edgar, 2013]. Sequences with ≥97% similarity were assigned to the same OTU. The Silva database was used based on the Mothur algorithm to annotate taxonomic information of each representative sequence of each OTU. In order to assess the phylogenetic relationships among different OTUs and the differences among the dominant species of different samples (groups), multiple sequence alignment was conducted using MUSCLE version 3.8.31 software [Edgar, 2004]. The abundance of each OTU was normalized using a standardized sequence number corresponding to the sample with the least sequences.

Analyses of the alpha and beta diversity values of the output normalized data were performed. Alpha diversity was applied to analyze the complexity of species diversity for a sample with the use of six indices (Observed-species, Chao1, Shannon, Simpson, ACE, and Good-coverage), as determined with the QIIME (version 1.7.0) open-source bioinformatics pipeline [Caporaso et al., 2010] and displayed with R software (version 2.15.3). Beta diversity analysis was used to evaluate differences in species complexity among the samples. The beta diversities of both weighted (quantitative) and unweighted (qualitative) UniFrac values were calculated with the use of QIME software (version 1.7.0).

Cluster analysis was preceded by principal component analysis, which was applied to reduce the dimension of the original variables using the FactoMineR package and ggplot2 package in R software (version 2.15.3). Principal coordinate analysis (PCoA) was performed to obtain and visualize principal coordinates from complex, multidimensional data. A distance matrix of weighted or un-weighted UniFrac values among samples was obtained and then transformed to a new set of orthogonal axes, by which the maximum variation factor was demonstrated by the first principal coordinate and the second by the second principal coordinate, and so on. PCoA analysis was conducted with the use of the WGCNA package, stat package, and ggplot2 package in R software (version 2.15.3). The clustering of unweighted pair-group method with
arithmetic means (UPGMA) was performed using QIIME software (version 1.7.0), as a type of hierarchical clustering method to interpret the distance matrix using average linkage values.
