Eastern equine encephalitis virus (EEEV) is perpetuated in an enzootic cycle involving *Culiseta melanura* mosquitoes and avian hosts. Other mosquito species that feed opportunistically on mammals have been incriminated as bridge vectors to humans and horses. To evaluate the capacity of these mosquitoes to acquire, replicate, and potentially transmit EEEV, we estimated the infection prevalence and virus titers in mosquitoes collected in Connecticut, USA, by cell culture, plaque titration, and quantitative reverse transcription–PCR. *Cs. melanura* mosquitoes were the predominant source of EEEV (83 [68%] of 122 virus isolations) and the only species to support consistently high virus titers required for efficient transmission. Our findings suggest that *Cs. melanura* mosquitoes are primary enzootic and epidemic vectors of EEEV in this region, which may explain the relative paucity of human cases. This study emphasizes the need for evaluating virus titers from field-collected mosquitoes to help assess their role as vectors.

During the past 6 years, eastern equine encephalitis virus (EEEV; family *Togaviridae*, genus *Alphavirus*) has reemerged in the northeastern United States and resulted in 26 human cases of infection and 9 deaths (ArboNET; Centers for Disease Control and Prevention, Atlanta, GA, USA). Virus transmission has intensified throughout this region, spread to locales where it had not been previously detected, and extended north into New Hampshire and Maine, USA, and Nova Scotia, Canada (1). Disease outbreaks caused by EEEV occur at irregular intervals when underlying ecologic conditions favor virus amplification and overflow into human and equine populations.

DOI: 10.3201/eid1612.100640
In Connecticut in 2009, EEEV activity increased substantially, and we isolated numerous viruses from *Cs. melanura* mosquitoes and potential bridge vectors. To evaluate the capacity of these mosquitoes to replicate and potentially transmit virus, we estimated EEEV titers from virus-positive mosquito pools with the expectation that the most efficient vectors will support consistently high virus titers.

**Materials and Methods**

**Mosquito Collections**

Mosquitoes were collected at 91 trapping locations statewide as a part of the Connecticut Mosquito and Arbovirus Surveillance Program during June–October 2009. Each trapping site was sampled on average weekly and at least every 10 days by means of CO2-baited Centers for Disease Control light traps and gravid traps that were operated overnight. Adult mosquitoes were transported back to the laboratory alive and sorted on chill tables by trap location and according to species by using taxonomic keys (19). Mosquitoes containing visible blood in the abdomen were removed and not included in this study. Mosquitoes were combined into pools of ≤50 individuals, placed in microcentrifuge tubes containing a copper BB, and stored at −70°C until virus testing.

**Virus Isolation and Identification**

Mosquitoes were homogenized in 1.0–1.5 mL of phosphate-buffered saline supplemented with 30% heat-inactivated rabbit serum, 0.5% gelatin, and antibacterial and antifungal drugs by using a vibration mill set for 4 min at 25 cycles/s. Homogenates were centrifuged at 4°C for 7 min at 520 × g, and 100 μL of the supernatant was plated on confluent Vero cells growing in 25-cm² flasks containing minimal essential media, 5% fetal bovine serum, and antibacterial and antifungal drugs. Cell cultures were maintained at 37°C in an atmosphere of 5% CO₂ and monitored daily for cytopathic effect during days 3–7 postinfection. Infected cell supernatants were harvested and stored at −80°C until virus testing.

Plaque titrations were performed on confluent Vero cell cultures growing in 12-well plates. Ten-fold dilutions of mosquito pool homogenates were placed in triplicate onto cell monolayers and absorbed for 1 h at 37°C in an atmosphere of 5% CO₂. Cells were overlaid with 1% methylcellulose in minimal essential medium, 5% fetal bovine serum, and antimicrobial and antifungal drugs and returned to the incubator. After 3 days, cells were fixed overnight in 7.4% formaldehyde and stained with 1% crystal violet so plaques could be visualized.

**Statistical Analyses**

The Pooled Infection Rate add-in for Excel (Microsoft, Redmond, WA, USA) was used to calculate virus infection rates (per 1,000 mosquitoes) and 95% confidence intervals (CIs) on the basis of maximum likelihood estimation (MLE) (22). All other statistical tests were performed by using Instat version 3.06 (GraphPad Software, San Diego, CA, USA). The Mann-Whitney U test was used for comparing median virus titers in pools for *Cs. melanura* mosquitoes and 6 other species from which a minimum of 3 positive pools were obtained (*Ae. cinereus, Anopheles punctipennis, Culex salinarius, Oc. canadensis, and Uranotaenia sapphirina* mosquitoes). The relationship between CI values and log_{10} virus titers were analyzed by regression analysis. Statistical significance was assigned at p<0.05 or by nonoverlapping 95% confidence intervals.

**Results**

In 2009, a total of 291,641 mosquitoes (35 species) were collected and processed as 16,909 pools for virus isolation. EEEV was isolated from 122 mosquito pools, which represented 14 species and 7 genera (Table), obtained during August 17–October 27 in 25 of 91 trapping locations. *Cs. melanura* mosquitoes yielded the greatest number of EEEV isolations (n = 83) and was followed by *Oc. canadensis* (n = 10) and *Ae. cinereus* (n = 6) mosquitoes. Relatively few (≤4) or no EEEV isolates were obtained from the remaining mosquito species. EEEV infection rates were higher in *Cs. melanura* mosquitoes (MLE 3.44, 95% CI 2.76–4.24) than in all other mosquito species tested except *An. quadrimaculatus* (MLE 3.27, 95% CI 0.59–10.55) and *Ur. sapphirina* (MLE 1.35, 95% CI 0.44–3.23) mosquitoes.
Mosquito pools that yielded EEEV in cell culture were directly tested by qRT-PCR. A total of 108 mosquito pools had positive C_t values (<37) on the basis of criteria established by Lambert et al. (20), 7 mosquito pools were equivocal (C_t 37.6–39.0), and 7 isolates failed to amplify after 50 amplification cycles. All mosquito pools that were negative or had C_t values >30 by qRT-PCR were retested in Vero cell culture and confirmed by reisolation of EEEV. Mean C_t values were lowest for Cs. melanura mosquitoes (C_t 22.3) and exceeded 30 for all other mosquito species (Table), which suggested species-specific differences in virus titer.

Concentration of infectious virus was estimated from positive mosquito pools by plaque titration in Vero cell culture. Cs. melanura mosquitoes had significantly higher virus titers (mean 6.55 log_{10} PFU/mosquito pool) than all other mosquito species for which statistical comparisons were possible (p<0.01 by Mann-Whitney U test). Ae. c. c. and Oc. canadensis had the next highest virus titers (2.92 log_{10} PFU/mosquito pool and 2.82 log_{10} PFU/mosquito pool, respectively), and mean titers ranged from <0.8 log_{10} PFU/mosquito pool to 1.69 log_{10} PFU/mosquito pool in the remaining species. The percentage of Cs. melanura mosquito pools with high virus titers (>3.0 log_{10} PFU/mosquito pool) was 88% compared with 0%–16.7% for the 13 other mosquito species (Table).

The relationship between C_t values and PFU estimated from EEEV-infected mosquito pools is shown in the Figure. A strong negative correlation was found between C_t values and PFU/mL in positive mosquito pools by regression analysis (slope −3.1, y-intercept 39; p<0.0001), which indicated a predictive relationship between these 2 measures of virus concentration.

Discussion

Our analysis of EEEV-positive mosquito pools showed major differences in virus titer among different mosquito species obtained in Connecticut. Cs. melanura was the only species in which titers developed that were associated with EEEV transmission, estimated to be 4–7 logs of virus in virus-transmitting mosquitoes in previous studies (23–25). This finding suggests that EEEV is transmitted primarily by Cs. melanura mosquitoes in this region of the northeastern United States, despite repeated virus isolations from other mosquito species.

Infrequent human and horse infections by EEEV may arise when Cs. melanura mosquitoes occasionally feed on mammals rather than by participation of another epidemic/eipizootic bridge vector. Prior studies identified mammalian-derived blood meals in 1%–10% of Cs. melanura mosquitoes obtained in Massachusetts, Connecticut, and New York (10,12,15) and provided a direct conduit for virus transmission by this species to horses and humans. These analyses, in conjunction with observations on vector longevity (26), vector competence (8,25,27), and prevalence of EEEV infection in Cs. melanura mosquitoes (ArboNET), suggest that this species could serve as an enzootic and epidemic/eipizootic bridge vector of EEEV. We provide additional support for this hypothesis by estimating virus titers in field-collected mosquitoes, which enabled us to determine which infected mosquitoes could potentially transmit virus.

In this study and previous studies, most EEEV isolations have been from either Cs. melanura or Cs. morsitans mosquitoes, depending on the region. These 2 species comprised 46%–100% of all isolations from field-collected mosquitoes in published studies (1,28–35) and 62%–92%
...occurs during periods of heavy rainfall. Host-seeking females feed mainly on mammals, including horses and humans and occasionally birds (11,14). This finding suggests that *Oc. canadensis* mosquitoes may be a bridge vector in Connecticut, but its relative contribution appears to be minor when virus titers in field-collected mosquito pools are considered. We detected high virus titers in only 1 pool of *Oc. canadensis* mosquitoes (3.2 log₁₀ PFU/mL), which is consistent with observations in which 0 of 2 EEEV-positive pools of *Oc. canadensis* mosquitoes contained high titers of virus (>3.0 log₁₀ PFU/mL) (17).

EEEV was also isolated from 6 *Ae. cinereus* mosquitoes, which represented the third most common source of virus. Of these pools, 1 contained high titers of virus (3.5 log₁₀ PFU/mL). This species may serve as a potential bridge vector on the basis of certain ecologic and behavioral criteria. Host-seeking females are abundant during June–October in many habitats throughout Connecticut (19). This species feeds opportunistically on mammals and birds but prefers mammals (11). The ability of this species to transmit EEEV has not been evaluated in the laboratory. Therefore, its contribution as a vector requires further evaluation.

We did not isolate EEEV from *Oc. sollicitans* or *Cq. perturbans*, 2 mosquito species implicated as likely bridge vectors in other epidemiologic settings (4,5,34,37). The eastern salt marsh mosquito, *Oc. sollicitans*, is an aggressive biter of humans that may transmit virus in the mid-Atlantic region but its coastal distribution does not overlap with that of human and equine cases in New England. *Cq. perturbans* mosquitoes are commonly trapped in Connecticut (35,389 females collected in 2009) and are found near EEEV foci. Host-seeking females emerge as 1 generation that peaks in early July and then decrease sharply by mid-August when EEEV begins to amplify in Connecticut (19). EEEV has been isolated from *Cq. perturbans* mosquitoes throughout the eastern United States, including Connecticut in other years (6,28,33,37) (ArboNET). In the study by Naisci and Mitchell (17), 13 (65%) of 20 pools of *Cq. perturbans* mosquitoes contained high titers of EEEV (>3.0 log₁₀ PFU/mL), which suggested a bridge role for this species. However, its low abundance in late August and September when EEE activity is greatest argues against its involvement as a primary epidemic vector in this region.

Our results obtained by qRT-PCR corresponded to those estimated by plaque titration, which provided a basis for interpreting C<sub>t</sub> values estimated directly from mosquito pools. On the basis of the fitted line estimated by regression analysis in the Figure, a C<sub>t</sub>=29.8 corresponded to virus titers >3.0 log₁₀ PFU/mL. We used this titer as a threshold for classifying low or high virus titers in mosquito pools for purposes of comparison and to discern whether a virus infection was established and replication occurred in the...
mosquito vector. Competent vectors must support virus replication during the extrinsic incubation period to be able to transmit virus. However, quantitative data for the minimum virus titer necessary for transmission are limited or absent for most virus-vector systems. Despite these uncertainties, investigations showed that mosquitoes transmitted virus when their body titers exceeded 4–5 logs of virus for EEEV (23–25) and western equine encephalitis virus (38,39). Virus transmission was usually associated with mosquitoes containing >5 logs of virus. However, some females with high virus titers failed to transmit virus in these studies. On the basis of these considerations, we believe that mosquito pools exhibiting low virus titers (<3.0 log10 PFU/mosquito pool) would be highly unlikely to contain mosquitoes capable of transmitting virus at the time of sampling, whereas detection of high virus titers does not necessarily predict that infected mosquitoes are capable of virus transmission. The strength of the data in our study is based on consistent detection of high virus titers from only 1 competent mosquito vector (Cs. melanura).

Most of the pools that showed EEEV in cell culture also showed positive results by qRT-PCR (C ≤37). However, our ability to reisolate EEEV from another 14 mosquito pools with either equivocal or negative results indicates that Vero cell culture is a highly sensitive assay for detection of EEEV. Mosquito pools containing infectious virus should be reconfirmed and quantified by another independent method; qRT-PCR is currently the most convenient method to accomplish this test.

Published data on virus titers from field-collected mosquitoes are currently limited to 1 study by Nasci and Mitchell (17), and their findings were consistent with our observations in Cs. melanura, Ae. vexans, and Oc. canadensis mosquitoes. Virus titer variation observed among mosquito species could reflect differences in vector competence. EEEV was shown to infect, replicate, and disseminate rapidly in Cs. melanura mosquitoes and was detected in the salivary glands 2–3 days after infection (25). Moreover, a larger proportion of Cs. melanura mosquitoes transmitted EEEV than Aedes, Anopheles, Coquillettidia, Culex, and Ochlerotatus mosquitoes in a direct laboratory comparison (8). Virus titers will also vary according to the duration of the extrinsic incubation period. One limitation of our study is that because we did not know the age structure of the mosquito population, we could not control this variable.

Low virus titers may have also been caused by contamination of infected mosquito fragments during sorting and testing procedures. Although we cannot preclude this possibility, we made concerted efforts to ensure accurate testing. Mosquitoes were sorted into mosquito pools on chill tables, and mosquito pools were processed for virus isolation in a separate facility according to standard practices. EEEV-positive pools were directly tested and quantified by using 2 independent tests (plaque titration and qRT-PCR). Our results were consistent with those of other studies (1,28–35), which showed that most EEEV isolations were from Cs. melanura mosquitoes and several other mosquito species.

Our findings highlight the need to consider virus titer when interpreting virus isolation or PCR detection data for field-collected mosquitoes. Although we isolated EEEV from several mosquito species, Cs. melanura was the only species that had consistently high titers of EEEV sufficient for transmission. This finding may help reconcile the paucity of symptomatic human and equine cases, despite frequent detection or isolation of virus from mammalophilic mosquitoes during episodes of virus amplification. These results should be verified in other regions, where involvement of other locally abundant mosquitoes is suspected during disease outbreaks. When information on virus titers in mosquitoes is considered, the number of candidate vectors may be reduced to a few key species that are capable of supporting virus transmission in nature.
