Classification and Reconstruction of High-Dimensional Signals from Low-Dimensional Noisy Features in the Presence of Side Information

Francesco Renna, Liming Wang, Xin Yuan, Jianbo Yang, Galen Reeves, Robert Calderbank, Lawrence Carin, and Miguel R. D. Rodrigues

Abstract

This paper offers a characterization of fundamental limits in the classification and reconstruction of high-dimensional signals from low-dimensional features, in the presence of side information. In particular, we consider a scenario where a decoder has access both to noisy linear features of the signal of interest and to noisy linear features of the side information signal; while the side information may be in a compressed form, the objective is recovery or classification of the primary signal, not the side information. We assume the signal of interest and the side information signal are drawn from a correlated mixture of distributions/components, where each component associated with a specific class label follows a Gaussian mixture model (GMM).

By considering bounds to the misclassification probability associated with the recovery of the underlying class label of the signal of interest, and bounds to the reconstruction error associated with the recovery of the signal of interest itself, we then provide sharp sufficient and/or necessary conditions for the phase transition of these quantities in the low-noise regime. These conditions, which are reminiscent of the well-known Slepian-Wolf and Wyner-Ziv conditions, are a function of the number of linear features extracted from the signal of interest, the number of linear features extracted from the side information signal, and the geometry of these signals and their interplay.

Our framework, which also offers a principled mechanism to integrate side information in high-dimensional data problems, is also tested in the context of imaging applications. In particular, we report state-of-the-art results in compressive hyperspectral imaging applications, where the accompanying side information is a conventional digital photograph.

I. INTRODUCTION

A significant focus of recent research concerns approaches to represent and extract the salient information of a high-dimensional signal from low-dimensional signal features. Methods such as feature extraction, supervised dimensionality reduction and unsupervised dimensionality reduction have thus been the object of study of various disciplines [1]–[4].

Linear dimensionality reduction methods based on the second-order statistics of the source have been developed, such as linear discriminant analysis (LDA) [1] or principal component analysis (PCA) [1]. Linear dimensionality reduction methods based on higher-order statistics of the data have also been developed [5]–[17]. In particular, an information-theoretic supervised approach, which uses the mutual information [5], [6] or approximations of the mutual information, such as quadratic mutual information (with quadratic Rényi entropy) [8], [13], [14] as a criterion to linearly reduce dimensionality, have been shown to lead to state-of-the-art classification and reconstruction results. A generalization of Bregman divergence has also been used to express in a unified way the gradient of mutual information for Gaussian and Poisson channels, thus enabling efficient projection design for both signal classification and reconstruction [18], [19]. In addition, nonlinear (supervised) dimensionality reduction methods have also become popular recently [20], [21].

Compressive sensing (CS) – a signal acquisition paradigm that offers the means to simultaneously sense and compress a signal without any (or minimal) loss of information [22]–[27] – also seeks to extract a set of low-dimensional features from a high-dimensional signal. In particular, this emerging paradigm shows that it is possible to perfectly reconstruct an \(n\)-dimensional \(s\)-sparse signal (sparse in some orthonormal dictionary or frame) with overwhelming probability with only \(O(s \log(n/s))\) linear random measurements or projections [22], [24], [27] using tractable \(\ell_1\) minimization methods [26] or iterative methods, like greedy matching pursuit [28]–[30]. Generalizations of the compressive sensing paradigm to settings where one wishes to perform other signal processing operations in the compressive domain, such as detection and classification, have also become popular recently [31].

These dimensionality-reduction methods often attempt to explore structure in the signal, to aid in the dimensionality reduction process. Some prominent models that are used to capture the structure of a high-dimensional signal include union-of-subspaces [32]–[35], wavelet trees [32], [36] and manifolds [37], [38]. A signal drawn from a union-of-subspaces is assumed to lie in one out of a collection of \(K\) linear subspaces with dimension less than or equal to \(s\). By leveraging such structure, reliable reconstruction can be performed with a number of projections of the order \(O(s + \log(2K))\) [32] by using mixed \(\ell_2/\ell_1\)-norm approaches [34]. Tree models are usually adopted in conjunction with wavelet dictionaries, as they leverage the property that non-zero coefficients of wavelet transforms of smooth signals or images are usually organized in a rooted, connected tree [39]. In this case, the number of features needed for reliable reconstruction can be reduced to \(O(s)\) [36]. Finally, manifold structures are shown to
provide perfect recovery with a number of projections that grows linearly with the dimension of the manifold \( s \), logarithmically with the product of signal size \( n \) and parameters that characterize the volume and the regularity of the manifold \([37]\).

However, it is often the case that one is also presented at the encoder, at the decoder, or at both with additional information – known as side information – beyond signal structure, in the form of another signal that exhibits some correlation with the signal of interest. The key question concerns how to leverage side information to enhance the classification and reconstruction of high-dimensional signals from low-dimensional features. This paper proposes to study this aspect by using models that capture key attributes of high-dimensional signals, namely the fact that such signals often live on a union of low-dimensional subspaces or affine spaces, or on a union of approximately low-dimensional spaces. The high-dimensional signal to be measured and the side information are assumed to have distinct low-dimensional representations of this type, with shared or correlated latent structure.

A. Related Work

Our problem connects to source coding with side information and distributed source coding, as the number of features extracted from high-dimensional signals can be related to the compression rate, whereas performance metrics for classification and reconstruction can be related to distortion. The foundations of distributed source coding theory were laid by Slepian and Wolf \([40]\), whereas those of source coding with side information by Ahlswede and Körner \([41]\), and by Wyner and Ziv \([42]\). Namely, \([40]\) characterized the rates at which two discrete input sources can be compressed independently by guaranteeing lossless reconstruction at the decoder side. Perhaps surprisingly, the rates associated with independent compression at the two sources are shown to be identical to those associated with joint compression at the encoders. On the other hand, \([41]\) determined the rate at which a discrete source input can be compressed without losses in the presence of coded side information. In the lossy compression case, Wyner and Ziv \([42]\) proposed an encoding scheme to achieve the optimum tradeoff between compression rate and distortion when side information is available at the decoder. In contrast with the result in \([40]\), they proved that lossy compression without side information at the encoder suffers in general a rate loss compared to lossy compression with side information both at the encoder and the decoder \([43]\). However, such loss was shown to be vanishingly small for the case of memoryless Gaussian sources and squared-error distortion metrics \([42]\).

Our problem also relates to the problems of compressive sensing with side information/prior information \([44]-[49]\), distributed compressive sensing \([50]-[56]\) and multi-task compressive sensing \([57]\). The problem of compressive sensing with side information or prior information entails the reconstruction of a sparse signal in the presence of partial information about the desired signal, using reconstruction algorithms akin to those from CS. For example, \([44]\), \([45]\) consider the reconstruction of a signal by leveraging partial information about the support of the signal at the decoder side; \([46]\) considers the reconstruction of the signal by using an additional noisy version of the signal at the decoder side. \([47]\) takes the side information to be associated with the previous scans of a certain subject in dynamic tomographic imaging. In this case, \( \ell_1 \)-norm based minimization is used for recovery, by adding an additional term that accounts for the distance between the recovered image and the side information snapshot.
A similar approach has been adopted recently in [48], that is shown to require a smaller number of measurements
than traditional CS in recovering magnetic resonance images. A theoretical analysis of the number of measurements
sufficient for reliable recovery with high probability in the presence of side information for both $\ell_1/\ell_1$ and mixed
$\ell_1/\ell_2$ reconstruction strategies is provided in [49].

The problem of distributed compressive sensing, which has been considered by [50]–[56], involves the joint
reconstruction of multiple correlated sparse signals. In [50], [51] necessary and sufficient conditions on the minimum
number of measurements needed for perfect recovery (via $\ell_0$-norm minimization) are derived. Multiple signals are
described there via joint sparsity models that involve a common component for all signals and innovation components
specific to each signal. [53] also provides conditions on the number of measurements for approximately zero-
distortion recovery using an inversion procedure based on a generalized, multi-terminal approximate message passing
(AMP) algorithm. Reconstruction via AMP methods for distributed CS was also considered in [54], where the
minimum number of measurements needed for successful signal recovery was derived assuming that measurements
extracted from different signals are spatially coupled. Reconstruction obtained via $\ell_1$-norm minimization methods is
considered in [55], where restricted isometry property (RIP) conditions for block-diagonal, random linear projection
matrices are discussed. Namely, such matrices are shown to verify the RIP if the total number of rows scales linearly
with the signal sparsity $s$ and poly-logarithmically with the signal ambient dimension $n$. [56] considers the problem
of distributed recovery of two signals that are related through a sparse time-domain filtering operation, and it derives
sufficient conditions on the number of samples needed for reliable recovery as well as a computationally-efficient
reconstruction algorithm.

Multi-task compressive sensing [57] involves the description of multiple signals through a hierarchical Bayesian
framework, where a prior is imposed on the wavelet coefficients for the different signals. Such a prior is inferred
statistically from features extracted from the data and then used in the recovery process, thus demonstrating
reconstruction reliability and robustness with various types of experimental data.

B. Contributions

This paper studies the impact of side information on the classification and reconstruction of a high-dimensional
signal from low-dimensional, noisy, linear and random features, by assuming that both the signal of interest and
the side information are drawn from a joint Gaussian mixture model (GMM). Unlike distributed and multi-task CS,
here we are generally only interested in recovering or classifying the primary signal, and not necessarily interested
in recovering the underlying side information that is represented compressively.

There are multiple reasons for adopting a GMM representation, which is often used in conjunction with the
Bayesian CS formalism [58]:

- A GMM model represents the Bayesian counterpart of well-known high-dimensional signal models in the
  literature [32]–[35], [38]. In particular, signals drawn from a GMM can be seen to lie in a union of (linear
  or affine) subspaces, where each subspace is associated with the translation of the image of the (possibly
  low-rank) covariance matrix of each Gaussian component within the GMM. Moreover, low-rank GMM priors
have been shown to approximate signals in compact manifolds \[38\]. Also, a GMM can represent complex distributions subject to mild regularity conditions \[59\].

- A GMM model has also been shown to provide state-of-the-art results in practical problems in image processing \([60]–[62]\), dictionary learning \([38]\), image classification \([6]\) and video compression \([63]\).

- Optimal inversion of GMM sources from noisy, linear features can be performed via a closed-form classifier or estimator, which has computational complexity proportional to the number of Gaussian classes within the GMM. Moreover, moderate numbers of classes have been shown to model reliably real-world data as, for example, patches extracted from natural images or video frames \([5]\), \([63]\), \([64]\).

Of particular relevance, the adoption of GMM priors also offers an opportunity to analyze phase transitions in the classification or reconstruction error: in particular, and in line with the contributions in \([64]–[67]\), it is possible to adopt wireless communications-inspired metrics, akin to the diversity gain or the measurement gain \([68]\), \([69]\), in order to characterize performance more finely in certain asymptotic regimes.

Our main contributions, which generalize the analysis carried out in \([64]\), \([67]\) to the scenario where the decoder has access to side information, include:

- The definition of a joint GMM model both for the signal of interest and the side information, that generalizes the joint sparsity models in \([50]\), \([51]\).

- Sufficient conditions for perfect signal classification in the asymptotic limit of low-noise that are a function of the geometry of the signal of interest, the geometry of the side information, their interaction, and the number of features.

- Sufficient and necessary conditions for perfect signal reconstruction in the asymptotic limit of low-noise that are also a function of the geometries of the signal of interest, the side information, as well as the number of features.

- A range of results that illustrate not only how theory aligns with practice, but also how to use the ideas in real-world applications, such as high-resolution image reconstruction and compressive hyperspectral imaging in the presence of side information (here a traditional photograph constitutes the side information).

These contributions differ from other contributions in the literature in various aspects. Unlike previous works on the characterization of the minimum number of measurements needed for reliable reconstruction in distributed compressive sensing \([50]\), \([51]\), our Bayesian framework allows consideration of signals with different sizes that are sparse over different bases; our model also allows characterization of phase transitions in the classification error and in the reconstruction error. In addition, and unlike previous studies in the literature associated with \(\ell_1\)-norm minimization or AMP algorithms for reconstruction, the analysis carried out in this work is also valid in the finite signal length regime, providing a sharp characterization of signal processing performance as a function of the number of features extracted from both the input and the side information. To the best of our knowledge, this work represents the first contribution in the context of structured or model-based CS to consider both classification and reconstruction of signals in the presence of side information.
C. Organization

The remainder of the paper is organized as follows: Section II defines the signal and the system model used throughout the article. Section III provides results for classification with side information, containing an analysis of an upper bound to the misclassification probability, that also leads to a characterization of sufficient conditions for the phase transition in the misclassification probability. Section IV provides results for reconstruction with side information, most notably sufficient and necessary conditions for the phase transition in the reconstruction error in the asymptotic limit of low-noise; the sufficient and necessary conditions differ within a single measurement. Section V highlights the relation between classification/reconstruction with side information and distributed classification/reconstruction. Numerical examples both with synthetic and real data are presented in Section VI. Finally, conclusions are drawn in Section VII. The Appendices contain the proofs of the main theorems.

D. Notation

In the remainder of the paper, we adopt the following notation: boldface upper-case letters denote matrices (X) and boldface lower-case letters denote column vectors (x); the context defines whether the quantities are deterministic or random. The symbols $I_n$ and $0_{m \times n}$ represent the identity matrix of dimension $n \times n$ and the all-zero-entries matrix of dimension $m \times n$, respectively (subscripts will be dropped when the dimensions are clear from the context). $(\cdot)^T$, tr$(\cdot)$, rank$(\cdot)$ represent the transpose, trace and the rank operators, respectively. $(\cdot)^{\dagger}$ represents the Moore-Penrose pseudoinverse of a matrix. Im$(\cdot)$ and Null$(\cdot)$ denote the (column) image and null space of a matrix, respectively, and dim$(\cdot)$ denotes the dimension of a linear subspace. $E[\cdot]$ represents the expectation operator. The Gaussian distribution with mean $\mu$ and covariance matrix $\Sigma$ is denoted by $\mathcal{N}(\mu, \Sigma)$. The symbol Cov$(\cdot)$ denotes the covariance matrix of a given random vector.

II. Model

We consider both the classification and reconstruction of a high-dimensional signal from noisy linear features in the presence of side information, as shown in Fig. 1. In particular, we assume that the decoder has access to a set of noisy linear features $y_1 \in \mathbb{R}^{m_1}$ associated with the desired signal $x_1 \in \mathbb{R}^{n_1}$ given by:

$$y_1 = \Phi_1 x_1 + w_1,$$  \hspace{1cm} (1)

where $\Phi_1 \in \mathbb{R}^{m_1 \times n_1}$ is the projection kernel and $w_1 \sim \mathcal{N}(0, I \sigma^2)$ is additive Gaussian noise that models possible distortion introduced by the feature extraction system (or model mismatch). We also assume that the decoder has access to another set of features $y_2 \in \mathbb{R}^{m_2}$ – called side information – associated with another signal $x_2 \in \mathbb{R}^{n_2}$ given by:

$$y_2 = \Phi_2 x_2 + w_2,$$ \hspace{1cm} (2)

1 In the remainder of the paper, we will use interchangeably the terms projection/measurement/sensing kernel or matrix.
where $\Phi_2 \in \mathbb{R}^{m_2 \times n_2}$ is the projection kernel associated with the side information and $w_2 \sim \mathcal{N}(0, \sigma^2)$ is Gaussian additive noise, which is assumed to have the same covariance as the noise $w_1$, for simplicity. For the sake of compact notation, we often re-write the models in (1) and (2) as:

$$y = \Phi x + w,$$

where

$$x = \begin{bmatrix} x_1 \\ x_2 \end{bmatrix}, \quad y = \begin{bmatrix} y_1 \\ y_2 \end{bmatrix}, \quad w = \begin{bmatrix} w_1 \\ w_2 \end{bmatrix}$$

and

$$\Phi = \begin{bmatrix} \Phi_1 & 0 \\ 0 & \Phi_2 \end{bmatrix}.$$

We focus on random projection kernels, where both matrices $\Phi_1$ and $\Phi_2$ are assumed to be drawn from left rotation-invariant distributions. We consider underlying class labels $C_1 \in \{1, \ldots, K_1\}$ and $C_2 \in \{1, \ldots, K_2\}$, where $C_1$ is associated with the signal of interest $x_1$ and $C_2$ is associated with the side information signal $x_2$. We assume that $x_1$ and $x_2$, conditioned on the underlying class labels $C_1 = i$ and $C_2 = k$, are drawn from a joint distribution $p(x_1, x_2|C_1 = i, C_2 = k)$, with the class labels drawn from probability $p_{C_1, C_2}(i, k)$. We assume that the decoder, for both classification and reconstruction purposes, knows perfectly the joint probability mass function (pmf) $p_{C_1, C_2}(i, k)$ of the discrete random variables corresponding to the class labels of $x_1$ and $x_2$, and the conditional distributions $p(x_1, x_2|C_1 = i, C_2 = k)$. For the problem of classification with side information, the objective is to estimate the value of the

---

2This assumption carries no loss of generality, because the following analysis holds even if we rescale $y_2$ by a factor equal to the ratio between the noise variances associated with $w_1$ and $w_2$.

3A random matrix $A \in \mathbb{R}^{m \times n}$ is said to be (left or right) rotation-invariant if the joint probability density function (pdf) of its entries $p(A)$ satisfies $p(\Theta A) = p(A)$, or $p(A \Psi) = p(A)$, respectively, for any orthogonal matrix $\Theta$ or $\Psi$. A special case of (left and right) rotation-invariant random matrices is represented by matrices with independent identically distributed (i.i.d.), zero-mean Gaussian entries with fixed variance.
index $C_1$ that identifies the distribution/component from which $x_1$ was drawn, on the basis of the observation of both vectors $y_1$ and $y_2$. The minimum average error probability in classifying $C_1$ from $y_1$ and $y_2$ is achieved by the maximum a posteriori (MAP) classifier \( \hat{C}_1 \), given by

\[
\hat{C}_1 = \arg \max_{i \in \{1, \ldots, K_1\}} p(C_1 = i | y_1, y_2)
\]

\[
= \arg \max_{i \in \{1, \ldots, K_1\}} \sum_{k=1}^{K_2} p_{C_1, C_2}(i, k)p(y_1, y_2|C_1 = i, C_2 = k), \tag{6}
\]

where $p(C_1 = i | y_1, y_2)$ is the a posteriori probability of class $C_1 = i$ conditioned on $y_1$ and $y_2$.

For the problem of reconstruction with side information, the objective of the decoder is to estimate the signal $x_1$ from the observation of $y_1$ and $y_2$. In particular, we consider reconstruction obtained via the conditional mean estimator

\[
\hat{x}_1(y_1, y_2) = E[x_1|y_1, y_2] = \int x_1 p(x_1|y_1, y_2) dx_1, \tag{8}
\]

where $p(x_1|y_1, y_2)$ is the posterior pdf of $x_1$ given the observations $y_1$ and $y_2$, which minimizes the reconstruction error.

We emphasize the key distinction between the previously studied problems of distributed \cite{50,51} or multi-task compressive sensing \cite{57}: our goal is to recover $x_1$ or its label $C_1$, based upon compressive $y_1$ and $y_2$, while previous work considered joint recovery of $x_1$ and $x_2$ (or joint estimation of $C_1$ and $C_2$). Note that our theory allows the special case for which $\Phi_2$ is the identity matrix, in which case $y_2 = x_2$ and the side information is not measured compressively. In addition, and more closely connected to previous work, we will consider the objectives of jointly determining the pair of index values $(C_1, C_2)$ that identify the distributions/components\(^4\) from which $x_1$ and $x_2$ were drawn, in the case of classification, and to estimate jointly $x_1$ and $x_2$, in the case of reconstruction. The solution to these latter problems follows immediately from the solution to the side information problems. Moreover, as is evident from \cite{3}, the distributed classification and reconstruction problem can be mapped into a standard classification or reconstruction problem of a single signal, in which we are forcing the sensing matrix to obey a block diagonal structure.

### A. Signal, Side Information and Correlation Models

The key aspect now relates to the definition of the signal, side information, and the respective correlation models. In particular, we adopt a multivariate Gaussian model for the distribution of $x_1$ and $x_2$, conditioned on $(C_1, C_2) = (i, k)$, i.e.

\[
p(x_1, x_2|C_1 = i, C_2 = k) = \mathcal{N}(\mu_x^{(ik)}, \Sigma_x^{(ik)}), \tag{9}
\]

\(^4\)In the remainder of the paper we will also call $C_1$ and $C_2$ the classes associated to the input and side information signals, respectively.
where
\[
\mu^{(ik)} = \begin{bmatrix} \mu_{\mathbf{x}_1}^{(ik)} \\ \mu_{\mathbf{x}_2}^{(ik)} \end{bmatrix}, \quad \Sigma^{(ik)} = \begin{bmatrix} \Sigma_{\mathbf{x}_1}^{(ik)} & \Sigma_{\mathbf{x}_1,\mathbf{x}_2}^{(ik)} \\ \Sigma_{\mathbf{x}_1,\mathbf{x}_2}^{(ik)} & \Sigma_{\mathbf{x}_2}^{(ik)} \end{bmatrix},
\]
so that \( p(x_1|C_1 = i, C_2 = k) = \mathcal{N}(\mu_{\mathbf{x}_1}^{(ik)}, \Sigma_{\mathbf{x}_1}^{(ik)}) \) and \( p(x_2|C_1 = i, C_2 = k) = \mathcal{N}(\mu_{\mathbf{x}_2}^{(ik)}, \Sigma_{\mathbf{x}_2}^{(ik)}) \), where \( \mu_{\mathbf{x}_1}^{(ik)} \) and \( \Sigma_{\mathbf{x}_1}^{(ik)} \) are the mean and covariance matrix of \( \mathbf{x}_1 \) conditioned on the pair of classes \((i, k)\), respectively, \( \mu_{\mathbf{x}_2}^{(ik)} \) and \( \Sigma_{\mathbf{x}_2}^{(ik)} \) are the mean and covariance matrix of \( \mathbf{x}_2 \) conditioned on the pair of classes \((i, k)\), respectively, and \( \Sigma_{\mathbf{x}_1,\mathbf{x}_2}^{(ik)} \) is the cross-covariance matrix between \( \mathbf{x}_1 \) and \( \mathbf{x}_2 \) conditioned on the pair of classes \((i, k)\).

The motivation for this choice is associated by the fact that this apparently simple model can accommodate a wide range of signal distributions. In fact, note that the joint pdf of \( \mathbf{x}_1 \) and \( \mathbf{x}_2 \) follows a GMM model:
\[
p(x_1, x_2) = \sum_{i=1}^{K_1} \sum_{k=1}^{K_2} p_{C_1,C_2}(i, k)p(x_1, x_2|C_1 = i, C_2 = k),
\]
so that we can in principle approximate very complex distributions by incorporating additional terms in the decomposition [59]. Note also that the conditional marginal pdfs of \( \mathbf{x}_1 \) and \( \mathbf{x}_2 \) also follow GMM models:
\[
p(x_1|C_1 = i) = \sum_{k=1}^{K_2} p_{C_1|C_2}(k|i) \int dx_2 p(x_1, x_2|C_1 = i, C_2 = k)
\]
\[
= \sum_{k=1}^{K_2} p_{C_1|C_2}(k|i) \mathcal{N}(\mu_{\mathbf{x}_1}^{(ik)}, \Sigma_{\mathbf{x}_1}^{(ik)})
\]
and
\[
p(x_2|C_2 = k) = \sum_{i=1}^{K_1} p_{C_1|C_2}(i|k) \int dx_1 p(x_1, x_2|C_1 = i, C_2 = k)
\]
\[
= \sum_{i=1}^{K_1} p_{C_1|C_2}(i|k) \mathcal{N}(\mu_{\mathbf{x}_2}^{(ik)}, \Sigma_{\mathbf{x}_2}^{(ik)}),
\]
where \( p_{C_1|C_2}(k|i) = \frac{p_{C_1,C_2}(i,k)}{p_{C_1}(i)} \) and \( p_{C_1|C_2}(i|k) = \frac{p_{C_1,C_2}(i,k)}{p_{C_2}(k)} \) are the conditional pmfs of \( C_2 \) and \( C_1 \). Therefore, our model naturally subsumes the standard GMM models used in the literature to deliver state-of-the-art results in reconstruction and classification problems, hyperspectral imaging and digit recognition applications [6].

We also adopt a framework that allows common and innovative components in the representation of \( \mathbf{x}_1 \) and \( \mathbf{x}_2 \) conditioned on \((C_1, C_2) = (i, k)\), generalizing the one in [50], [51]. In particular, note that
\[
p(x_1, x_2|C_1 = i, C_2 = k) = \mathcal{N}(\mu_{\mathbf{x}}^{(ik)}, \Sigma_{\mathbf{x}}^{(ik)})
\]
is equivalent to expressing \( \mathbf{x}_1 \) and \( \mathbf{x}_2 \) conditioned on the pair of classes \((i, k)\) as
\[
\mathbf{x}_1 = \mathbf{x}_{c_1} + \mathbf{x}_{1}^{(ik)} = \mathbf{P}_{c_1}^{(ik)} \mathbf{z}_c + \mathbf{P}_1^{(ik)} \mathbf{z}_1 + \mu_{\mathbf{x}_1}^{(ik)}
\]
\[
\mathbf{x}_2 = \mathbf{x}_{c_2} + \mathbf{x}_{2}^{(ik)} = \mathbf{P}_{c_2}^{(ik)} \mathbf{z}_c + \mathbf{P}_2^{(ik)} \mathbf{z}_2 + \mu_{\mathbf{x}_2}^{(ik)}
\]
for an appropriate choice of the matrices \( \mathbf{P}_{c_1}^{(ik)} \in \mathbb{R}^{n_1 \times s_1^{(ik)}} \), \( \mathbf{P}_{c_2}^{(ik)} \in \mathbb{R}^{n_2 \times s_1^{(ik)}} \), \( \mathbf{P}_1^{(ik)} \in \mathbb{R}^{n_1 \times s_1^{(ik)}} \), \( \mathbf{P}_2^{(ik)} \in \mathbb{R}^{n_2 \times s_2^{(ik)}} \).
and where the vectors \( \mathbf{z}_c \sim \mathcal{N}(0, \mathbf{I}_{\varsigma_e}) \), \( \mathbf{z}_1 \sim \mathcal{N}(0, \mathbf{I}_{\varsigma_{s_1}}) \) and \( \mathbf{z}_2 \sim \mathcal{N}(0, \mathbf{I}_{\varsigma_{s_2}}) \) are independent. Note that (17) and (18) correspond to a factor or union-of-subspace model; the vector \( \mathbf{z}_c \) characterizes a shared latent process, and \( \mathbf{P}_{c_1}^{(ik)} \) and \( \mathbf{P}_{c_2}^{(ik)} \) are linear subspaces (dictionaries) that are a function of the properties of the signal and side information, respectively. The vectors \( \mathbf{z}_1 \) and \( \mathbf{z}_2 \) are distinct latent processes, associated with respective linear subspaces \( \mathbf{P}_1^{(ik)} \) and \( \mathbf{P}_2^{(ik)} \). So the model may be viewed from the perspective of generalizing previous union-of-subspaces models [32]–[35].

In our scenario, the covariance matrix of \( \mathbf{x}_1 \) and \( \mathbf{x}_2 \) conditioned on the pair of classes \((i, k)\) can be also written as \( \Sigma_{\mathbf{x}}^{(ik)} = \mathbf{P}^{(ik)} (\mathbf{P}^{(ik)})^T \), with

\[
\mathbf{P}^{(ik)} = \begin{bmatrix} \mathbf{P}_{c_1}^{(ik)} & \mathbf{P}_1^{(ik)} & 0 \\ \mathbf{P}_{c_2}^{(ik)} & 0 & \mathbf{P}_2^{(ik)} \end{bmatrix},
\]

where \( \mathbf{P}_{c_1}^{(ik)} \), \( \mathbf{P}_{c_2}^{(ik)} \), \( \mathbf{P}_1^{(ik)} \) and \( \mathbf{P}_2^{(ik)} \) are such that

\[
\Sigma_{\mathbf{x}_1}^{(ik)} = \mathbf{P}_{c_1}^{(ik)} (\mathbf{P}_{c_1}^{(ik)})^T + \mathbf{P}_1^{(ik)} (\mathbf{P}_1^{(ik)})^T, \quad \Sigma_{\mathbf{x}_2}^{(ik)} = \mathbf{P}_{c_2}^{(ik)} (\mathbf{P}_{c_2}^{(ik)})^T + \mathbf{P}_2^{(ik)} (\mathbf{P}_2^{(ik)})^T, \quad \Sigma_{\mathbf{x}_{12}}^{(ik)} = \mathbf{P}_{c_1}^{(ik)} (\mathbf{P}_{c_2}^{(ik)})^T.
\]

We refer to the vectors \( \mathbf{x}_{c_1} \sim \mathcal{N}(0, \mathbf{P}_{c_1}^{(ik)} (\mathbf{P}_{c_1}^{(ik)})^T) \) and \( \mathbf{x}_{c_2} \sim \mathcal{N}(0, \mathbf{P}_{c_2}^{(ik)} (\mathbf{P}_{c_2}^{(ik)})^T) \) as the common components: these components of \( \mathbf{x}_1 \) and \( \mathbf{x}_2 \) are correlated, as they are obtained as linear combinations of atoms in two different dictionaries (the columns of \( \mathbf{P}_{c_1}^{(ik)} \) and \( \mathbf{P}_{c_2}^{(ik)} \), respectively) but with the same weights, that are contained in the vector \( \mathbf{z}_c \), and therefore can be seen to model some underlying phenomena common to both \( \mathbf{x}_1 \) and \( \mathbf{x}_2 \) (conditioned on the classes). On the other hand, we refer to \( \mathbf{x}_1' \sim \mathcal{N}(0, \mathbf{P}_1^{(ik)} (\mathbf{P}_1^{(ik)})^T) \) and \( \mathbf{x}_2' \sim \mathcal{N}(0, \mathbf{P}_2^{(ik)} (\mathbf{P}_2^{(ik)})^T) \) as innovation components: these components are statistically independent and thus can be seen to model phenomena specific to \( \mathbf{x}_1 \) and \( \mathbf{x}_2 \) (conditioned on the classes).

Therefore, we can now express the ranks of the matrices appearing in the model in (10) as a function of ranks of the matrices appearing in the models in (17) and (18) as follows:

\[
k_{\mathbf{x}_1}^{(ik)} = \text{rank}(\Sigma_{\mathbf{x}_1}^{(ik)}) = \text{rank}(|\mathbf{P}_{c_1}^{(ik)} \mathbf{P}_1^{(ik)}|) \]

which represents the dimension of the subspace spanned by input signals \( \mathbf{x}_1 \) drawn from the Gaussian distribution

---

5Note that the common and innovation component representation proposed here is redundant, i.e., there are various choices of matrices \( \mathbf{P}_{c_1}^{(ik)}, \mathbf{P}_{c_2}^{(ik)}, \mathbf{P}_1^{(ik)}, \mathbf{P}_2^{(ik)} \) that satisfy (20). We also emphasize that the results obtained in the following analysis hold irrespective of the particular choice of the matrices \( \mathbf{P}_{c_1}^{(ik)}, \mathbf{P}_{c_2}^{(ik)}, \mathbf{P}_1^{(ik)}, \mathbf{P}_2^{(ik)} \) that satisfy (20). Then, although the adoption of the common and innovation component representation is not required to prove the results contained in this work, we leverage such representation in order to give a clear interpretation of the interaction between \( \mathbf{x}_1 \) and \( \mathbf{x}_2 \) and to underline the connection of our work with previous results in the literature.

6The representation in (17) and (18) is reminiscent of the joint sparsity models JSM-1 and JSM-3 in [50], where signals sensed by multiple sensors were also described in terms of the sum of a common component plus innovation components. However, fundamental differences characterize our formulation with respect to such models: i) we consider a Bayesian framework in which the input signal and side information signal are picked from a mixture of components, where each component is described by a GMM distribution, whereas in JSM-1 and JSM-3 all the components are deterministic; ii) in our model, the common components are correlated, but they are not exactly the same for \( \mathbf{x}_1 \) and \( \mathbf{x}_2 \), as it is instead for signals in JSM-1 and JSM-3; iii) in our case, the common and innovation components can be sparse over four different bases, corresponding to the ranges of the matrices \( \mathbf{P}_{c_1}^{(ik)}, \mathbf{P}_{c_2}^{(ik)}, \mathbf{P}_1^{(ik)} \) and \( \mathbf{P}_2^{(ik)} \); on the other hand, all signals in JSM-1 and JSM-3 are assumed to be sparse over the same basis.
corresponding to the indices $C_1 = i, C_2 = k$;

\[ r_{x_2}^{(ik)} = \text{rank}(\Sigma_{x_2}) = \text{rank}[P_{c_2}^{(ik)} P_2^{(ik)}] \]  

(22)

which represents the dimension of the subspace spanned by side information signals $x_2$ drawn from the Gaussian distribution corresponding to the indices $C_1 = i, C_2 = k$;

\[ r_{x_1}^{(ik,j\ell)} = \text{rank}(\Sigma_{x_1}^{(ik)} + \Sigma_{x_2}^{(j\ell)}) = \text{rank}[P_{c_1}^{(ik)} P_{c_1}^{(j\ell)} P_1^{(ik)} P_1^{(j\ell)}] \]  

(23)

which represents the dimension of the sum of the subspaces spanned by input signals drawn from the Gaussian distribution corresponding to the indices $C_1 = i, C_2 = k$ and those from the Gaussian distribution corresponding to the indices $C_1 = j, C_2 = \ell$;

\[ r_{x_2}^{(ik,j\ell)} = \text{rank}(\Sigma_{x_2}^{(ik)} + \Sigma_{x_2}^{(j\ell)}) = \text{rank}[P_{c_2}^{(ik)} P_{c_2}^{(j\ell)} P_2^{(ik)} P_2^{(j\ell)}] \]  

(24)

which represents the dimension of the sum of the subspaces spanned by side information signals drawn from the Gaussian distribution corresponding to the indices $C_1 = i, C_2 = k$ and those from the Gaussian distribution corresponding to the indices $C_1 = j, C_2 = \ell$; and finally, the corresponding dimensions spanned collectively by input and side information signals are given by

\[ r_{x}^{(ik)} = \text{rank}(\Sigma_{x}^{(ik)}) = \text{rank} \begin{bmatrix} P_{c_1}^{(ik)} & P_1^{(ik)} & 0 \\ P_{c_2}^{(ik)} & 0 & P_2^{(ik)} \end{bmatrix} \]  

(25)

\[ r_{x}^{(ik,j\ell)} = \text{rank}(\Sigma_{x}^{(ik)} + \Sigma_{x}^{(j\ell)}) = \text{rank} \begin{bmatrix} P_{c_1}^{(ik,j\ell)} & P_1^{(ik,j\ell)} & 0 \\ P_{c_2}^{(ik,j\ell)} & 0 & P_2^{(ik,j\ell)} \end{bmatrix}, \]  

(26)

where we have introduced the compact notation $P_{c_1}^{(ik,j\ell)} = [P_{c_1}^{(ik)} P_1^{(j\ell)}], P_{c_2}^{(ik,j\ell)} = [P_{c_2}^{(ik)} P_2^{(j\ell)}], P_1^{(ik,j\ell)} = [P_1^{(ik)} P_1^{(j\ell)}]$ and $P_2^{(ik,j\ell)} = [P_2^{(ik)} P_2^{(j\ell)}]$.

We also define the rank:

\[ r^{(ik)} = \text{rank} \left( \Phi \Sigma_{x}^{(ik)} \Phi^T \right), \]  

(27)

that represents the dimension of the subspace in $\mathbb{R}^{m_1+m_2}$ spanned collectively by the projections of input signals and the projections of side information signals drawn from the Gaussian distribution identified by the component indices $C_1 = i, C_2 = k$; and

\[ r^{(ik,j\ell)} = \text{rank} \left( \Phi (\Sigma_{x}^{(ik)} + \Sigma_{x}^{(j\ell)}) \Phi^T \right), \]  

(28)

that represents the dimension of the subspace obtained by summing the subspace in $\mathbb{R}^{m_1+m_2}$ spanned collectively by the projections of input signals and the projections of side information signals drawn from the Gaussian distribution identified by the component indices $C_1 = i, C_2 = k$ with the subspace spanned by the projections of input signals and the projections of side information signals drawn from the Gaussian distribution identified by the component indices $C_1 = j, C_2 = \ell$. 

11
The quantities in (21)–(28), which provide a concise description of the geometry of the input source, the side information source, and the geometry of the interaction of such sources with the projections kernels, will be fundamental to determining the performance of the classification and reconstruction of high-dimensional signals from low-dimensional features in the presence of side information.

III. CLASSIFICATION WITH SIDE INFORMATION

We first consider signal classification in the presence of side information. The basis of the analysis is an asymptotic characterization – in the limit of \( \sigma^2 \to 0 \) – of the behavior of an upper bound to the misclassification probability associated with the optimal MAP classifier (rather than the exact misclassification probability which is not tractable). In particular, for a two class problem \(^7\), i.e., when \( K_1 = 2 \), via the Bhattacharyya bound \([1]\), the misclassification probability can be upper bounded as follows:

\[
\bar{P}_{\text{err}} = \sqrt{pc_{1}(1)pc_{1}(2)} \int \sqrt{p(y|C_1 = 1)p(y|C_1 = 2)} dy \tag{29}
\]

\[
= \sqrt{pc_{1}(1)pc_{1}(2)} \int \sum_{k, \ell = 1}^{K_2} p_{C_2|C_1}(k|1)p_{C_2|C_1}(\ell|2)p(y|C_1 = 1, C_2 = k)p(y|C_1 = 2, C_2 = \ell) dy. \tag{30}
\]

For a multiple class problem, via the Bhattacharyya bound in conjunction with the union bound, the misclassification probability can be upper bounded as follows:

\[
\bar{P}_{\text{err}} = \sum_{i=1}^{K_1} \sum_{j=1}^{K_1} pc_{1}(i) \int \sum_{k, \ell = 1}^{K_2} p_{C_2|C_1}(k|i)p_{C_2|C_1}(\ell|j)p(y|C_1 = i, C_2 = k)p(y|C_1 = j, C_2 = \ell) dy. \tag{31}
\]

The asymptotic characterization that we discuss below – akin to that in \([67]\) – is based on two key metrics. The first one identifies the presence or absence of an error floor in the upper bound to the misclassification probability as \( \sigma^2 \to 0 \), leading to conditions on the number of features that guarantee perfect classification in the low-noise regime, i.e.,

\[
\lim_{\sigma^2 \to 0} \bar{P}_{\text{err}}(\sigma^2) = 0. \tag{32}
\]

Note that the characterization of the presence or absence of an error floor in the upper bound of the misclassification probability also leads to the characterization of a phase transition region in terms of \( m_1 \) and \( m_2 \), where within this region \( \lim_{\sigma^2 \to 0} \bar{P}_{\text{err}}(\sigma^2) = 0 \) and outside the region \( \lim_{\sigma^2 \to 0} \bar{P}_{\text{err}}(\sigma^2) > 0 \). Note also that the boundaries of the region associated to the upper bound of the misclassification probability represent also lower bounds of the boundaries of the corresponding region associated with the true error probability.

The second metric offers a more refined description of the behavior of the upper bound to the misclassification probability by considering the slope at which \( \log \bar{P}_{\text{err}} \) decays (in a \( \log \sigma^2 \) scale) in the low-noise regime. Such

\(^7\)The number of classes corresponding to the side information signal, \( K_2 \), can be arbitrary.
value is named the diversity-order and is given by
\[ d = \lim_{\sigma^2 \to 0} \frac{\log \bar{P}_{\text{err}}(\sigma^2)}{\log \sigma^2}. \] (33)

Note also that the diversity-order associated with the upper bound of the error probability represents a lower bound on (the absolute value of) the slope of the true error probability in the low-noise regime.

We next characterize these quantities as a function of the number of features/measurements \( m_1 \) and \( m_2 \) and as a function of the underlying geometry of the signal and the side information, both for zero-mean classes (signal lives in a union of linear subspaces) and nonzero-mean ones (signal lives in a union of affine spaces). We also characterize the quantities in (32) and (33) in terms of the diversity-order associated with the classification of two Gaussian distributions \( \mathcal{N}(\mu_x^{(ik)}, \Sigma_x^{(ik)}) \) and \( \mathcal{N}(\mu_x^{(j\ell)}, \Sigma_x^{(j\ell)}) \) from the observation of the noisy linear features \( y \) in (3).

Moreover, all the pairs of indices \((i, k)\) such that \( p_{C_1, C_2}(i, k) = 0 \) clearly do not affect the diversity-order associated to classification with side information. Therefore, we can define the set of index pairs of interest as
\[ S = \{(i, k) \in \{1, \ldots, K_1\} \times \{1, \ldots, K_2\} : p_{C_1, C_2}(i, k) > 0\}. \] (35)

We also define the set of index quadruples
\[ S_{\text{SIC}} = \{(i, k, j, \ell) : (i, k), (j, \ell) \in S, i \neq j\}, \] (36)
that play a key role in the computation of the diversity-order associated to classification with side information.

### A. Zero-Mean Classes

We now provide a low-noise expansion of the upper bound to the misclassification probability associated with the system with side information in (1) and (2), when assuming that the signals involved are all zero-mean, i.e., \( \mu^{(ik)}_x = 0, \forall (i, k) \).

**Theorem 1:** Consider the model in (1) and (2), where the input signal \( x_1 \) is drawn according to the class-conditioned distribution (13), the side information \( x_2 \) is drawn according to the class-conditioned distribution (15), and the class-conditioned joint distribution of \( x_1 \) and \( x_2 \) is given by (9) with \( \mu^{(ik)}_x = 0, \forall (i, k) \). Then, with probability 1, in the low-noise regime, i.e., when \( \sigma^2 \to 0 \), the upper bound to the misclassification probability (31) can be expanded as
\[ \bar{P}_{\text{err}}(\sigma^2) = A \cdot (\sigma^2)^d + o((\sigma^2)^d), \] (37)
for a fixed constant \( A > 0 \), where
\[ d = \min_{(i, k, j, \ell) \in S_{\text{SIC}}} d(i, k, j, \ell), \] (38)
In particular, observe that:

for the case of zero-mean classes, in terms of the number of features and the geometrical description of the sources.

\[ d(ik, j\ell) = \frac{1}{2} \left( r^{(ik, j\ell)} - \frac{r^{(ik)} + r^{(j\ell)}}{2} \right), \]  

(39)

and

\[ r^{(ik, j\ell)} = \text{rank} \left( \Phi (\Sigma^{(ik)} + \Sigma^{(j\ell)}_x) \Phi^T \right) \]
\[ = \min \{ r^{(ik)}_{x}, \min \{ m_1, r^{(ik)}_{x_1} \} + \min \{ m_2, r^{(ik)}_{x_2} \} \}, \]  

(40)

\[ r^{(ik)} = \text{rank} \left( \Phi \Sigma^{(ik)}_x \Phi^T \right) \]
\[ = \min \{ r^{(ik)}_{x}, \min \{ m_1, r^{(ik)}_{x_1} \} + \min \{ m_2, r^{(ik)}_{x_2} \} \} \]  

(41)

(42)

(43)

and \( r^{(j\ell)} \) is obtained as \( r^{(ik)} \).

\[ \text{Proof: See Appendix A} \]

Theorem \[ \text{I} \] provides a complete characterization of the slope of the upper bound to the misclassification probability for the case of zero-mean classes, in terms of the number of features and the geometrical description of the sources. In particular, observe that:

- The diversity-order \( d \) associated with the estimation of the component index \( C_1 \) from noisy linear features with side information is given by the worst-case diversity-order term \( d(ik, j\ell) \) associated with pair-wise classification problems for which the indices corresponding to \( C_1 \) are not the same \( (i \neq j) \).

- The diversity-order in \( (38) \), which depends on the pairwise diversity-order in \( (39) \), can also be seen to depend on the difference between the dimension of the sum of the linear spaces collectively spanned by signals \( \Phi_1 x_1 \) and \( \Phi_2 x_2 \) drawn from the Gaussian distributions with indices \( (i, k) \) and \( (j, \ell) \) and the dimension of those spaces taken individually. This dependence in the presence of side information is akin to that in the absence of side information: the additional information, however, provides subspaces with increased dimensions over which it is possible to discriminate among signals belonging to different classes.

- The effect of the correlation between \( x_1 \) and \( x_2 \) is embodied in the rank expressions \( (41) \) and \( (43) \). In particular, we note that, in case \( x_1 \) and \( x_2 \) are conditionally independent given any pairs of classes \( (C_1, C_2) \), i.e., \( p(x_1, x_2 | C_1 = i, C_2 = k) = p(x_1 | C_1 = i)p(x_2 | C_2 = k) \), then \( r^{(ik)} = r^{(ik)}_{x_1} + r^{(ik)}_{x_2} \), \( r^{(j\ell)} = r^{(j\ell)}_{x_1} + r^{(j\ell)}_{x_2} \) and \( r^{(ik, j\ell)} = r^{(ik, j\ell)}_{x_1} + r^{(ik, j\ell)}_{x_2} \). Then, the diversity-order is given by the sum of the diversity-order values corresponding to the classification of \( x_1 \) from \( y_1 \) and that corresponding to the classification of \( x_2 \) from \( y_2 \). From a geometrical point of view, when \( x_1 \) and \( x_2 \) are conditionally independent, the linear spaces spanned by the side information offer new dimensions over which the decoder can discriminate among classes, which are completely decoupled from the dimensions corresponding to linear spaces spanned by the realizations of \( x_1 \). Otherwise, when \( x_1 \) and \( x_2 \) are not conditionally independent, the diversity-order can be in general larger than, smaller than, or equal to the sum of the diversity-order values corresponding to the classification of \( x_1 \) from \( y_1 \) and that corresponding to the classification of \( x_2 \) from \( y_2 \).
A direct consequence of the asymptotic characterization of the upper bound to the misclassification probability in (31) is access to conditions on the number of features $m_1$ and $m_2$ that are both necessary and sufficient to drive the upper bound to the misclassification probability to zero when $\sigma^2 \to 0$, that is, in order to achieve the phase transition of the upper bound to the misclassification probability, and hence a condition on the number of features $m_1$ and $m_2$ that is sufficient to drive the true misclassification probability to zero when $\sigma^2 \to 0$.

**Corollary 1**: Consider the model in (1) and (2), where the input signal $x_1$ is drawn according to the class-conditioned distribution (13), the side information $x_2$ is drawn according to the class-conditioned distribution (15), and the class-conditioned joint distribution of $x_1$ and $x_2$ is given by (9) with $\mu^{(ik)} = 0$, $\forall (i,k)$.

If there exists an index quadruple $(i,k,j,\ell) \in S_{\text{SIC}}$ such that $r^{(ik,j\ell)}_x = r^{(ik)}_x = r^{(j\ell)}_x$, then, $d = 0$ and the upper bound to the misclassification probability (31) exhibits an error floor in the low-noise regime. Otherwise, if $r^{(ik,j\ell)}_x > r^{(ik)}_x$, $r^{(j\ell)}_x$, $\forall (i,k,j,\ell) \in S_{\text{SIC}}$, then, with probability 1, the upper bound to the misclassification probability (31) approaches zero when $\sigma^2 \to 0$ if and only if the following conditions hold $\forall (i,k,j,\ell) \in S_{\text{SIC}}$:

1) if $r^{(ik,j\ell)}_x > r^{(ik)}_x$, $r^{(j\ell)}_x$ and $r^{(ik,j\ell)}_x > r^{(ik)}_x$, $r^{(j\ell)}_x$:

$$m_1 > \min \{r^{(ik)}_{x_1}, r^{(j\ell)}_{x_1}\} \quad \text{or} \quad m_2 > \min \{r^{(ik)}_{x_2}, r^{(j\ell)}_{x_2}\} \quad \text{or} \quad m_1 + m_2 > \min \{r^{(ik)}_x, r^{(j\ell)}_x\};$$

2) if $r^{(ik,j\ell)}_x = r^{(ik)}_x = r^{(j\ell)}_x$ and $r^{(ik,j\ell)}_x = r^{(ik)}_x = r^{(j\ell)}_x$:

$$m_1 > \min \{r^{(ik)}_{x_1}, r^{(j\ell)}_{x_1}\} \quad \text{or} \quad m_2 > \min \{r^{(ik)}_{x_2}, r^{(j\ell)}_{x_2}\} \quad \text{or} \quad m_1 + m_2 > \min \{r^{(ik)}_x, r^{(j\ell)}_x\};$$

3) if $r^{(ik,j\ell)}_x > r^{(ik)}_x$, $r^{(j\ell)}_x$ and $r^{(ik,j\ell)}_x = r^{(ik)}_x = r^{(j\ell)}_x$:

$$m_1 > \min \{r^{(ik)}_{x_1}, r^{(j\ell)}_{x_1}\} \quad \text{or} \quad \left\{
\begin{array}{l}
m_1 > \min \{r^{(ik)}_{x_1}, r^{(j\ell)}_{x_1}, r^{(ik)}_{x_2}, r^{(j\ell)}_{x_2}\}; \\
m_1 + m_2 > \min \{r^{(ik)}_x, r^{(j\ell)}_x\};
\end{array}\right.$$

4) if $r^{(ik,j\ell)}_x = r^{(ik)}_x = r^{(j\ell)}_x$ and $r^{(ik,j\ell)}_x > r^{(ik)}_x$, $r^{(j\ell)}_x$:

$$m_2 > \min \{r^{(ik)}_{x_2}, r^{(j\ell)}_{x_2}\} \quad \text{or} \quad \left\{
\begin{array}{l}
m_2 > \min \{r^{(ik)}_{x_2}, r^{(j\ell)}_{x_2}, r^{(ik)}_{x_1}, r^{(j\ell)}_{x_1}\}; \\
m_1 + m_2 > \min \{r^{(ik)}_x, r^{(j\ell)}_x\};
\end{array}\right.$$

**Proof**: See Appendix B.

The characterization of the numbers of features $m_1$ and $m_2$ that are both necessary and sufficient to achieve the phase transition in the upper bound to the misclassification probability is divided in 4 cases, depending on whether the range spaces $\text{Im}(\Sigma^{(ik)}_{x_1})$ and $\text{Im}(\Sigma^{(j\ell)}_{x_1})$, or the range spaces $\text{Im}(\Sigma^{(ik)}_{x_2})$ and $\text{Im}(\Sigma^{(j\ell)}_{x_2})$, are distinct or not. Fig. 2 depicts the tradeoff between the values of $m_1$ and $m_2$ associated with these different cases. Note also that the values of $m_1$ and $m_2$ associated with the phase transition of the upper bound of the misclassification probability

---

8We recall that, given two positive semidefinite matrices $A$ and $B$ with ranks $r_A = \text{rank}(A)$, $r_B = \text{rank}(B)$, $r_{AB} = \text{rank}(A + B)$, $\text{Im}(A) = \text{Im}(B)$ if and only if $r_{AB} = \frac{r_A + r_B}{2}$ [64 Lemma 2] and then, if and only if $r_{AB} = r_A = r_B$. 

15
lie in the intersection of the regions corresponding to index quadruples \((i, k, j, \ell) \in \mathcal{S}_{\text{SIC}}\).

In case 1), the range spaces associated to the input covariance matrices are all distinct, and by observing (44) we can clearly determine the beneficial effect of the correlation between \(x_1\) and \(x_2\) in guaranteeing the phase transition for the upper bound to the misclassification probability. Namely, we note that the phase transition is achieved either when error-free classification is possible from the observation of \(y_1\) alone \((m_1 > \min\{r_{x_1}^{(ik)}, r_{x_1}^{(jl)}\})\) or from the observation of \(y_2\) alone \((m_2 > \min\{r_{x_2}^{(ik)}, r_{x_2}^{(jl)}\})\) cf. [67], but, more importantly, the condition \(m_1 + m_2 > \min\{r_{x_1}^{(ik)}, r_{x_1}^{(jl)}\}\) shows the benefit of side information in order to obtain the phase transition with a lower number of features. In fact, when \(r_{\infty}^{(ik)} < r_{\infty}^{(ik)} + r_{\infty}^{(ik)}\), joint classification of \(y_1\) and \(y_2\) leads to a clear advantage in the number of features needed to achieve the phase transition with respect to the case in which classification is carried independently from \(y_1\) and \(y_2\), despite the fact that linear features are extracted independently from \(x_1\) and \(x_2\).

In case 2), the range spaces associated to the input covariance matrices are such that \(\text{Im}(\Sigma_{x_1}^{(ik)}) = \text{Im}(\Sigma_{x_1}^{(jl)})\) and \(\text{Im}(\Sigma_{x_2}^{(ik)}) = \text{Im}(\Sigma_{x_2}^{(jl)})\) so that classification based on the observation of \(y_1\) or \(y_2\) alone yields an error floor in the upper bound of the misclassification probability [67]. In other terms, input signals and side information signals from classes \((i, k)\) and \((j, \ell)\) are never perfectly distinguishable. In this case, the impact of correlation between the input signal and the side information signal is clear when observing (45). In fact, when combining features extracted independently from the vectors \(x_1\) and \(x_2\), it is possible to drive to zero the misclassification probability, in the low-noise regime, provided that the number of features extracted \(m_1\) and \(m_2\) verify the conditions in (45).

Finally, cases 3) and 4) represent intermediate scenarios in which range spaces associated to \(x_1\) are distinct, but those related to \(x_2\) are completely overlapping, and vice versa. We note then how the necessary and sufficient conditions for phase transition in (46) and (47) are given by combinations of the conditions in (44) and (45).

We further note in passing that the conditions in (45) are reminiscent of the conditions on compression rates for lossless joint source coding in [40].
B. Nonzero-Mean Classes

We now provide a low-noise expansion of the upper bound to the misclassification probability associated with the feature extraction system with side information in (1) and (2), for the case of nonzero-mean classes, i.e., $\mu_x^{(ik)} \neq 0$. The presence of non-zero mean classes – as already noted in [67, Theorem 3], for compressive classification without side information – offers a unique characteristic, that is, the misclassification probability can decay exponentially with $1/\sigma^2$ (i.e., the diversity-order tends to infinity) under certain conditions on the number of linear features extracted and the geometrical description of the source.

**Theorem 2:** Consider the model in (1) and (2), where the input signal $x_1$ is drawn according to the class-conditioned distribution (13), the side information $x_2$ is drawn according to the class-conditioned distribution (15), and the class-conditioned joint distribution of $x_1$ and $x_2$ is given by (9).

If, for all the index quadruples $(i, k, j, \ell) \in S_{\text{SIC}}$, it holds, $\mu_x^{(ik)} - \mu_x^{(ij)} \notin \text{Im}(\Sigma_x^{(ik)} + \Sigma_x^{(ij)})$, then, with probability 1, in the low-noise regime, i.e., when $\sigma^2 \to 0$, the upper bound to the misclassification probability for classification with side information (31) can be expanded as

$$P_{\text{err}}(\sigma^2) = B \cdot e^{-C/\sigma^2} + o\left(e^{-C/\sigma^2}\right),$$

for fixed constants $B, C > 0$, if and only if the following conditions hold $\forall (i, k, j, \ell) \in S_{\text{SIC}}$:

1) if $\mu_x^{(ik)} - \mu_x^{(ij)} \notin \text{Im}(\Sigma_x^{(ik)} + \Sigma_x^{(ij)})$ and $\mu_x^{(ik)} - \mu_x^{(ij)} \notin \text{Im}(\Sigma_x^{(ik)} + \Sigma_x^{(ij)})$:

$$m_1 > r^{(ik,j\ell)}_{x_1} \quad \text{or} \quad m_2 > r^{(ik,j\ell)}_{x_2} \quad \text{or} \quad m_1 + m_2 > r^{(ik,j\ell)}_{x},$$

2) if $\mu_x^{(ik)} - \mu_x^{(ij)} \in \text{Im}(\Sigma_x^{(ik)} + \Sigma_x^{(ij)})$ and $\mu_x^{(ik)} - \mu_x^{(ij)} \in \text{Im}(\Sigma_x^{(ik)} + \Sigma_x^{(ij)})$:

$$\begin{cases} m_1 > r^{(ik,j\ell)}_{x_1} - r^{(ik,j\ell)}_{x_2} \\ m_2 > r^{(ik,j\ell)}_{x_1} - r^{(ik,j\ell)}_{x_2} \quad ; \\ m_1 + m_2 > r^{(ik,j\ell)}_{x} \end{cases}$$

3) if $\mu_x^{(ik)} - \mu_x^{(ij)} \notin \text{Im}(\Sigma_x^{(ik)} + \Sigma_x^{(ij)})$ and $\mu_x^{(ik)} - \mu_x^{(ij)} \notin \text{Im}(\Sigma_x^{(ik)} + \Sigma_x^{(ij)})$:

$$m_1 > r^{(ik,j\ell)}_{x_1} \quad \text{or} \quad \begin{cases} m_1 > r^{(ik,j\ell)}_{x_1} - r^{(ik,j\ell)}_{x_2} \\ m_1 + m_2 > r^{(ik,j\ell)}_{x} \end{cases}$$

4) if $\mu_x^{(ik)} - \mu_x^{(ij)} \in \text{Im}(\Sigma_x^{(ik)} + \Sigma_x^{(ij)})$ and $\mu_x^{(ik)} - \mu_x^{(ij)} \notin \text{Im}(\Sigma_x^{(ik)} + \Sigma_x^{(ij)})$:

$$m_2 > r^{(ik,j\ell)}_{x_2} \quad \text{or} \quad \begin{cases} m_2 > r^{(ik,j\ell)}_{x_2} - r^{(ik,j\ell)}_{x} \\ m_1 + m_2 > r^{(ik,j\ell)}_{x} \end{cases}.$$
From a geometrical point of view, if the affine spaces spanned by the overall signal are realization in the Gaussian classes bound to the misclassification probability depend on whether the affine spaces spanned by signal and side information misclassification probability, provided that conditions (49)–(52) on the numbers of features extracted from \(x\) then classification based on both \(y\) of extracted features \(m\) of input signal and side information do not intersect, then equations (49)–(52) determine conditions on the number of \(x\) as well, thus guaranteeing enhanced discrimination among classes.

We emphasize that MMSE \(\sigma_2\) can guarantee infinite diversity-order even when classification based on \(y_1\) or \(y_2\) alone cannot. In particular, if there exists an index quadruple for which both \(\mu^{(ik)}_{x_1} - \mu^{(ij)}_{x_1} \in \text{Im}(\Sigma^{(ik)}_{x_1} + \Sigma^{(ij)}_{x_1})\) and \(\mu^{(ik)}_{x_2} - \mu^{(ij)}_{x_2} \in \text{Im}(\Sigma^{(ik)}_{x_2} + \Sigma^{(ij)}_{x_2})\), then, irrespective of the number of features \(m_1\) and \(m_2\) and of the specific values of the projection kernels \(\Phi_1\) and \(\Phi_2\), we have

\[
\Phi_1(\mu^{(ik)}_{x_1} - \mu^{(ij)}_{x_1}) \in \text{Im}(\Phi_1(\Sigma^{(ik)}_{x_1} + \Sigma^{(ij)}_{x_1})\Phi^T_1) \quad \text{and} \quad \Phi_2(\mu^{(ik)}_{x_2} - \mu^{(ij)}_{x_2}) \in \text{Im}(\Phi_2(\Sigma^{(ik)}_{x_2} + \Sigma^{(ij)}_{x_2})\Phi^T_2)
\]

and, therefore, the conditions in [67] Theorem 3] are not verified, thus implying that both the upper bounds to the error probability associated to classification based on \(y_1\) or \(y_2\) do not decay exponentially with \(1/\sigma^2\) when \(\sigma^2 \to 0\). On the other hand, if \(\mu^{(ik)}_{x} - \mu^{(ij)}_{x} \notin \text{Im}(\Sigma^{(ik)}_{x} + \Sigma^{(ij)}_{x})\) for all index quadruples \((i, k, j, \ell) \in S_{\text{SIC}}\), then classification based on both \(y_1\) and \(y_2\) is characterized by an exponential decay of the upper bound to the misclassification probability, provided that conditions (49)–(52) on the numbers of features extracted from \(x_1\) and \(x_2\) are verified.

Moreover, the conditions on the number of features needed to achieve an exponential decay in \(1/\sigma^2\) of the upper bound to the misclassification probability depend on whether the affine spaces spanned by signal and side information realization in the Gaussian classes \((i, k)\) and \((j, \ell)\) do intersect or not, for all index quadruples \((i, k, j, \ell) \in S_{\text{SIC}}\). From a geometrical point of view, if the affine spaces spanned by the overall signal \(x\) obtained by the concatenation of input signal and side information do not intersect, then equations (49)–(52) determine conditions on the number of extracted features \(m_1\) and \(m_2\) such that the affine spaces spanned by the projected signals \(\Phi x\) do not intersect as well, thus guaranteeing enhanced discrimination among classes.

**IV. Reconstruction with Side Information**

We now consider signal reconstruction in the presence of side information. We are interested in the asymptotic characterization of the minimum mean-squared error (MMSE) incurred in reconstructing \(x_1\) from the observation of the signal features \(y_1\) and the side information features \(y_2\), given by

\[
\text{MMSE}_{1|1,2}(\sigma^2) = \mathbb{E}[\|x_1 - \hat{x}_1(y_1, y_2)\|^2],
\]

\(^9\)We emphasize that \(\text{MMSE}_{1|1,2}(\sigma^2)\) is a function of \(\sigma^2\).
where \( \hat{x}_1(y_1, y_2) \) is the conditional mean estimator in (8). In particular, we are interested in determining conditions on the number of linear features \( m_1 \) and \( m_2 \) that guarantee perfect reconstruction in the low-noise regime, i.e., when \( \sigma^2 \to 0 \), that is

\[
\lim_{\sigma^2 \to 0} \text{MMSE}_{1|1,2}(\sigma^2) = 0, \tag{57}
\]

thus generalizing the results in [64] to the case when side information is available at the decoder; the misclassification results will be key to address this problem.

Note the characterization of such conditions also leads to the characterization of a phase transition region in terms of \( m_1 \) and \( m_2 \), where within this region \( \lim_{\sigma^2 \to 0} \text{MMSE}_{1|1,2}(\sigma^2) = 0 \) and outside the region \( \lim_{\sigma^2 \to 0} \text{MMSE}_{1|1,2}(\sigma^2) > 0 \).

A. Preliminaries: Gaussian Sources

We first consider the simplified case in which \( K_1 = K_2 = 1 \), i.e., when the signals \( x_1 \) and \( x_2 \) obey the joint Gaussian distribution \( \mathcal{N}(\mu_x, \Sigma_x) \), where

\[
\mu_x = \begin{bmatrix} \mu_{x_1} \\ \mu_{x_2} \end{bmatrix}, \quad \Sigma_x = \begin{bmatrix} \Sigma_{x_1} & \Sigma_{x_12} \\ \Sigma_{x_21} & \Sigma_{x_2} \end{bmatrix}, \tag{58}
\]

and with ranks \( r_{x_1} = \text{rank}(\Sigma_{x_1}), r_{x_2} = \text{rank}(\Sigma_{x_2}) \) and \( r_x = \text{rank}(\Sigma_x) \).

For this case, the conditional mean estimator is given by (70)

\[
\hat{x}_1(y) = \mu_{x_1} + W_{x_1}(y - \Phi \mu_x), \tag{59}
\]

where

\[
W_{x_1} = [\Sigma_{x_1} \Sigma_{x_12}] \Phi^T \left( \sigma^2 I + \Phi \Sigma_x \Phi^T \right)^{-1}. \tag{60}
\]

Moreover, the MMSE in this case can be expressed as

\[
\text{MMSE}_{1|1,2}^G(\sigma^2) = \text{tr} \left( \Sigma_{x_1} - [\Sigma_{x_1} \Sigma_{x_12}] \Phi^T \left( \sigma^2 I + \Phi \Sigma_x \Phi^T \right)^{-1} \Phi \begin{bmatrix} \Sigma_{x_1}^T \\ \Sigma_{x_2}^T \end{bmatrix} \right). \tag{61}
\]

In the following, we provide necessary and sufficient conditions on the number of features \( m_1, m_2 \) that guarantee that, in the low-noise regime, the reconstruction MMSE for Gaussian sources approaches zero. Sufficient conditions are based on the analysis of two different upper bounds to \( \text{MMSE}_{1|1,2}^G(\sigma^2) \). The first upper bound is obtained by considering the MMSE associated with the reconstruction of the signal \( x_1 \) from the observation of \( y_1 \) alone, i.e., without side information, which is denoted by

\[
\text{MMSE}_{1|1}^G(\sigma^2) = \mathbb{E} \left[ ||x_1 - \hat{x}_1(y_1)||^2 \right], \tag{62}
\]

where \( \hat{x}_1(y_1) = \mathbb{E} [x_1|y_1] \) and whose behavior in the low-noise regime has been analyzed in [64].

The second upper bound is obtained by considering the MMSE associated with the distributed reconstruction
problem, i.e., the joint recovery of \( x_1 \) and \( x_2 \) from the observation of both \( y_1 \) and \( y_2 \) (i.e., the reconstruction of \( x \) from \( y \)), which is denoted by

\[
\text{MMSE}_G^{1|2}(\sigma^2) = E \left[ \| x - \hat{x}(y) \|^2 \right],
\]  

(63)

where

\[
\hat{x}(y) = E[x|y] = \int x p(x|y) dx.
\]  

(64)

Note that the analysis of the second upper bound cannot be directly performed on the basis of the results in [64], due to the particular block diagonal structure of \( \Phi \).

Based on the properties of the MMSE [70], it is straightforward to show that

\[
\text{MMSE}_G^{1|1,2}(\sigma^2) \leq \text{MMSE}_G^{1|1}(\sigma^2)
\]

and

\[
\text{MMSE}_G^{1|1,2}(\sigma^2) \leq \text{MMSE}_G^{1|1,2}(\sigma^2).
\]

On the other hand, necessary conditions are derived from the analysis of the lower bound to the MMSE obtained by feeding the decoder not only with the noisy features \( y_1 \) and \( y_2 \), but also with the values of the realizations of the noise vectors \( w_1 \) and \( w_2 \). The following theorem stems from the fact that the necessary and sufficient conditions for the phase transition of the MMSE coincide.

**Theorem 3:** Consider the model in (1) and (2). Assume that the vectors \( x_1, x_2 \) are jointly Gaussian, with distribution \( N(\mu_x, \Sigma_x) \), with mean and covariance matrix specified in (58), and with \( r_{x_1} = \text{rank}(\Sigma_{x_1}), r_{x_2} = \text{rank}(\Sigma_{x_2}) \) and \( r_x = \text{rank}(\Sigma_x) \). Then, with probability 1, we have

\[
\lim_{\sigma^2 \to 0} \text{MMSE}_G^{1|1,2}(\sigma^2) = 0 \iff m_1 \geq r_{x_1} \quad \text{or} \quad \begin{cases} 
m_1 \geq r_x - r_{x_2} \\
m_1 + m_2 \geq r_x
\end{cases}
\]

(65)

**Proof:** See Appendix D. 

Without side information, it is known that \( m_1 \geq r_{x_1} \) represents a necessary and sufficient condition on the number of features needed to drive the MMSE to zero in the low-noise regime [64]. With side information, it is possible to reliably recover the input signal \( x_1 \) with a lower number of features, as described by the conditions in (65). In fact, whenever \( r_x < r_{x_1} + r_{x_2} \), it is possible to perfectly reconstruct \( x_1 \) when \( \sigma^2 \to 0 \) even with less than \( r_{x_1} \) features, provided that \( m_1 + m_2 \geq r_x \). This happens when the dimension of the overall space spanned by the projected signals obtained by concatenating the input signal and the side information signal, i.e., \( \Phi x \), is greater than or equal to the dimension of the space spanned by \( x \) in the signal domain. Moreover, the \( m_1 \) features extracted from \( x_1 \) need to be enough to span a space with dimension equal to the difference between the dimension of the space spanned by \( x \) and that spanned by \( x_2 \) alone. In this sense, linear projections extracted from the input signal must be enough to capture signal features that are characteristic of \( x_1 \) and are not “shared” with \( x_2 \), meaning that they are not correlated.

The values of \( m_1 \) and \( m_2 \) that satisfy the necessary and sufficient conditions (65) are reported in Fig. 3.
B. GMM Sources

We now consider the more general case where the signals \( x_1 \) and \( x_2 \) follow the models in Section II-A. It is possible to express the conditional mean estimator in closed form, but not the MMSE, which we denote by \( \text{MMSE}_{1|1,2}^{\text{GM}}(\sigma^2) \). Therefore, we will determine necessary and sufficient conditions on the numbers of features \( m_1 \) and \( m_2 \) that guarantee \( \text{MMSE}_{1|1,2}^{\text{GM}}(\sigma^2) \to 0 \) in the low-noise regime, by leveraging the result in Theorem 3 together with steps akin to those in [64, Section IV].

1) Sufficient Conditions: In order to provide sufficient conditions for the MMSE to approach zero in the low-noise regime, we analyze the upper bound to the MMSE corresponding to the mean squared error (MSE) associated with a (sub-optimal) classify and reconstruct decoder, which we denote by \( \text{MSE}_{\text{CR}}(\sigma^2) \). This decoder operates in two steps as follows:

- First, the decoder estimates the pair of class indices associated to the input signal and the side information signal via the MAP classifier\(^{10}\)
  \[
  (\hat{C}_1, \hat{C}_2) = \arg \max_{(i,k)} p(y|C_1 = i, C_2 = k) p_{C_1, C_2}(i, k); \quad (66)
  \]

- Second, in view of the fact that, conditioned on \((C_1, C_2) = (i, k)\), the vectors \( x_1 \) and \( x_2 \) are jointly Gaussian distributed with mean \( \mu_{(ik)}^{x} \) and covariance \( \Sigma_{(ik)}^{x} \), the decoder reconstructs the input signal \( x_1 \) by using the conditional mean estimator corresponding to the estimated classes \( \hat{C}_1, \hat{C}_2 \)
  \[
  \hat{x}_1(y; C_1 = \hat{C}_1, C_2 = \hat{C}_2) = \mu_{x_1}^{(\hat{C}_1 \hat{C}_2)} + \mathbf{W}_{x_1}^{(\hat{C}_1 \hat{C}_2)} \left( y - \Phi \mu_{x}^{(\hat{C}_1 \hat{C}_2)} \right), \quad (67)
  \]

\(^{10}\)This MAP classifier is associated with the distributed classification problem, which will be shown to be closely related to the problem of classification with side information in the next section.
where
\[
W_{x_1}^{(\hat{C}_1, \hat{C}_2)} = \left[ \Sigma_{x_1}^{(\hat{C}_1, \hat{C}_2)} \Sigma_{x_1}^{(\hat{C}_1, \hat{C}_2)} \right] \Phi^T \left( \sigma^2 I + \Phi \Sigma_x^{(\hat{C}_1, \hat{C}_2)} \Phi^T \right)^{-1}.
\]  

(68)

The optimality of the MMSE estimator immediately implies that \(\text{MMSE}^{\text{GM}}_{1/1,2}(\sigma^2) \leq \text{MSE}_{\text{CR}}(\sigma^2)\). Therefore, we can immediately leverage the analysis of the misclassification probability carried out in Section III and the result in Theorem 3 in order to characterize the behavior of \(\text{MSE}^{\text{GM}}_{\text{CR}}(\sigma^2)\) in the low-noise regime, in order to determine sufficient condition for the phase transition of \(\text{MMSE}^{\text{GM}}_{1/1,2}(\sigma^2)\).

**Theorem 4:** Consider the model in (1) and (2). Assume that the input signal \(x_1\) is drawn according to the class-conditioned distribution (13), \(x_2\) is drawn according to the class-conditioned distribution (15) and the class-conditioned joint distribution of \(x_1\) and \(x_2\) is given by (3). Then, with probability 1, we have
\[
m_1 > r_{x_1}^{(ik)} \text{ or } \left\{ \begin{array}{l}
m_1 > r_{x_2}^{(ik)} \quad \forall (i, k) \in \mathcal{S} \Rightarrow \lim_{\sigma^2 \to 0} \text{MMSE}^{\text{GM}}_{1/1,2}(\sigma^2) = 0.
\end{array} \right.
\]

(69)

**Proof:** See Appendix E.

The sufficient conditions in (69) show that – akin to the Gaussian case – the numbers of features extracted from \(x_1\) and \(x_2\) have to be collectively greater than the largest among the dimensions of the spaces spanned by signals \(x = [x_1^T \ x_2^T]^T\) in the Gaussian components corresponding to indices \((C_1, C_2) = (i, k)\), for \(i = 1, \ldots, K_1\), \(k = 1, \ldots, K_2\). Moreover, the features extracted from \(x_1\) need to be enough to capture signal components which are not correlated with the side information, for all Gaussian components. Finally, the condition \(m_1 > r_{x_1}^{(ik)}\) is obtained trivially by considering reconstruction of \(x_1\) from the features collected in the vector \(y_1\), thus disregarding side information.

Note that the values of \(m_1\) and \(m_2\) that are sufficient for the MMSE phase transition are obtained by considering the intersection of regions akin to that in Fig. 3 for all the pairs of classes \((i, k) \in \mathcal{S}\).

Appendix E shows that the conditions in (69) guarantee that the decoder can reliably estimate the class indices \((C_1, C_2)\) and hence reliably reconstruct the signal \(x_1\) in the low-noise regime.

2) **Necessary conditions:** We now derive necessary conditions for the phase transition of the MMSE of GMM sources with side information. We obtain such conditions from the analysis of a lower bound to the MMSE that is obtained by observing that
\[
\text{MMSE}^{\text{GM}}_{1/1,2}(\sigma^2) = \mathbb{E} \left[ \| x_1 - \hat{x}_1(y_1, y_2) \|^2 \right]
\]
\[
= \sum_{(i, k) \in \mathcal{S}} p_{C_1, C_2}(i, k) \mathbb{E} \left[ \| x_1 - \hat{x}_1(y_1, y_2) \|^2 \mid C_1 = i, C_2 = k \right]
\]
\[
\geq \sum_{(i, k) \in \mathcal{S}} p_{C_1, C_2}(i, k) \text{MMSE}^{\text{GM}}_{1/1,2}(\sigma^2) = \text{MSE}_{\text{LB}}(\sigma^2),
\]

(70)

(71)

(72)

where \(\text{MMSE}^{\text{GM}}_{1/1,2}(\sigma^2)\) denotes the MMSE associated with the reconstruction of the Gaussian signal \(x_1\) corresponding to class indexes \((i, k)\) from the observation of the vector \(y_1\) and the side information \(y_2\). Note that the equality in (71) is obtained via the total probability formula and the inequality in (72) is a consequence of the
The optimality of the MMSE estimator for joint Gaussian input and side information signals.

The analysis of $\text{MSE}_{LB}(\sigma^2)$ leads to the derivation of the following necessary conditions on the number of features $m_1$ and $m_2$ needed to drive $\text{MMSE}_{|1,2}^{\text{GM}}(\sigma^2)$ to zero when $\sigma^2 \to 0$.

**Theorem 5:** Consider the model in (1) and (2). Assume that the input signal $x_1$ is drawn according to the class-conditioned distribution (13), $x_2$ is drawn according to the class-conditioned distribution (15) and the class-conditioned joint distribution of $x_1$ and $x_2$ is given by (9). Then, with probability 1, we have

$$
\lim_{\sigma^2 \to 0} \text{MMSE}_{|1,2}^{\text{GM}}(\sigma^2) = 0 \Rightarrow m_1 \geq r_{x_1}^{(ik)} \quad \text{or} \quad m_1 + m_2 \geq r_{x_2}^{(ik)}, \forall (i,k) \in S.
$$

(73)

**Proof:** The proof is based on the result in Theorem 3, which implies that, if $\text{MMSE}_{i,j}^{G(i,k)}(\sigma^2) \to 0$ when $\sigma^2 \to 0$, $\forall (i,k) \in S$, then, with probability 1, the conditions on the numbers of features $m_1$ and $m_2$ in (73) must be satisfied for all $(i,k) \in S$.

It is interesting to note that the necessary conditions for the phase transition of the MMSE of GMM inputs are one feature away from the corresponding sufficient conditions, akin to our previous results for the case without side information [64]. In this way, Theorems 4 and 5 provide a sharp characterization of the region associated to the phase transition of the MMSE of GMM inputs with side information.

V. DISTRIBUTED CLASSIFICATION AND RECONSTRUCTION

The problem of classification and reconstruction with side information are intimately related to the problems of distributed classification and reconstruction, and our tools immediately generalize to provide insight about these problems.

A. Distributed Classification

The problem of distributed classification involves the estimation of the pair of classes $(C_1, C_2)$ from the low-dimensional feature vectors $y_1$ and $y_2$, where

$$
(\hat{C}_1, \hat{C}_2) = \arg \max_{(i,k)} p(y|C_1 = i, C_2 = k)p_{C_1, C_2}(i, k);
$$

(74)

Via the Bhattacharyya bound and the union bound, it is possible to write an upper bound to the misclassification probability of distributed classification as

$$
\bar{P}_{err} = \sum_{(i,k,j,\ell) \in S_{DC}} p_{C_1, C_2}(i, k) \int \sqrt{p(y|C_1 = i, C_2 = k)p(y|C_1 = j, C_2 = \ell)} dy,
$$

(75)

where

$$
S_{DC} = \{(i,k,j,\ell) : (i,k), (j,\ell) \in S, (i,k) \neq (j,\ell)\},
$$

(76)

is a set corresponding to all couples of class index pairs that are different in at least one of the values for $C_1$ or $C_2$. We can also explore the previous methodology to construct an asymptotic characterization of the upper bound

23
to the misclassification probability. We first consider the case of zero-mean classes, i.e., we assume \( \mu_{x}^{(i,k)} = 0 \), \( \forall(i,k) \).

**Theorem 6:** Consider the model in (1) and (2), where \( x_1 \) is drawn according to the class-conditioned distribution (13), \( x_2 \) is drawn according to the class-conditioned distribution (15), and the class-conditioned joint distribution of \( x_1 \) and \( x_2 \) is given by (9) with \( \mu_{x}^{(i,k)} = 0, \forall(i,k) \). Then, with probability 1, in the low-noise regime, i.e., when \( \sigma^2 \to 0 \), the upper bound to the misclassification probability for distributed classification (75) can be expanded as

\[
\bar{P}_{err}(\sigma^2) = A \cdot (\sigma^2)^d + o\left( (\sigma^2)^d \right),
\]

for a fixed constant \( A > 0 \), where

\[
d = \min_{(i,k,j,\ell) \in \mathcal{S}_{DC}} d^{(ik, j\ell)},
\]

and where \( d^{(ik, j\ell)}, r^{(ik, j\ell)} \) and \( r^{(ik)} \) are as in (39), (41) and (43), respectively.

**Proof:** We report here only sketches of the proof, which follows steps similar to those in Appendix A. It starts by considering the closed-form expression of the integrals in (75) and their low-noise expansions, which are expressed in terms of the pair-wise diversity-orders \( d^{(ik, j\ell)} \). The main difference with respect to the proof in Appendix A consists in the fact that the upper bound (75) is given by the sum of all terms corresponding to index quadruples \( (i,k,j,\ell) \in \mathcal{S}_{DC} \), whereas the upper bound for classification with side information (31) contains only terms associated to index quadruples \( (i,k,j,\ell) \in \mathcal{S}_{SIC} \). Finally, the values of \( d^{(ik, j\ell)} \) are obtained also in this case by leveraging the rank computation provided by Lemma 1.

The main difference between the asymptotic expansion in Theorem 1 and the asymptotic expansion in this Theorem relates to the computation of the diversity-order. In particular, the diversity-order for classification with side information is obtained as the worst-case diversity-order associated with the classification between Gaussian distributions identified by the couples of index pairs \( (i,k) \) and \( (j,\ell) \) among all couples for which the indices corresponding to \( C_1 \) are not the same \( (i \neq j) \), and among all possible choices for the indices corresponding to \( C_2 \). On the other hand, the diversity-order of distributed classification is dictated by the lowest diversity-order in classifying all possible pairs of Gaussian distributions, whether they are associated or not to different input classes \( C_1 \). This reflects the fact that a misclassification event occurs even when the estimate on \( C_1 \) is correct, that is when \( \hat{C}_1 = C_1 \), but \( \hat{C}_2 \neq C_2 \). In other terms, the diversity-order for the classification with side information problem is entirely determined by the *inter-class* diversity, which means the diversity among Gaussian distributions pertaining to different classes \( C_1 \). On the other hand, the performance in discriminating among all possible pairs \( (C_1, C_2) \), i.e., the distributed classification problem, depends also from the *intra-class* diversity. Therefore, we can also note that, as expected, the diversity-order associated to distributed classification is a lower bound to the diversity-order corresponding to classification with side information.

We can also leverage the previous analysis – together with the expansion in Theorem 1 – to determine conditions on the number of features that are both necessary and sufficient for the upper bound to the misclassification probability to approach zero and hence conditions on the number of features that are sufficient for the true
misclassification probability to approach zero.

**Corollary 2:** Consider the model in (1) and (2), where \( x_1 \) is drawn according to the class-conditioned distribution (13), \( x_2 \) is drawn according to the class-conditioned distribution (15), and the class-conditioned joint distribution of \( x_1 \) and \( x_2 \) is given by (9) with \( \mu_{X}^{(ik)} = 0, \forall (i,k) \).

If there exists an index quadruple \((i,k,j,\ell) \in S_{DC}\) such that \( r_{X}^{(ik,j\ell)} = r_{X}^{(ik)} = r_{X}^{(j\ell)} \), then, \( d = 0 \) and the upper bound to the misclassification probability for distributed classification (75) exhibits an error floor in the low-noise regime. Otherwise, if \( r_{X}^{(ik,j\ell)} > r_{X}^{(ik)}, r_{X}^{(j\ell)}, \forall (i,k,j,\ell) \in S_{DC} \), then, with probability 1, the upper bound to the misclassification probability (75) approaches zero when \( \sigma^2 \to 0 \) if and only conditions (44)–(47) hold \( \forall (i,k,j,\ell) \in S_{DC} \).

As a consequence of the expression of the low-noise expansion in Theorem 6, the main difference between Corollary 1 and this corollary lies in the fact that the conditions on the number of features extracted \( m_1, m_2 \) to guarantee that \( d(i,k,j,\ell) > 0 \) must be satisfied for all index quadruples \((i,k,j,\ell) \in S_{DC}\), i.e., pair-wise discrimination must be guaranteed for all pairs of Gaussian distributions within the joint GMM describing \( x_1 \) and \( x_2 \).

We also note that a similar result holds for the characterization of the low-noise expansion of the upper bound of the misclassification probability for distributed classification with nonzero-mean classes. In fact, by following steps similar to those presented in Appendix C, it is possible to provide a low-noise expansion of the upper bound (75) for the case when \( \mu_{X}^{(ik)} \neq 0 \) akin to that in Theorem 2. Also, in this case the main difference between the expansion of the misclassification probability for distributed classification and that in Theorem 2 lies in the fact that conditions (49)–(52) must be verified for all the index quadruples \((i,k,j,\ell) \in S_{DC}\) in order to guarantee that the upper bound decays exponentially with \( 1/\sigma^2 \) as \( \sigma^2 \to 0 \).

**B. Distributed Reconstruction**

The problem of distributed reconstruction involves the estimation of the pair of vectors \( x_1 \) and \( x_2 \) from the low-dimensional feature vectors \( y_1 \) and \( y_2 \) via the conditional mean estimator in (64) [38]. We can immediately specialize the results in Theorem 3 to distributed reconstruction for Gaussian sources, thus providing necessary and sufficient conditions for the low-noise phase transition of MMSE\(_{1,2|1,2}(\sigma^2)\).

**Theorem 7:** Consider the model in (1) and (2). Assume that the vectors \( x_1, x_2 \) are jointly Gaussian, with distribution \( \mathcal{N}(\mu_X, \Sigma_X) \), with mean and covariance matrix specified in (58), and with \( r_{x_1} = \text{rank} (\Sigma_{X_1}), r_{x_2} = \text{rank} (\Sigma_{X_2}) \) and \( r_{x} = \text{rank} (\Sigma_{X}) \). Then, with probability 1, we have

\[
\lim_{\sigma^2 \to 0} \text{MMSE}_{1,2|1,2}(\sigma^2) = 0 \iff \begin{cases} 
  m_1 \geq r_X - r_{x_2} \\
  m_2 \geq r_X - r_{x_1} \\
  m_1 + m_2 \geq r_X 
\end{cases}
\]

**Proof:** The proof of this result is presented in Appendix D as part of the proof of Theorem 3. It is based on the low-noise expansion of the MMSE for Gaussian sources provided in [64] and on the rank characterization offered.
We immediately observe that the conditions (79) mimic the Slepian-Wolf condition for joint source coding [40], where \( r_x - r_{x_2} \) is the counterpart of the conditional entropy of \( x_1 \) given \( x_2 \), \( r_x - r_{x_1} \) is the counterpart of the conditional entropy of \( x_2 \) given \( x_1 \), and \( r_x \) corresponds to the joint entropy of \( x_1 \) and \( x_2 \).

It is also interesting to note that these conditions (which apply to signals that are sparse in different basis) immediately specialize (for the two-sensor case) to the conditions in [51, Theorem 1 and 2], which pertain to signals that are sparse in the same basis, and provide necessary and sufficient conditions for the joint reconstruction of sparse signals when the common/innovation ensemble sparsity model is known at the decoder.

We can also specialize the results in Theorems 4 and 5 to distributed reconstruction for GMM sources, thus providing sufficient and necessary conditions for the low-noise phase transition of the MMSE, which is denoted in this case by \( \text{MMSE}_{1,2|1,2}(\sigma^2) \).

**Theorem 8:** Consider the model in (1) and (2). Assume that the input signal \( x_1 \) is drawn according to the class-conditioned distribution (13), \( x_2 \) is drawn according to the class-conditioned distribution (15) and the class-conditioned joint distribution of \( x_1 \) and \( x_2 \) is given by (9). Then, with probability 1, we have

\[
\begin{align*}
    m_1 &> r_{x_1}^{(ik)} - r_{x_2}^{(ik)},
    m_2 &> r_{x_2}^{(ik)} - r_{x_1}^{(ik)},
    m_1 + m_2 &> r_{x}^{(ik)},
\end{align*}
\]

\( \forall (i,k) \in S \Rightarrow \lim_{\sigma^2 \to 0} \text{MMSE}_{1,2|1,2}(\sigma^2) = 0. \) (80)

**Proof:** We briefly outline the proof for this theorem, which follows steps similar to those in Appendix E. Also in this case, the derivation of sufficient conditions for the low-noise phase transition of the MMSE is based on the analysis of the MSE associated to a classify and reconstruct approach akin to that specified in Section IV-B, where the decoder first derives an estimate \((\hat{C}_1, \hat{C}_2)\) of the pair of classes from which \( x_1 \) and \( x_2 \) are drawn and then uses the Wiener filter associated to the estimated classes in order to recover \( x \) from \( y \).

Then, the analysis of such upper bound is carried out by leveraging the characterization of the phase transition of the upper bound to the misclassification probability given by Corollary 2 and the conditions for the phase transition of the MMSE for Gaussian sources in Theorem 7.

**Theorem 9:** Consider the model in (1) and (2). Assume that the input signal \( x_1 \) is drawn according to the class-conditioned distribution (13), \( x_2 \) is drawn according to the class-conditioned distribution (15) and the class-conditioned joint distribution of \( x_1 \) and \( x_2 \) is given by (9). Then, with probability 1, we have

\[
\begin{align*}
    m_1 &> r_{x_1}^{(ik)} - r_{x_2}^{(ik)},
    m_2 &> r_{x_2}^{(ik)} - r_{x_1}^{(ik)},
    m_1 + m_2 &> r_{x}^{(ik)},
\end{align*}
\]

\( \forall (i,k) \in S \Rightarrow \lim_{\sigma^2 \to 0} \text{MMSE}_{1,2|1,2}(\sigma^2) = 0. \) (81)

**Proof:** The proof is based on the analysis of a lower bound to the MMSE akin to that described in (71) and (72) for the case of reconstruction with side information, which is based on the total probability formula and the optimality of the MMSE estimator for joint Gaussian \( x_1 \) and \( x_2 \). Then, necessary conditions for the phase transition
of such lower bound are derived from the result in Theorem 7 on the phase transition of the MMSE of Gaussian sources.

Note that conditions (80) imply that conditions for reliable reconstruction of Gaussian inputs (79) must be met for all possible Gaussian distributions within the GMM, with a further gap of one feature.

We also note that conditions (80) can be interpreted as a generalization of the result in [51, Theorem 3], for the two sensors scenario, which encompasses also the case where the signals have different sizes. Namely, on considering the joint GMM prior (15) and its common and innovation component representation in (17) and (18), if each class \((i, k)\) is chosen so that the corresponding \(P^{(ik)}\) in (19) can be mapped into a matrix of the common/innovation ensemble sparsity model in [51], then conditions (80) show that only an additional feature for each signal is needed in order to reconstruct both \(x_1\) and \(x_2\), in case their joint sparsity pattern is not known \textit{a priori}.

VI. NUMERICAL RESULTS

We now report a series of numerical results, both with synthetic and real data, that cast further light on the role of side information to aid signal classification or reconstruction. Results with synthetic data aim to showcase how theory is able to predict the phase transition and the diversity-order of the true misclassification probability for classification problems, or to approximate well the phase transition of the MMSE.

A. Synthetic Data: Classification

We first present numerical results that showcase how the predictions on the diversity-order characterization based on the upper bound (from Theorem 1) match well the behavior of the experimental misclassification probability.

We consider \(x_1\) and \(x_2\) with dimensions respectively \(n_1 = 20\) and \(n_2 = 12\), with \(K_1 = K_2 = 2\), so that the marginal pdfs for both signals are given by the mixture of two GMMs, each of them consisting of two Gaussian classes. All Gaussian classes are assumed to be zero-mean, i.e., \(\mu^{(ik)} = 0, \forall i, k \in \{1, 2\}\). The columns of the matrices \(P^{(ik)}_{c_1}, P^{(ik)}_{c_2}, P^{(ik)}_1\) and \(P^{(ik)}_2\) are generated with i.i.d., zero-mean, unit-variance Gaussian entries. The dimensions of the linear spaces spanned by signals in the different classes are such that \(r^{(ik)}_{x_1} = 7, r^{(ik)}_{x_2} = 6\) and \(r^{(ik)}_x = 9, \forall i, k \in \{1, 2\}\). Moreover, the matrices \(P^{(ik)}_{c_1}, P^{(ik)}_{c_2}, P^{(ik)}_1\) and \(P^{(ik)}_2\), associated with different classes share some of their columns, so that the dimensions of the sums of spaces spanned by signals in different classes are such that the corresponding ranks associated to pairs of class-conditioned input covariance matrices are given in Table I. The projection kernels \(\Phi_1, \Phi_2\) are taken with i.i.d., zero-mean, Gaussian entries, with fixed variance.

We compare the phase-transition and the diversity-orders yielded by the Bhattacharyya-based upper bound (31) with the error probability obtained by numerical simulation. We report in Fig. 4(a) the experimental error probability and in Fig. 4(b) the upper bound \(\bar{P}_{err}^U\) in (94) for the case in which no side information is available to the decoder (cf. [67]), i.e., \(m_2 = 0\). In this case, the phase transition for the misclassification probability is obtained when \(m_1 > 7\) [67], and we note how the analysis based on the upper bound reflects well the behavior of the true error probability both in terms of phase transition and diversity-order.
TABLE I
RANKS ASSOCIATED TO PAIRS OF CLASS-CONDITIONED INPUT COVARIANCE MATRICES IN THE NUMERICAL EXAMPLE OF CLASSIFICATION WITH SIDE INFORMATION.

(b) Misclassification probability upper bound in (94)

Fig. 4. True misclassification probability (based on numerical experiments) and upper bound vs. \( 1/\sigma^2 \) for classification without side information (i.e., \( m_2 = 0 \)).

(a) True misclassification probability
(b) Misclassification probability upper bound in (94)

Fig. 5. True misclassification probability (based on numerical experiments) and upper bound vs. \( 1/\sigma^2 \) for classification with side information with \( m_2 = 4 \).
Fig. 6. Results of numerical experiments, depicting MMSE vs. $1/\sigma^2$ for Gaussian signal reconstruction with side information. $m_1 = 1, 2, 3$, $m_2 = 1$ (solid lines), $m_2 = 2$ (dashed lines) and $m_2 = 3$ (dashed-dotted lines).

We now evaluate the impact of the side information $y_2$ in the classification of the input signal $x_1$. We consider the case in which the number of features representing the side information is $m_2 = 4$ and for different values of $m_1$. In Fig. 5(a) we show the experimental error probability and in Fig. 5(b) the upper bound $\bar{P}_{err}$ in (94). We observe how the presence of side information can be leveraged in order to obtain the phase transition for the error probability with only $m_1 > 5$ features on the input signal. In fact, when $m_1 + m_2 > 9$, the linear spaces spanned collectively by the projections of signals $x_1$ and $x_2$ drawn from different Gaussian components are not completely overlapping, since they are 9-dimensional spaces in $\mathbb{R}^{m_1+m_2}$. Moreover, increasing the number of linear features extracted above 4 leads to increased diversity-order values. Also in this case, we note how the behavior analytically predicted from the characterization of the Bhattacharyya-based upper bound matches well the true behavior of the actual error probability both in terms of phase transition and diversity-order.

B. Synthetic Data: Reconstruction

We now aim to show how numerical results for reconstruction of synthetic signals also align well with the analysis reported in Section IV in particular for what regards the characterization of the number of features needed to drive the MMSE to zero when $\sigma^2 \rightarrow 0$. We start by considering the case in which $x_1$ and $x_2$ are described by a single Gaussian joint distribution. In particular, we set the signal sizes to $n_1 = 5$ and $n_2 = 4$, and we build the joint input covariance matrix using the common/innovation component representation in (17) and (18), where $P_{c_1} \in \mathbb{R}^{5\times 2}, P_{c_2} \in \mathbb{R}^{4\times 2}, P_1 \in \mathbb{R}^{5\times 1}$ and $P_2 \in \mathbb{R}^{4\times 1}$ have i.i.d., zero-mean, unit-variance Gaussian entries, thus obtaining $r_{x_1} = 3, r_{x_2} = 3$ and $r_x = 4$. We also assume that the projection kernels $\Phi_1$ and $\Phi_2$ have i.i.d., zero-mean, Gaussian entries with fixed variance.

Fig. 6 shows the values of the reconstruction MMSE for Gaussian inputs in (61), for different values of the number of features $m_1$ and $m_2$. We observe that the necessary and sufficient conditions in (65) are verified by the
numerical results: in particular, when \( m_2 = 1 \), the phase transition for the MMSE occurs only when \( m_1 \geq 3 \), when \( m_2 = 2 \), the phase transition is obtained with \( m_1 \geq 2 \) and, finally, when \( m_2 = 3 \), a single feature extracted from the input signal is sufficient to guarantee the phase transition.

We now consider signal reconstruction for GMM inputs. In particular, we assume that the vectors \( x_1 \) and \( x_2 \) are drawn from the joint GMM prior described in Section VI-A for the case of signal classification, and we assume again to use projection kernels with i.i.d., zero-mean, Gaussian entries. Reconstruction is performed via the conditional mean estimator, that is now given by

\[
\hat{x}_1(y) = \mathbb{E}[x_1|y] = \int x_1 p(x_1|y) dx_1 = \int x_1 \left( \int \frac{p(x_1, x_2)p(y|x_1, x_1)}{p(x)p(y|x)} dx_2 \right) dx_1
\]

\[
= \int x_1 \left( \sum_{i=1}^{K_1} \sum_{k=1}^{K_2} \tilde{p}_{C_1, C_2}(i, k) N(x_1, x_2; \tilde{\mu}^{(ik)}, \tilde{\Sigma}^{(ik)}) dx_2 \right) dx_1
\]

where \[38\]

\[
\tilde{p}_{C_1, C_2}(i, k) = \frac{p_{C_1, C_2}(i, k) N(y; \Phi \mu^{(ik)}_x, \sigma^2 I + \Phi \Sigma^{(ik)}_x \Phi^T)}{\sum_{i=1}^{K_1} \sum_{k=1}^{K_2} p_{C_1, C_2}(i, k) N(y; \Phi \mu^{(ik)}_x, \sigma^2 I + \Phi \Sigma^{(ik)}_x \Phi^T)}
\]

\[
\tilde{\mu}^{(ik)} = \mu^{(ik)} + \Sigma^{(ik)} \Phi^T (\sigma^2 I + \Phi \Sigma^{(ik)} \Phi^T)^{-1} (y - \Phi \mu^{(ik)}_x)
\]

\[
\tilde{\Sigma}^{(ik)} = \Sigma^{(ik)} - \Sigma^{(ik)} \Phi^T (\sigma^2 I + \Phi \Sigma^{(ik)} \Phi^T)^{-1} \Phi \Sigma^{(ik)}_x
\]

and we have used the notation \( N(x; \mu, \Sigma) \) to express explicitly the argument of the Gaussian distribution. Then, on marginalizing out \( x_2 \), we obtain

\[
\hat{x}_1(y) = \sum_{i=1}^{K_1} \sum_{k=1}^{K_2} \tilde{p}_{C_1, C_2}(i, k) \left( \mu^{(ik)} + \Phi \mu^{(ik)}_x \right)
\]

\[\text{(88)}\]

and, as expected from the properties of the MMSE estimator \[70\], \( \hat{x}_1(y) \) can be also obtained by retaining the first \( n_1 \) entries of the joint conditional mean estimator \( \hat{x}(y) = \mathbb{E}[x|y] \) \[38\].

Fig. 7 shows the MMSE values for reconstruction both with side information (subfigure (a)), where we set \( m_2 = 4 \), and without side information (subfigure (b)), where we set \( m_2 = 0 \). When side information is not available at the decoder, the phase transition is obtained when \( m_1 > \max_{(ik)} r^{(ik)}_{x_1} = 7 \) \[64\]. On the other hand, as predicted by the sufficient conditions in \[69\], the presence of side information allows to guarantee the phase transition with only \( m_1 > 5 \) features. Notice also in this case how the theoretical analysis matches well the behavior shown by the numerical results.

**C. Experimental Results: Natural Imaging**

In this section, we consider a two-dimensional image compressive sensing example. The input signal is represented in this case by the image “Lena” with resolution \( 512 \times 512 \) and the side information is given by a low-resolution version of the same subject, which consists of \( 128 \times 128 \) pixels (see Fig. 8). Note also that, as a low-resolution
version of the signal of interest, side information in this case can be related to the scaling coefficients of the wavelet transform of the input signal. Both images are then partitioned into non-overlapping patches, so that the input vector $x_1$ represents $8 \times 8$ patches extracted from the $512 \times 512$ picture and $x_2$ represents $2 \times 2$ patches extracted from the low-resolution image. In this way, the input image and the side information are divided into the same number of patches, which represent the same spatial portion of the subject (see [5], [64] for a detailed description of the imaging setup).

We assume that the signals $x_1$ and $x_2$ are described by a joint GMM as that in Section II-A with $K_1 = K_2 = 20$. The class variables $C_1$ and $C_2$ are assumed to be perfectly correlated, so that $p_{C_1,C_2}(i,k) = 0$ if $i \neq k$. The parameters of the joint GMM, i.e., the prior probabilities, the mean and the covariance matrices associated to each
Gaussian distribution within the GMM, are learned from the “Caltech 101” dataset [71], that does not include the test image, via the expectation-maximization (EM) algorithm [72]. The covariance matrices $\Sigma_{(ik)}^x \in \mathbb{R}^{68 \times 68}$ obtained with the training algorithm have full rank. Therefore, in order to fit the trained model to an exactly low-rank GMM, to showcase further how theory aligns with practice, we modify the covariance matrices by retaining only the first 15 principal components and setting to zero the remaining 53 eigenvalues. In this way, we obtain $r_{x_1}^{(ik)} = 15$, $r_{x_2}^{(ik)} = 4$ and $r_x^{(ik)} = 15$ for all $(i, k) \in S$. Moreover, patches extracted from the test image and the side information image are also adapted to such low-dimensional model by projecting the vector $x = [x_1^T x_2^T]^T$ onto the 15-dimensional subspace corresponding to the range of the matrix $\Sigma_{(ik)}^x$ of the Gaussian distribution associated to each patch. We notice that this procedure does not introduce substantial distortion, and the relative peak signal-to-noise ratio (PSNR) values for the test image and the side information image are equal to 34 dB and 46 dB, respectively. This is due to the fact that the eigenvalues of the trained covariance matrices decay exponentially fast, thus implying that “almost low-rank” GMM priors model well patches extracted from natural images.

We consider the problem of reconstructing the test image “Lena” from noisy linear features, in the presence of the side information represented by the low-resolution image. Linear features are extracted from the input signal via the matrix $\Phi_1 \in \mathbb{R}^{m_1 \times n_1}$, which is generated with i.i.d., zero-mean, Gaussian entries with fixed variance. On the other hand, we assume that the side information image is not compressed, i.e., we assume $\Phi_2 = I$. Reconstruction is performed via the closed-form, conditional mean estimator (88).

Fig. 9 reports the PSNR vs. $1/\sigma^2$ curves obtained for different numbers of linear features extracted from the test image patches. For comparison, we also show the corresponding curves for the case of reconstruction without side information [64]. We clearly observe how the phase transition for reconstruction obtained with natural images matches the predictions obtained with the mathematical analysis developed in Section IV. In particular, when side
information is not available at the decoder, the phase transition occurs when \( m_1 > \max_{i,k} r_{x_1}^{(ik)} = 15 \) \[64\]. On the other hand, the presence of side information allows for reliable reconstruction in the low-noise regime with a reduced number of features extracted from each patch. Namely, in the case under consideration, the conditions \(69\) are equivalent to \( m_1 > 11 \), which is shown to match well the PSNR behavior in Fig. \(9\) (b).

As already observed in \[64\], we underline the fact that the theory developed in Sections \(III\) and \(IV\) yields significant results only for the case of low-rank GMMs rather than “approximately low-rank” models. On the other hand, GMM priors obtained via learning algorithms applied to natural images are not exactly low-rank. In fact, input covariance matrices obtained with such methods are typically described as

\[
\Sigma_{x}^{(ik)} = \bar{\Sigma}_{x}^{(ik)} + \varepsilon I,
\]

(89)

where \( \bar{\Sigma}_{x}^{(ik)} \) is low-rank and the term \( \varepsilon I \) accounts for the model mismatch between the real data and their projection onto the principal components containing the majority of the information associated to the data. In this way, we can observe that the feature extraction model in \(3\) with full-rank covariances \( \Sigma_{x}^{(ik)} \) is mathematically equivalent to a feature extraction model akin to \(3\) with low-rank covariances \( \bar{\Sigma}_{x}^{(ik)} \) and where the additive noise \( w \) is substituted by additive noise with distribution \( \mathcal{N}(0, \varepsilon \Phi \Phi^T + \sigma^2 I) \). Therefore, on noticing that the matrix \( \Phi \Phi^T \) approximate well the identity matrices when \( \Phi \) has non-zero entries that are i.i.d., zero-mean, Gaussian with unit variance, we can conclude that performance associated to “approximately low-rank” models for a given noise variance \( \sigma^2 \) is comparable to the performance of the corresponding exactly low-rank models for noise variance equal to \( \sigma^2 + \varepsilon \).

D. Experimental Results: Compressive Hyperspectral Imaging

Finally, we present an example to showcase how the proposed framework also offers a principled approach to design systems able to leverage effectively side information in reconstruction tasks. In this case, we do not reveal the presence of phase transitions in the reconstruction error, due to the fact that the signal model describing the data is a full-rank model. However, we can notice how side information can be used in order to improve reconstruction performance.

We consider a compressive hyperspectral imaging example, in which hyperspectral images of a subject are recovered from compressive measurements in the presence of side information. In particular, we consider measurements collected by the coded aperture snapshot spectral imager (CASSI) apparatus described in \[73\]. Side information is represented in this case by an RGB snapshot of the same scene, which can be easily obtained without requiring expensive hyperspectral imaging devices. The information contained in the RGB image is expected to improve the reconstruction quality of the input signal, also due to the fact that, in contrast to the measurements taken by the CASSI camera, the RGB image is not affected by coded aperture modulation.

In this case the vector \( x_1 \) represents patches extracted from the hyperspectral image, whereas \( x_2 \) represents patches extracted from the corresponding RGB image (see \[73\] for details on how data from this system are analyzed). The vectors \( x_1 \) and \( x_2 \) are assumed to be modeled by the joint GMM described in Section \(II-A\) with \( K_1 = K_2 = 20 \).
The parameters of the joint GMM are learned from the hyperspectral image dataset used in [74] again via the EM algorithm. Note that the images in the training dataset are associated to wavelength values that do not match perfectly those characterizing the CASSI camera. Therefore, the training algorithm is run by selecting each time wavelengths that are closest to the nominal values of the CASSI camera.

Fig. 10. Left: hyperspectral image (reference). Middle: RGB image. Right: CASSI measurement.

Fig. 11. Left: reconstruction without side information. Right: reconstruction with side information.

We consider real data captured by the CASSI camera, so that the entries of the projection kernel $\Phi_1$ reflect the physical implementation of the compressive imaging system [75], and they are constrained to belong to the interval $[0, 1]$. On the other hand, the side information RGB image is not compressed, so that we have $\Phi_2 = I$. The bird dataset is used and a single measurement is used, thus meaning that 24 images of size $1021 \times 703$ corresponding

[http://personalpages.manchester.ac.uk/staff/d.h.foster/Hyperspectral_images_of_natural_scenes_04.html](http://personalpages.manchester.ac.uk/staff/d.h.foster/Hyperspectral_images_of_natural_scenes_04.html)
Fig. 12. Zoom-in of reconstructed images for six different channels. The corresponding PSNRs for reconstruction with and without side information are reported in Table II.

Table II

Reconstruction PSNR (in dB) for the six selected regions in Fig. 12, with and without side information.

| Region     | 1   | 2   | 3   | 4   | 5   | 6   |
|------------|-----|-----|-----|-----|-----|-----|
| without side information | 12.50 | 16.42 | 12.71 | 15.49 | 16.20 | 18.86 |
| with side information       | 13.81 | 18.66 | 17.24 | 17.80 | 19.21 | 20.07 |

to 24 different wavelengths from 398.6 nm to 699.5 nm are compressed into a single snapshot of the same size. In order to evaluate the reconstruction accuracy, reference images are acquired using a different (and non-compressive) hyperspectral imaging setup. Therefore, the reference images and the side information image are not perfectly aligned with the CASSI measurement shown in the right part of Fig. 10. The reconstructed hyperspectral images without and with side information are shown in Fig. 11. It can be seen clearly that the reconstruction with side information has better quality. Furthermore, though the reference is not aligned well with the CASSI measurement, we can still compare the reconstruction PSNR in correspondence of some selected blocks in the image. Fig. 12 shows the reconstruction of six channels and the corresponding PSNR values are reported in Table II. It can be noticed that the PSNR improvement due to side information is significant.

VII. Conclusions

We have developed a principled framework that can be used not only to study fundamental limits in the classification and reconstruction of high-dimensional signals from low-dimensional signal features in the presence of side information, but also to obtain state-of-the-art results in imaging problems.
In particular, we have considered a linear feature-extraction model, where a decoder has access to noisy linear features of both the signal of interest and the side information signal, in order to carry out either classification or reconstruction. We have also considered a model where the joint distribution of the signal of interest and the side information, conditioned on some underlying class labels is a multivariate Gaussian, which embodies the correlation between these signals. The marginal distribution of the signal conditioned on a class label is a Gaussian mixture, and likewise the marginal distribution of the side information conditioned on the class label is also a Gaussian mixture.

This modeling approach, which can be used to encapsulate a wide range of distributions, has then offered the opportunity to capitalize on tractable bounds to the misclassification probability and the reconstruction error, to construct an asymptotic characterization of the behavior of these quantities in the low-noise regime. In addition, this modeling approach has also led to a characterization of sharp sufficient conditions for a phase transition in the misclassification probability and necessary and sufficient conditions for the phase transition of the reconstruction error (the performance quantities under consideration), as a function of the geometry of the sources, the geometry of the linear feature extraction process and their interplay, reminiscent of the Slepian-Wolf and the Wyner-Ziv conditions.

It has been shown that our theory is well aligned with practice via a range of numerical results associated with low-rank data models. Of particular relevance, it has also been shown that our framework offers a principled mechanism to integrate side information in data classification and reconstruction problems in the context of compressive hyperspectral imaging in the presence of side information.

This work also points to various possible future directions:

- It is of interest to extend the results from consideration of only one side information source to settings where there are multiple sources of side information. It is possible to generalize the models immediately, but the analysis is considerably more complex (as pointed out in Appendix A).
- There is interest in generalization of the results from the scenario where the linear features are extracted randomly to scenarios where the linear features are designed [5], [6], [64] (or indeed nonlinear features are designed [21]) is relevant. This could lead to additional gains in the phase transition.
- The generalization of the results from scenarios where only the decoder has access to the side information to scenarios where both the encoder and the decoder have access to the side information is also relevant. This may also lead to additional gains both in the presence of random linear features or designed ones.
- Finally, it is believed that the framework, which applies to settings where both the signal of interest and the side information signal follow correlated Gaussian mixture models, can also be generalized to other data models – this can then translate into applications of the framework to scenarios where signals conform to different modalities.
APPENDIX A

PROOF OF THEOREM

We start by considering the case, \( K_1 = 2 \). We recall that the Batthacharyya upper bound for the misclassification probability of \( C_1 \) is given by

\[
\bar{P}_{\text{err}} = \sqrt{p_{C_1}(1)p_{C_1}(2)} \int \sqrt{p(y|C_1 = 1)p(y|C_1 = 2)} dy
\]

\[
= \sqrt{p_{C_1}(1)p_{C_1}(2)} \int \left[ \sum_{k, \ell=1}^{K_2} p_{C_2|C_1}(k|1)p_{C_2|C_1}(\ell|2)p(y|C_1 = 1, C_2 = k)p(y|C_1 = 2, C_2 = \ell) \right] dy. \tag{91}
\]

An upper and a lower bound to the expression in (91) are simply obtained by considering the following fact. Given \( n \) non-negative numbers \( a_1, \ldots, a_n \geq 0 \), it holds

\[
\frac{1}{\sqrt{n}} \sum_{i=1}^{n} \sqrt{a_i} \leq \sum_{i=1}^{n} a_i \leq \sum_{i=1}^{n} \sqrt{a_i}, \tag{92}
\]

where the first inequality derives from the concavity of the function \( f(x) = \sqrt{x} \) and the second inequality can be simply proved by induction starting from \( n = 2 \).

Then, an upper bound to \( \bar{P}_{\text{err}} \) is obtained as

\[
\bar{P}_{\text{err}}^{U} = \sqrt{p_{C_1}(1)p_{C_1}(2)} \sum_{k, \ell=1}^{K_2} \sqrt{p_{C_2|C_1}(k|1)p_{C_2|C_1}(\ell|2)} \int \sqrt{p(y|C_1 = 1, C_2 = k)p(y|C_1 = 2, C_2 = \ell)} dy, \tag{93}
\]

and, similarly, a lower bound is given by \( \bar{P}_{\text{err}}^{L} = \bar{P}_{\text{err}}^{U}/K_2 \). The generalization of this result to the case \( K_1 > 2 \), is based on the evaluation of the union bound (31), which, together with (92), yields the upper bound

\[
\bar{P}_{\text{err}}^{U} = \sum_{i=1}^{K_1} \sum_{j=1}^{K_1} \sum_{k, \ell=1}^{K_2} p_{C_i}(i) \sqrt{p_{C_2|C_1}(k|i)p_{C_2|C_1}(\ell|j)} \int \sqrt{p(y|C_1 = i, C_2 = k)p(y|C_1 = j, C_2 = \ell)} dy, \tag{94}
\]

and the corresponding lower bound \( \bar{P}_{\text{err}}^{L} = \bar{P}_{\text{err}}^{U}/K_2 \).

Note that the lower and the upper bounds differ only by the multiplicative constant \( K_2 \). Therefore, they are tight bounds in terms of the diversity-order, and it is possible to derive the diversity-order associated to \( \bar{P}_{\text{err}} \) from the analysis of such bounds.

We now observe that the integral in (94) also appears in the analysis of the upper bound to the misclassification probability associated to the classification between two Gaussian distributions without side information as described in [67]. In particular, such integral can be expressed as

\[
\int \sqrt{p(y|C_1 = i, C_2 = k)p(y|C_1 = j, C_2 = \ell)} dy = e^{-K(k,j,\ell)}, \tag{95}
\]
where

\[
K(ik, j\ell) = \frac{1}{8} (\mu^{(ik)}_x - \mu^{(j\ell)}_x)^T \Phi T \left[ \Phi (\Sigma^{(ik)}_x + \Sigma^{(j\ell)}_x) \Phi^T + 2\sigma^2 I \right]^{-1} \Phi (\mu^{(ik)}_x - \mu^{(j\ell)}_x) + \frac{1}{2} \log \frac{\det \left( \Phi (\Sigma^{(ik)}_x + \Sigma^{(j\ell)}_x) \Phi^T + 2\sigma^2 I \right)}{\sqrt{\det(\Phi \Sigma^{(ik)}_x \Phi^T + \sigma^2 I) \sqrt{\det(\Phi \Sigma^{(j\ell)}_x \Phi^T + \sigma^2 I)}}}.
\]  

(96)

For the case of zero-mean classes, i.e., assuming \( \mu^{(ik)}_x = \mu^{(j\ell)}_x = 0 \), a low-noise expansion for the integral in (94) is given by [67, Theorem 1]

\[ e^{-K(ik, j\ell)} = A^{(ik, j\ell)} \cdot (\sigma^2)^{d(ik, j\ell)} + o \left( (\sigma^2)^{d(ik, j\ell)} \right), \]  

(97)

for a fixed constant \( A^{(ik, j\ell)} > 0 \), and with \( d(ik, j\ell) \) given by

\[ d(ik, j\ell) = \frac{1}{2} \left( r^{(ik, j\ell)} - \frac{r^{(ik)} + r^{(j\ell)}}{2} \right), \]  

(98)

where

\[ r^{(ik)} = \text{rank} \left( \Phi \Sigma^{(ik)}_x \Phi^T \right) \quad \text{and} \quad r^{(j\ell)} = \text{rank} \left( \Phi \Sigma^{(j\ell)}_x \Phi^T \right), \]  

(99)

Therefore, we can conclude that a low-noise expansion for the upper bound of the misclassification probability [31] is given by

\[ \bar{P}_{err}(\sigma^2) = A \cdot (\sigma^2)^d + o \left( (\sigma^2)^d \right), \]  

(100)

where \( A > 0 \) is a fixed constant and

\[ d = \min_{i \neq j \in \{1, \ldots, K_1\}} \min_{k, \ell \in \{1, \ldots, K_2\}} d(ik, j\ell) = \min_{i, k, j, \ell, i \neq j} d(ik, j\ell). \]  

(101)

is the worst-case diversity-order associated to the misclassification of pairs of Gaussian distributions identified by the index pairs \((i, k)\) and \((j, \ell)\), such that \(i \neq j\).

It is then clear that the computation of the expansion of \( \bar{P}_{err} \) for classification with side information requires the computation of the diversity-order terms (98), and, therefore, the computation of the ranks \( r^{(ik)} = \text{rank}(\Gamma^{(ik)}) \) and \( r^{(ik, j\ell)} = \text{rank}(\Gamma^{(ik, j\ell)}) \), with \( \Gamma^{(ik)} = \Phi \mathbf{P}^{(ik)} \) and \( \Gamma^{(ik, j\ell)} = \Phi \mathbf{P}^{(ik, j\ell)} \), where

\[
\mathbf{P}^{(ik)} = \begin{bmatrix}
P^{(ik)}_{c_1} & P^{(ik)}_{1} & 0 \\
P^{(ik)}_{c_2} & 0 & P^{(ik)}_{2}
\end{bmatrix}
\]  

(102)

\[
\mathbf{P}^{(ik, j\ell)} = \begin{bmatrix}
P^{(ik, j\ell)}_{c_1} & P^{(ik, j\ell)}_{1} & 0 \\
P^{(ik, j\ell)}_{c_2} & 0 & P^{(ik, j\ell)}_{2}
\end{bmatrix}
\]  

(103)

and

\[
\Phi = \begin{bmatrix}
\Phi_1 & 0 \\
0 & \Phi_2
\end{bmatrix}.
\]  

(104)
Therefore, in the following we will provide a characterization of such ranks as a function of the numbers of features \( m_1 \) and \( m_2 \). For ease of a compact notation, we drop superscripts when results hold for all possible choices of index pairs \( (i, k) \) or quadruples \( (i, k, j, \ell) \). For the ease of notation, we will assume in the following \( n_1 \geq m_1 \) and \( n_2 \geq m_2 \). However, the extension to the case where \( n_1 < m_1 \) or \( n_2 < m_2 \) is straightforward.

**Lemma 1:** Let \( P_{c_1} \in \mathbb{R}^{n_1 \times s_c}, P_{c_2} \in \mathbb{R}^{n_2 \times s_c}, P_1 \in \mathbb{R}^{n_1 \times s_1}, P_2 \in \mathbb{R}^{n_2 \times s_2} \). Let \( \Phi \in \mathbb{R}^{(m_1+m_2) \times (n_1+n_2)} \) as in (104), such that the row spaces associated to \( \Phi_1 \) and \( \Phi_2 \) are \( m_1 \)- and \( m_2 \)-dimensional spaces, isotropically distributed at random in \( \mathbb{R}^{n_1} \) and \( \mathbb{R}^{n_2} \), respectively, and let \( P \) as

\[
P = \begin{bmatrix} P_{c_1} & P_1 & 0 \\ P_{c_2} & 0 & P_2 \end{bmatrix}.
\]

Then, with probability 1, the rank of the matrix \( \Gamma = \Phi P \) is given by

\[
r = \text{rank}(\Gamma) = \min \{ r_x, \min \{ m_1, r_{x_1} \} + \min \{ m_2, r_{x_2} \} \},
\]

where \( r_{x_1} = \text{rank}[P_{c_1} P_1], r_{x_2} = \text{rank}[P_{c_2} P_2] \) and \( r_x = \text{rank}(P) \).

**Proof:** It is easy to observe that the expression in (106) represents an upper bound to the rank \( r = \text{rank}(\Phi \Phi^T) \) as \( \text{rank}(\Phi \Phi^T) \leq \text{rank}(\Phi) \) and \( \text{rank}(\Gamma) \) is always less than or equal to the sum of the ranks of the matrices obtained by considering separately its first \( m_1 \) and the remaining \( m_2 \) rows, i.e., \( \text{rank}(\Phi_1[P_{c_1} P_1 0]) \) and \( \text{rank}(\Phi_2[P_{c_2} 0 P_2]) \).

Therefore, in the rest of the proof, we will aim at showing that such upper bound is actually tight, by proving that we can find at least \( r \) linear independent columns in \( \Gamma \).

We start by considering the special case in which we impose \( \Phi_2 = I_{n_2} \), and we show that in this case it holds

\[
r_{I_2} = \text{rank} \left( \begin{bmatrix} \Phi_1 & 0 \\ 0 & I \end{bmatrix} \begin{bmatrix} P_{c_1} & P_1 & 0 \\ P_{c_2} & 0 & P_2 \end{bmatrix} \right) = \min \{ r_x, \min \{ m_1, r_{x_1} \} + r_{x_2} \}.
\]

On recalling Sylvester’s rank theorem [76], which states

\[
\text{rank}(AB) = \text{rank}(B) - \dim(\text{Im}(B) \cap \text{Null}(A)),
\]

we can write

\[
r_{I_2} = \text{rank}(P) - \dim \left( \text{Im}(P) \cap \text{Null} \left[ \begin{bmatrix} \Phi_1 & 0 \\ 0 & I \end{bmatrix} \right] \right).
\]

Then, we consider the matrix \( \Psi_1 \in \mathbb{R}^{n_1 \times (n_1-m_1)} \), whose columns form a basis for the null space \( \text{Null}(\Phi_1) \), which is isotropically distributed among the \((n_1-m_1)\)-dimensional spaces in \( \mathbb{R}^{n_1} \). It is then straightforward to show that the columns of the matrix \( [\Psi_1^T 0_{n_2 \times (n_1-m_1)}]^T \) span the null space

\[
\text{Null} \left[ \begin{bmatrix} \Phi_1 & 0 \\ 0 & I \end{bmatrix} \right]
\]
and we can write
\[ r_{I_2} = r_X - \dim \left( \text{Im}(P) \cap \text{Im} \begin{bmatrix} \Psi_1 \\ 0 \end{bmatrix} \right) \] (111)
\[ = \text{rank} \begin{bmatrix} P_{c_1} & P_1 & 0 & \Psi_1 \\ P_{c_2} & 0 & P_2 & 0 \end{bmatrix} - (n_1 - m_1), \] (112)
in which we have leveraged the rank equality for block matrices [77].
\[ \text{rank} [A \ B] = \text{rank}(A) + \text{rank}(B) - \dim(\text{Im}(A) \cap \text{Im}(B)), \] (113)
and the fact that \( \text{rank}(\Psi_1) = n_1 - m_1 \) and \( \text{rank}(P) = r_X \). Consider now the computation of the rank
\[ r_{\Psi_1} = \text{rank} \begin{bmatrix} P_{c_1} & P_1 & 0 & \Psi_1 \\ P_{c_2} & 0 & P_2 & 0 \end{bmatrix}. \] (114)

In order to compute such rank, we will leverage the generalized singular value decomposition (GSVD) as described in [78]. In particular, consider two matrices \( A \in \mathbb{R}^{n \times p} \) and \( B \in \mathbb{R}^{m \times p} \), with the same number of columns, and with \( r_A = \text{rank}(A), r_B = \text{rank}(B), r_{AB} = \text{rank}[A^T B^T]^T \) and \( s_{AB} = r_A + r_B - r_{AB} \). Then, there exist two orthogonal matrices \( U \in \mathbb{R}^{n \times n}, V \in \mathbb{R}^{m \times m} \) and a non-singular matrix \( X \in \mathbb{R}^{p \times p} \) such that
\[ U^T A X = \begin{bmatrix} \Lambda_A & 0_{n \times (p-r_{AB})} \end{bmatrix}, \quad U^T B X = \begin{bmatrix} \Lambda_B & 0_{m \times (p-r_{AB})} \end{bmatrix}, \] (115)
where
\[ \Lambda_A = \begin{bmatrix} r_{AB} - r_B & s_{AB} & r_{AB} - r_A \\ s_{AB} & r_{AB} - r_A & 0 \\ r_{AB} - r_A & 0 & \end{bmatrix}, \quad \Lambda_B = \begin{bmatrix} r_{AB} - r_B & s_{AB} & r_{AB} - r_A \\ s_{AB} & r_{AB} - r_A & 0 \\ r_{AB} - r_A & 0 & \end{bmatrix}. \] (116)
and \( D_A = \text{diag}(\alpha_1, \ldots, \alpha_{s_{AB}}), D_B = \text{diag}(\beta_1, \ldots, \beta_{s_{AB}}) \), such that \( 1 < \alpha_1 \leq \cdots \leq \alpha_{s_{AB}} < 0 \) and \( 0 < \beta_1 \leq \cdots \leq \beta_{s_{AB}} < 1 \), and \( \alpha_i^2 + \beta_i^2 = 1 \), for \( i = 1, \ldots, s_{AB} \).

Therefore, on applying the GSVD to the two matrices \( [P_{c_1} \ P_1 \ 0] \) and \( [P_{c_2} \ 0 \ P_2] \), we can write
\[ r_{\Psi_1} = \text{rank} \begin{bmatrix} U^T & 0 \\ 0 & V^T \end{bmatrix} \begin{bmatrix} P_{c_1} & P_1 & 0 & \Psi_1 \\ P_{c_2} & 0 & P_2 & 0 \end{bmatrix} \begin{bmatrix} X & 0 \\ 0 & I_{n_1-m_1} \end{bmatrix} \] (117)
\[ = \text{rank} \begin{bmatrix} \Lambda_1 & 0 & \Psi'_1 \\ \Lambda_2 & 0 & 0 \end{bmatrix} \] (118)
where

$$
\Lambda_1 = \begin{bmatrix}
- & - & - & - \\
- & - & - & - \\
- & - & - & - \\
- & - & - & - \\
\end{bmatrix}
$$

and where $\Psi_1' = U^T \Psi_1$ is a matrix whose column space is still isotropically distributed at random among the $(n_1 - m_1)$-dimensional subspaces of $\mathbb{R}^{n_1}$. Now, by considering the first $r_{x_2} - r_{x_2}$ columns of the matrix in (118) together with its last $n_1 - m_1$ columns, given the fact the columns in $\Psi_1'$ form a random space in $\mathbb{R}^{n_1}$, we can conclude that, with probability 1, we can pick from such columns $\min\{r_{x_2} + n_1 - m_1, n_1\}$ independent columns, which are also independent from the remaining $(r_{x_1} + r_{x_2} - r_{x}) + (r_{x} - r_{x_1}) = r_{x_2}$ non-zero columns of the same matrix. Therefore, we have

$$
r_{\Psi_1} = \min\{r_{x} - r_{x_2} + n_1 - m_1, n_1\} + r_{x_2}
$$

and then

$$
r_{I_2} = \min\{r_{x} - r_{x_2} + n_1 - m_1, n_1\} + r_{x_2} - (n_1 - m_1)
$$

$$
= \min\{r_{x}, m_1 + r_{x_2}\}
$$

$$
= \min\{r_{x}, \min\{m_1, r_{x_1}\} + r_{x_2}\},
$$

where the last equality is obtained by observing that $r_{x} \leq r_{x_1} + r_{x_2}$.

Consider now the general case, in which $\Phi_2$ is not forced to be equal to the identity matrix. In this case, by leveraging (123), we can write

$$
r = \text{rank} \left( \begin{bmatrix}
\Phi_1 & 0 \\
0 & \Phi_2 \\
\end{bmatrix} \begin{bmatrix}
P_{c_1} & P_1 & 0 \\
P_{c_2} & 0 & P_2 \\
\end{bmatrix} \right)
$$

$$
= \text{rank} \left( \begin{bmatrix}
\Phi_1 & 0 \\
0 & I \\
\end{bmatrix} \begin{bmatrix}
P_{c_1} & P_1 & 0 \\
\Phi_2 P_{c_2} & 0 & \Phi_2 P_2 \\
\end{bmatrix} \right)
$$

$$
= \min\{r_{I_1}, \min\{m_1, r_{x_1}\} + \min\{m_2, r_{x_2}\}\},
$$

in which we have introduced the symbol

$$
r_{I_1} = \text{rank} \left( \begin{bmatrix}
P_{c_1} & P_1 & 0 \\
\Phi_2 P_{c_2} & 0 & \Phi_2 P_2 \\
\end{bmatrix} \right)
$$

$$
= \text{rank} \left( \begin{bmatrix}
I & 0 \\
0 & \Phi_2 \\
\end{bmatrix} \begin{bmatrix}
P_{c_1} & P_1 & 0 \\
P_{c_2} & 0 & P_2 \\
\end{bmatrix} \right),
$$

and where we have used the fact that $\text{rank}[\Phi_2 P_{c_2} 0 \Phi_2 P_2] = \min\{m_2, r_{x_2}\}$. Then, with a procedure similar to
that used to compute $r_{L_2}$, it is possible to show that $r_{L_1} = \min\{r_x, r_{x_1} + \min\{m_2, r_{x_2}\}\}$, thus leading to

$$r = \min\{r_x, r_{x_1} + \min\{m_2, r_{x_2}\}\}, \min\{m_1, r_{x_1}\} + \min\{m_2, r_{x_2}\}\}$$

(129)

$$= \min\{r_x, \min\{m_1, r_{x_1}\} + \min\{m_2, r_{x_2}\}\}.$$  

(130)

Finally, note that Lemma 1 can be immediately applied to compute $r^{(ik)}$, $r^{(j\ell)}$, and $r^{(ik,j\ell)}$, thus concluding the proof of Theorem 1.

We also note in passing that the generalization of Lemma 1 to the case of multiple side information sources, $x_2, x_3, \ldots, x_L$, seems to be considerably more complex, due to the absence of a transform akin to the GSVD in [115] and [116] that jointly diagonalizes more than two matrices.

**APPENDIX B**

**PROOF OF COROLLARY 1**

On the basis of the low-noise regime expansion for the upper bound to the misclassification probability (31) contained in Theorem 1, we can state that the phase transition (32) occurs if and only if $d > 0$, which is equivalent to $d^{(ik, j\ell)} > 0$, $\forall (i, k, j, \ell) \in S_{SIC}$. Moreover, on observing that the matrices $\Phi \Sigma^{(ik)}_x \Phi^T$ and $\Phi \Sigma^{(j\ell)}_x \Phi^T$ are positive semidefinite, we can immediately state that $d^{(ik, j\ell)} = 0$ if and only if $r^{(ik,j\ell)} = r^{(ik)} = r^{(j\ell)}$, which is verified if only if [64], Lemma 2

$$\text{Im} (\Phi \Sigma^{(ik)}_x \Phi^T) = \text{Im} (\Phi \Sigma^{(j\ell)}_x \Phi^T).$$  

Then, $r^{(ik,j\ell)} = r^{(ik)} = r^{(j\ell)}$ implies that $\text{Im} \Sigma^{(ik)}_x = \text{Im} \Sigma^{(j\ell)}_x$, and, therefore, (131) holds regardless of the expression of the projection kernel $\Phi$, thus leading to $d^{(ik, j\ell)} = 0$.

Assume now $r^{(ik,j\ell)} > r^{(ik)}$, $r^{(j\ell)}$. We can then use the rank expression (106) and consider separately the following cases:

1) $r^{(ik,j\ell)} > r^{(ik)}$, $r^{(j\ell)}$ and $r^{(ik)} > r^{(j\ell)}, r^{(ik,j\ell)}$; in this case, if $m_1 > \min\{r^{(ik)}_{x_1}, r^{(j\ell)}_{x_1}\}$ or $m_2 > \min\{r^{(ik)}_{x_2}, r^{(j\ell)}_{x_2}\}$, we can immediately conclude that $d^{(ik, j\ell)} > 0$, by simply considering the classification from the observation of $y_1$ or $y_2$ alone, respectively, and by leveraging the results in [67], Theorem 2. On the other hand, if we assume $m_1 \leq \min\{r^{(ik)}_{x_1}, r^{(j\ell)}_{x_1}\}$, $m_2 \leq \min\{r^{(ik)}_{x_2}, r^{(j\ell)}_{x_2}\}$ and $m_1 + m_2 > \min\{r^{(ik)}_{x_1}, r^{(j\ell)}_{x_1}\}$, then we have $r^{(ik)} = \min\{r^{(ik)}_{x_1}, m_1 + m_2\}$, $r^{(j\ell)} = \min\{r^{(j\ell)}_{x_2}, m_1 + m_2\}$ and $r^{(ik,j\ell)} = \min\{r^{(ik,j\ell)}_{x_1}, m_1 + m_2\}$. Then, since $m_1 + m_2 > \min\{r^{(ik)}_{x_1}, r^{(j\ell)}_{x_1}\}$, we have immediately that $r^{(ik,j\ell)} > \min\{r^{(ik)}, r^{(j\ell)}\}$, and thus $d^{(ik, j\ell)} > 0$. Such sufficient conditions on the minimum number of measurements $m_1, m_2$ needed to guarantee $d^{(ik, j\ell)} > 0$ are also necessary. In fact, if $m_1 \leq \min\{r^{(ik)}_{x_1}, r^{(j\ell)}_{x_1}\}$, $m_2 \leq \min\{r^{(ik)}_{x_2}, r^{(j\ell)}_{x_2}\}$ and $m_1 + m_2 \leq \min\{r^{(ik)}_{x_1}, r^{(j\ell)}_{x_1}\}$, then $r^{(ik,j\ell)} = r^{(ik)} = r^{(j\ell)} = m_1 + m_2$.

2) $r^{(ik,j\ell)} = r^{(ik)}_{x_1} = r^{(j\ell)}_{x_2}$ and $r^{(ik)} = r^{(j\ell)}$. In this case, we note that $\min\{m_1, r^{(ik)}_{x_1}\} + \min\{m_2, r^{(ik)}_{x_2}\} = \min\{m_1, r^{(ik, j\ell)}_{x_1}\} = \min\{m_1, r^{(ik)}_{x_1}\} + \min\{m_2, r^{(ik)}_{x_2}\} = \min\{m_1, r^{(ik, j\ell)}_{x_1}\} = \min\{m_2, r^{(ik, j\ell)}_{x_2}\}$, $D$, and then $d^{(ik, j\ell)} > 0$ if and only if $D > \min\{r^{(ik)}_{x_1}, r^{(j\ell)}_{x_2}\}$. Then, we can split the analysis in further subcases as follows:
• if $m_1 \leq r_{x_1}^{(ik)}$ and $m_2 \leq r_{x_2}^{(ik)}$, then $d(ik, j\ell) > 0$ if and only if $m_1 + m_2 > \min\{r_{x_1}^{(ik)}, r_{x_2}^{(j\ell)}\}$;
• if $m_1 > r_{x_1}^{(ik)}$ and $m_2 \leq r_{x_2}^{(ik)}$, then $d(ik, j\ell) > 0$ if and only if $m_2 > \min\{r_{x_1}^{(ik)} - r_{x_1}^{(ik)}, r_{x_2}^{(j\ell)} - r_{x_1}^{(ik)}\}$;
• if $m_1 \leq r_{x_1}^{(ik)}$ and $m_2 > r_{x_2}^{(ik)}$, then $d(ik, j\ell) > 0$ if and only if $m_1 > \min\{r_{x_1}^{(ik)} - r_{x_1}^{(ik)}, r_{x_2}^{(j\ell)} - r_{x_2}^{(ik)}\}$;
• if $m_1 > r_{x_1}^{(ik)}$ and $m_2 > r_{x_2}^{(ik)}$, then $r_{x_1}^{(ik)} + r_{x_2}^{(ik)} = r_{x_1}^{(j\ell)} + r_{x_2}^{(j\ell)} > \min\{r_{x_1}^{(ik)}, r_{x_2}^{(j\ell)}\}$ and therefore $d(ik, j\ell) > 0$.

Finally, we can combine the previous expressions to obtain necessary and sufficient conditions to guarantee $d(ik, j\ell) > 0$ as

$$
\begin{align*}
&\begin{cases} 
  m_1 > \min\{r_{x_1}^{(ik)}, r_{x_2}^{(j\ell)}\} \\
  m_2 > \min\{r_{x_1}^{(ik)}, r_{x_2}^{(j\ell)} - r_{x_1}^{(ik)}\} \\
  m_1 + m_2 > \min\{r_{x_1}^{(ik)}, r_{x_2}^{(j\ell)}\}
\end{cases} \\
&\text{or} \quad \begin{cases} 
  m_1 > \min\{r_{x_1}^{(ik)}, r_{x_2}^{(j\ell)}\} \\
  m_1 + m_2 > \min\{r_{x_1}^{(ik)}, r_{x_2}^{(j\ell)}\}
\end{cases}
\end{align*}
$$

3) $r_{x_1}^{(ik), j\ell} > r_{x_1}^{(ik)}, r_{x_2}^{(j\ell)} = r_{x_2}^{(ik)}$, we can prove immediately that, in this case, if $m_1 > \min\{r_{x_1}^{(ik)}, r_{x_2}^{(j\ell)}\}$, then $d(ik, j\ell) > 0$, simply by considering classification based on the observation of only $y_1$. Assume now $m_1 \leq \min\{r_{x_1}^{(ik)}, r_{x_2}^{(j\ell)}\}$. Then, it holds $r^{(ik)} = \min\{r_{x_1}^{(ik)}, m_1 + \min\{m_2, r_{x_2}^{(j\ell)}\}\}$, $r^{(j\ell)} = \min\{r_{x_2}^{(j\ell)}, m_1 + \min\{m_2, r_{x_2}^{(j\ell)}\}\}$, and, on observing that $\min\{m_2, r_{x_2}^{(j\ell)}\} = \min\{m_2, r_{x_2}^{(j\ell)}\}$, we have immediately that $d(ik, j\ell) > 0$ if and only if $\min\{r_{x_1}^{(ik)}, r_{x_2}^{(j\ell)}\} < m_1 + \min\{m_2, r_{x_2}^{(j\ell)}\}$. In particular, if $m_2 \leq r_{x_2}^{(ik)}$, then $d(ik, j\ell) > 0$ if and only if $m_1 + m_2 > \min\{r_{x_1}^{(ik)}, r_{x_2}^{(j\ell)}\}$, whereas if $m_2 > r_{x_2}^{(ik)}$, then $d(ik, j\ell) > 0$ if and only if $m_1 > \min\{r_{x_1}^{(ik)} - r_{x_2}^{(ik)}, r_{x_2}^{(j\ell)} - r_{x_2}^{(ik)}\}$. Finally, on combining these expressions, we can write necessary and sufficient conditions for $d(ik, j\ell) > 0$ as

$$
\begin{align*}
&\begin{cases} 
  m_1 > \min\{r_{x_1}^{(ik)}, r_{x_2}^{(j\ell)}\} \\
  m_1 + m_2 > \min\{r_{x_1}^{(ik)}, r_{x_2}^{(j\ell)}\}
\end{cases} \\
&\text{or} \quad \begin{cases} 
  m_1 > \min\{r_{x_1}^{(ik)}, r_{x_2}^{(j\ell)}\} \\
  m_1 + m_2 > \min\{r_{x_1}^{(ik)}, r_{x_2}^{(j\ell)}\}
\end{cases}
\end{align*}
$$

4) $r_{x_1}^{(ik), j\ell} = r_{x_1}^{(ik)} = r_{x_2}^{(ik)}$ and $r_{x_1}^{(ik), j\ell} > r_{x_2}^{(ik)}, r_{x_2}^{(j\ell)}$. the proof for this case follows steps similar to the case $r_{x_1}^{(ik), j\ell} > r_{x_1}^{(ik)}, r_{x_2}^{(j\ell)}$ and $r_{x_2}^{(ik), j\ell} = r_{x_2}^{(j\ell)}$.

**APPENDIX C**

**PROOF OF THEOREM (2)**

The characterization of the low-noise expansion of the upper bound to the misclassification probability in (31) for the case of nonzero-mean classes starts from the analysis of its lower and upper bounds presented in Appendix A. We focus on the expressions in (94), (95) and (96), and we leverage the low-noise expansion of the integral in (95) presented in (67) Theorem 3 for the case of two nonzero-mean Gaussian classes. Namely, we recall that

$$
e^{-K(ik,j\ell)} = B^{(ik,j\ell)} \cdot e^{-C^{(ik,j\ell)}/\sigma^2} + o\left(e^{-C^{(ik,j\ell)}/\sigma^2}\right),
$$

for fixed constants $B^{(ik,j\ell)}, C^{(ik,j\ell)} > 0$ if and only if

$$
\Phi(\mu^{(ik)}_x - \mu^{(j\ell)}_x) \notin \text{Im} \left( \Phi(\Sigma^{(ik)}_x + \Sigma^{(j\ell)}_x) \Phi^T \right),
$$
Otherwise, the integral in (95) can be expanded as in (97). Therefore, if condition (135) is verified for all the index quadruples \((i, k, j, \ell) \in S_{\text{SIC}}\), then we can expand the upper bound to the misclassification probability in (31) as

\[
\hat{P}_{\text{err}}(\sigma^2) = B \cdot e^{-C\sigma^2} + o \left( e^{-C\sigma^2} \right),
\]

for fixed constants \(B, C > 0\). Otherwise, the upper bound of the misclassification probability is expanded as

\[
\hat{P}_{\text{err}}(\sigma^2) = A \cdot (\sigma^2)^d + o \left( (\sigma^2)^d \right),
\]

for a fixed \(A > 0\) and

\[
d = \min_{(i,k,j,\ell) \in S'} d(ik, j\ell),
\]

where \(S'\) is the set of the index quadruples \((i, k, j, \ell) \in S_{\text{SIC}}\) for which (135) is not verified and \(d(ik, j\ell)\) is as in (98).

We can now provide necessary and sufficient conditions on \(m_1\) and \(m_2\) such that (135) is verified. We observe that (135) holds if and only if \(r_{\mu}^{(ik,j\ell)} > r^{(ik,j\ell)}\), where we have defined

\[
r_{\mu}^{(ik,j\ell)} = \text{rank} \left( \begin{bmatrix} \Phi_1 & 0 \\ 0 & \Phi_2 \end{bmatrix} \begin{bmatrix} \mu_{x_1}^{(ik)} - \mu_{x_2}^{(ik)} & P_{11}^{(ik,j\ell)} & P_{12}^{(ik,j\ell)} \\ \mu_{x_2}^{(ik)} - \mu_{x_2}^{(j\ell)} & P_{21}^{(ik,j\ell)} & 0 \end{bmatrix} \right). \tag{139}
\]

Assume first that \(\mu_{x_1}^{(ik)} - \mu_{x_2}^{(j\ell)} \notin \text{Im} \left( \Sigma_{x_1}^{(ik)} + \Sigma_{x_2}^{(j\ell)} \right)\). Then \(r_{\mu}^{(ik,j\ell)} = r^{(ik,j\ell)}\), and, therefore (135) does not hold, irrespectively of the exact matrix \(\Phi\).

Assume now \(\mu_{x_1}^{(ik)} - \mu_{x_2}^{(j\ell)} \notin \text{Im} \left( \Sigma_{x_1}^{(ik)} + \Sigma_{x_2}^{(j\ell)} \right)\). We can use the rank expression (106) and similar steps to those in the proof of Corollary 1 in order to consider separately the following cases:

1) \(\mu_{x_1}^{(ik)} - \mu_{x_1}^{(j\ell)} \notin \text{Im}(\Sigma_{x_1}^{(ik)} + \Sigma_{x_1}^{(j\ell)})\) and \(\mu_{x_2}^{(ik)} - \mu_{x_2}^{(j\ell)} \notin \text{Im}(\Sigma_{x_2}^{(ik)} + \Sigma_{x_2}^{(j\ell)})\); on leveraging [64, Lemma 3], we can observe that if \(m_1 > r_{x_1}^{(ik,j\ell)}\) or \(m_2 > r_{x_2}^{(ik,j\ell)}\), then (135) holds, as the upper bound to the error probability obtained by classification based on the observation of \(y_1\) or \(y_2\) alone, respectively, decreases exponentially with \(1/\sigma^2\). On the other hand, if \(m_1 \leq r_{x_1}^{(ik,j\ell)}\), \(m_2 \leq r_{x_2}^{(ik,j\ell)}\) and \(m_1 + m_2 > r_x^{(ik,j\ell)}\), then it holds \(r_{\mu}^{(ik,j\ell)} = \min \{r_{x_1}^{(ik,j\ell)} + 1, m_1 + m_2\} > r^{(ik,j\ell)}\) and thus (135) is verified. The previous conditions are also shown to be necessary by noting that, if \(m_1 \leq r_{x_1}^{(ik,j\ell)}\), \(m_2 \leq r_{x_2}^{(ik,j\ell)}\) and \(m_1 + m_2 \leq r_x^{(ik,j\ell)}\), then \(r_{\mu}^{(ik,j\ell)} = r^{(ik,j\ell)} = m_1 + m_2\).  

2) \(\mu_{x_1}^{(ik)} - \mu_{x_1}^{(j\ell)} \in \text{Im}(\Sigma_{x_1}^{(ik)} + \Sigma_{x_1}^{(j\ell)})\) and \(\mu_{x_2}^{(ik)} - \mu_{x_2}^{(j\ell)} \in \text{Im}(\Sigma_{x_2}^{(ik)} + \Sigma_{x_2}^{(j\ell)})\); in this case, \(r_{\mu}^{(ik,j\ell)} = \min \{r_{x_1}^{(ik,j\ell)} + 1, \min \{m_1, r_{x_1}^{(ik,j\ell)}\} + \min \{m_2, r_{x_2}^{(ik,j\ell)}\}\} > r_{x_1}^{(ik,j\ell)}\). Then, we can split the analysis in the following subcases:

- if \(m_1 \leq r_{x_1}^{(ik,j\ell)}\) and \(m_2 \leq r_{x_2}^{(ik,j\ell)}\), then (135) is verified if and only if \(m_1 + m_2 > r_{x_1}^{(ik,j\ell)}\);
- if \(m_1 > r_{x_1}^{(ik,j\ell)}\) and \(m_2 \leq r_{x_2}^{(ik,j\ell)}\), then (135) is verified if and only if \(m_2 > r_{x_2}^{(ik,j\ell)} - r_{x_1}^{(ik,j\ell)}\);
- if \(m_1 \leq r_{x_1}^{(ik,j\ell)}\) and \(m_2 > r_{x_2}^{(ik,j\ell)}\), then (135) is verified if and only if \(m_1 > r_{x_1}^{(ik,j\ell)} - r_{x_2}^{(ik,j\ell)}\);
• if $m_1 > r^{(ik,jf)}_x$ and $m_2 > r^{(ik,jf)}_x$ then (135) is verified, since

$$r^{(ik,jf)}_x + r^{(ik,jf)}_x = \text{rank} [\mu^{(ik)}_{x_1} - \mu^{(jf)}_{x_1} \Sigma_{c_1} P^{(ik,jf)}_1 ] + \text{rank} [\mu^{(ik)}_{x_2} - \mu^{(jf)}_{x_2} \Sigma_{c_2} P^{(ik,jf)}_2 ] \geq r^{(ik,jf)}_x + 1.$$ (140)

Finally, we can combine the previous expressions and write necessary and sufficient conditions to guarantee (135) as

$$\begin{cases} m_1 > r^{(ik,jf)}_x - r^{(ik,jf)}_x \\ m_2 > r^{(ik,jf)}_x - r^{(ik,jf)}_x \end{cases} \quad (141)$$

3) $\mu^{(ik)}_{x_1} - \mu^{(jf)}_{x_1} \notin \text{Im}(\Sigma^{(ik)}_{x_1} + \Sigma^{(jf)}_{x_1})$ and $\mu^{(ik)}_{x_2} - \mu^{(jf)}_{x_2} \in \text{Im}(\Sigma^{(ik)}_{x_2} + \Sigma^{(jf)}_{x_2})$: in this case, if $m_1 > r^{(ik,jf)}_x$, then we can state that (135) is true by considering simply classification on the basis of the observation of $y_1$ alone. Therefore, assume now that $m_1 \leq r^{(ik,jf)}_x$. In this case $r^{(ik,jf)}_x = \min \{ r^{(ik,jf)}_x + 1, m_1 + \min \{ m_2, r^{(ik,jf)}_x \} \}$.

Therefore, if $m_2 \leq r^{(ik,jf)}_x$, then (135) holds if and only if $m_1 + m_2 > r^{(ik,jf)}_x$. On the other hand, if $m_2 > r^{(ik,jf)}_x$, then (135) holds if and only if $m_1 > r^{(ik,jf)}_x - r^{(ik,jf)}_x$. We can combine the previous expressions and write necessary and sufficient conditions to guarantee (135) in this case as

$$m_1 > r^{(ik,jf)}_x \quad \text{or} \quad \begin{cases} m_1 > r^{(ik,jf)}_x - r^{(ik,jf)}_x \\ m_1 + m_2 > r^{(ik,jf)}_x \end{cases} \quad (142)$$

4) $\mu^{(ik)}_{x_1} - \mu^{(jf)}_{x_1} \in \text{Im}(\Sigma^{(ik)}_{x_1} + \Sigma^{(jf)}_{x_1})$ and $\mu^{(ik)}_{x_2} - \mu^{(jf)}_{x_2} \notin \text{Im}(\Sigma^{(ik)}_{x_2} + \Sigma^{(jf)}_{x_2})$: the proof for this case follows steps similar to the case $\mu^{(ik)}_{x_1} - \mu^{(jf)}_{x_1} \notin \text{Im}(\Sigma^{(ik)}_{x_1} + \Sigma^{(jf)}_{x_1})$ and $\mu^{(ik)}_{x_2} - \mu^{(jf)}_{x_2} \in \text{Im}(\Sigma^{(ik)}_{x_2} + \Sigma^{(jf)}_{x_2})$.

APPENDIX D

PROOF OF THEOREM 3

We start by proving that conditions (65) are sufficient in order to drive the MMSE to zero in the low-noise regime. The first condition in (65) is trivial, as it reflects the fact that it is possible to drive the reconstruction MMSE to zero in the low-noise regime from the observation of $y_1$ alone, provided that $m_1 \geq r_{x_1}$ [64].

Consider now the upper bound associated to the distributed classification problem, i.e., the MMSE incurred in recovering both $x_1$ and $x_2$ from $y_1$ and $y_2$ (or, equivalently, $x$ from $y$). Then, we can write

$$\text{MMSE}_{1|1,2}^c(\sigma^2) \leq \text{MMSE}_{1,2|1,2}^c(\sigma^2) \quad (143)$$

$$= \text{tr} \left( \Sigma_x - \Sigma_x \Phi^T (\sigma^2 \Phi \Sigma_x \Phi^T)^{-1} \Phi \Sigma_x \right) \quad (144)$$

and we can follow steps similar to those in [64 Appendix B] to show that, in the low-noise regime, $\text{MMSE}_{1,2|1,2}^c(\sigma^2)$ approaches zero if and only if

$$\text{rank} (\Phi \Sigma_x \Phi^T) = \text{rank} (\Sigma_x). \quad (145)$$
In fact, we can introduce the eigenvalue decomposition
\[
\Sigma_{x}^{\frac{1}{2}} \Phi^T \Phi \Sigma_{x}^{\frac{1}{2}} = U_{2} \Lambda U_{2}^T,
\]
where \( \Lambda = \text{diag}(\lambda_1, \ldots, \lambda_{r_{\Sigma}}, 0, \ldots, 0) \), with \( r_{\Sigma} = \text{rank} \left( \Sigma_{x}^{\frac{1}{2}} \Phi^T \Phi \Sigma_{x}^{\frac{1}{2}} \right) \), and by using the inversion Lemma [79 §0.7.4] we can write
\[
\text{MMSE}_{1,2}^{G}(\sigma^2) = \text{tr} \left( \Sigma_{x} \left( I + 1/\sigma^2 \Sigma_{x}^{\frac{1}{2}} \Phi^T \Phi \Sigma_{x}^{\frac{1}{2}} \right)^{-1} \right)
= \text{tr} \left( \Sigma_{x} U_{\Sigma} \left( I + 1/\sigma^2 \Lambda \right)^{-1} U_{\Sigma}^T \right),
\]
where \( \Lambda = \text{diag} \left( \frac{1}{1+\lambda_1/\sigma^2}, \ldots, \frac{1}{1+\lambda_{r_{\Sigma}}/\sigma^2}, 1, \ldots, 1 \right) \). It is then clear that \( \text{MMSE}_{1,2}^{G}(\sigma^2) \) approaches zero, when \( \sigma^2 \to 0 \), if and only if
\[
\text{Null} \left( \Sigma_{x}^{\frac{1}{2}} \Phi^T \Phi \Sigma_{x}^{\frac{1}{2}} \right) \subseteq \text{Null} \left( \Sigma_{x} \right).
\]
Moreover, on noting that \( \text{Null} \left( \Sigma_{x} \right) \subseteq \text{Null} \left( \Sigma_{x}^{\frac{1}{2}} \Phi^T \Phi \Sigma_{x}^{\frac{1}{2}} \right) \), we immediately conclude that (150) is equivalent to (145).

We can now determine conditions on the number of features \( m_1 \) and \( m_2 \) needed in order to verify (145) by leveraging the rank expression (106). In particular, note that (145) holds if and only if
\[
\min\{m_1, r_{x_1}\} + \min\{m_2, r_{x_2}\} \geq r_x.
\]
We can consider separately four different cases, and observe that, if \( m_1 \leq r_{x_1} \) and \( m_2 \leq r_{x_2} \), then (145) is verified if and only if \( m_1 + m_2 \geq r_x \). If \( m_1 \leq r_{x_1} \) and \( m_2 > r_{x_2} \), then (145) holds if and only if \( m_1 \geq r_x - r_{x_2} \) and symmetrically, \( m_1 > r_{x_1} \) and \( m_2 \leq r_{x_2} \), then (145) holds if and only if \( m_2 \geq r_x - r_{x_1} \). Finally, \( m_1 > r_{x_1} \) and \( m_2 > r_{x_2} \), then (145) always holds since \( r_{x_1} + r_{x_2} \geq r_x \). Then, the four previous cases can be summarized by stating that (145) is true if and only if \( m_1 \) and \( m_2 \) verify the conditions
\[
\begin{cases}
m_1 \geq r_x - r_{x_2} \\
m_2 \geq r_x - r_{x_1} \quad .
\end{cases}
\]
Then, the proof of sufficiency is concluded by simply considering the union of the set of values \( (m_1, m_2) \) which verify (152) with the set \( m_1 \geq r_{x_1} \).

We now prove that conditions (65) are also necessary to guarantee that the MMSE approaches zero when \( \sigma^2 \to 0 \). In the remainder of this proof, we denote the MMSE associated to the estimation of the random vector \( u \) from the observation vector \( v \) by
\[
\text{MMSE}(u|v) = E \left[ ||u - E[u|v]||^2 \right],
\]
where the expectation is taken with respect to the joint distribution of \( (u, v) \). Then, we obtain a lower bound to
where \( z \in \mathbb{R}^{n_1} \) is a Gaussian vector with covariance matrix equal to the conditional covariance of \( x_1 \) given \( \Phi_2 x_2 \), i.e., \( z \sim \mathcal{N}(0, \Sigma_z) \), where
\[
\Sigma_z = \text{Cov}(x_1|\Phi_2 x_2) = \Sigma_{x_1} - \Sigma_{x_12} \Phi_2^T (\Phi_2 \Sigma_{x_2} \Phi_2^T)^{-1} \Phi_2 \Sigma_{x_21} .
\]

Then, by leveraging the result in [64, Theorem 1], or by simply considering the set of linear equations corresponding to the rows of the matrix \( \Phi_1 \Sigma_z^{-1/2} \), a necessary condition for \( \text{MMSE}(z|\Phi_1 z) = 0 \), and therefore, a necessary condition for \( \lim_{\sigma^2 \to 0} \text{MMSE}_{11,2}(\sigma^2) = 0 \), is given by
\[
m_1 \geq r_z = \text{rank}(\Sigma_z) .
\]

We complete the proof by computing the rank \( r_z \) using a result on the generalized Schur complement of a positive semidefinite matrix [80]. Namely, \( \Sigma_z \) can be viewed as the generalized Schur complement of the block \( \Phi_2 \Sigma_{x_2} \Phi_2^T \) of the positive semidefinite matrix
\[
\Sigma_{x_1, \Phi_2 x_2} = \mathbb{E} \begin{bmatrix} x_1 \\ \Phi_2 x_2 \end{bmatrix} \begin{bmatrix} x_1^T \\ \Phi_2^T \end{bmatrix} = \begin{bmatrix} \Sigma_{x_1} & \Sigma_{x_12} \Phi_2^T \\ \Phi_2 \Sigma_{x_21} & \Phi_2 \Sigma_{x_2} \Phi_2^T \end{bmatrix} ,
\]
and, with probability 1, we have [80]
\[
\text{rank}(\Sigma_{x_1, \Phi_2 x_2}) = r_z + \text{rank}(\Phi_2 \Sigma_{x_2} \Phi_2^T) = r_z + \min\{m_2, r_{x_2}\} .
\]

In addition, on considering the matrix
\[
\Sigma_{\Phi_2 x_2 x_1} = \mathbb{E} \begin{bmatrix} \Phi_2 x_2 \\ x_1 \end{bmatrix} \begin{bmatrix} \Phi_2^T x_2 \\ x_1^T \end{bmatrix} = \begin{bmatrix} \Phi_2 \Sigma_{x_2} \Phi_2^T & \Phi_2 \Sigma_{x_21} \\ \Sigma_{x_12} \Phi_2^T & \Sigma_{x_1} \end{bmatrix} ,
\]
and on applying the same rank computation, we also have
\[
\text{rank}(\Sigma_{\Phi_2 x_2 x_1}) = \text{rank}(\Sigma_{x_1, \Phi_2 x_2}) = r_{x_1} + \text{rank}(\text{Cov}(\Phi_2 x_2|x_1)) = r_{x_1} + \text{rank} \left( \Phi_2 (\Sigma_{x_2} - \Sigma_{x_21} \Sigma_{x_1} \Sigma_{x_12}^T \Phi_2^T) \right) .
\]

Then, on recalling that the projection kernel \( \Phi_2 \) is rotation-invariant, and by using again the generalized Schur
complement rank computation, with probability 1, we have
\[
\text{rank}(\text{Cov}(\Phi_2\mathbf{x}_2|\mathbf{x}_1)) = \min\{m_2, r_x - r_{x_1}\}.
\] (162)

Finally, by substituting (161) and (162) in (159), we can rewrite (157) as
\[
m_1 \geq r_{x_1} - \min\{m_2, r_{x_2}\} + \min\{m_2, r_x - r_{x_1}\},
\] (163)

which can be immediately shown to be equivalent to conditions (65), thus concluding the necessity part of the proof.

APPENDIX E
PROOF OF THEOREM 3

This proof is based on steps similar to those in [64, Appendix C]. Nevertheless, we report here the key ideas used in the proof for completeness. On defining
\[
\nu_{x_1}^{(ik)} = \mu_{x_1}^{(ik)} + W_{x_1}^{(ik)}(y - \Phi \mu_x^{(ik)}),
\] (164)

where \(W_{x_1}^{(ik)}\) is as in (68), and by using the law of total probability, we can write
\[
\text{MSE}_{\text{CVI}}(\sigma^2) \leq \sum_{i,k} p_{C_1,C_2}(i,k) \text{E}[\|\mathbf{x}_1 - W_{x_1}^{(ik)}(y)\|^2|C_1 = i, C_2 = k]
\]
\[
+ \sum_{i,k} p_{C_1,C_2}(i,k) \sum_{(j,\ell) \neq (i,k)} p(\hat{C}_1 = j, \hat{C}_2 = \ell|C_1 = i, C_2 = k)
\]
\[
\cdot \text{E}[\|\mathbf{x}_1 - W_{x_1}^{(j\ell)}(y)\|^2|\hat{C}_1 = j, \hat{C}_2 = \ell, C_1 = i, C_2 = k].
\] (165)

We can observe immediately that, assuming the conditions in (69) are verified, Theorem 3 guarantees that the terms \(\text{E}[\|\mathbf{x}_1 - W_{x_1}^{(ik)}(y)\|^2|C_1 = i, C_2 = k]\) approach zero when \(\sigma^2 \to 0\). Then, we are left with proving
\[
\lim_{\sigma^2 \to 0} p(\hat{C}_1 = j, \hat{C}_2 = \ell|C_1 = i, C_2 = k) \text{E}[\|\mathbf{x}_1 - W_{x_1}^{(j\ell)}(y)\|^2|\hat{C}_1 = j, \hat{C}_2 = \ell, C_1 = i, C_2 = k] = 0
\] (166)

whenever \((j,\ell) \neq (i,k)\). Given the conditions (69) hold, if \(m_1 > r_{x_1}^{(ik)}\) and \(m_1 > r_{x_1}^{(j\ell)}\), then we can leverage the result in [64 Appendix C] on the reconstruction of \(\mathbf{x}_1\) from \(\mathbf{y}_1\) alone to show that (166) holds. Otherwise, if \(m_1 \leq r_{x_1}^{(ik)}\) or \(m_1 \leq r_{x_1}^{(j\ell)}\), then (69) implies that \(m_2 > r_{x_1}^{(ik)} - r_{x_1}^{(ik)}\) or \(m_2 > r_{x_1}^{(j\ell)} - r_{x_1}^{(j\ell)}\) respectively. At this point, we can consider separately two cases: i) \(r_{x_1}^{(ik,j\ell)} > r_{x_1}^{(ik)}\) and ii) \(r_{x_1}^{(ik,j\ell)} = r_{x_1}^{(ik)} = r_{x_1}^{(j\ell)}\). In the first case, the range spaces \(\text{Im}(\Sigma_x^{(ik)})\) and \(\text{Im}(\Sigma_x^{(j\ell)})\) are distinct, and we can leverage the characterization of the misclassification probability of the distributed classification problem in order to prove (166). In particular, by following steps similar to those in the proof of Corollary 1, we can show that
\[
\lim_{\sigma^2 \to 0} p(\hat{C}_1 = j, \hat{C}_2 = \ell|C_1 = i, C_2 = k) = 0.
\] (167)

48
Therefore, observe that the misclassification probability \( p(\hat{C}_1 = j, \hat{C}_2 = \ell | C_1 = i, C_2 = k) \) is the measure of the set representing the decision region of the MAP classifier for the distributed classification problem associated to the classes \((j, \ell)\) with respect to the Gaussian measure induced by the Gaussian distribution of classes \((i, k)\). Then, it is also possible to show that, in the limit \( \sigma^2 \to 0 \), the product in (166) is upper bounded by the integral of a measurable function over a set with measure zero, and then it converges to zero.

In the second case, instead, we have \( \text{Im}(\Sigma_x^{(ik)}) = \text{Im}(\Sigma_x^{(jf)}) \), and we can consider separately further two cases. If

\[
\mu_x^{(ik)} - \mu_x^{(ik)} \notin \text{Im}(\Sigma_x^{(ik)} + \Sigma_x^{(jf)}) = \text{Im}(\Sigma_x^{(ik)}),
\]

then Theorem 2 states that \( p(\hat{C}_1 = j, \hat{C}_2 = \ell | C_1 = i, C_2 = k) \) approaches zero in the low-noise regime, and we can prove that (166) holds by following a similar procedure to that used for case i). On the other hand, if

\[
\mu_x^{(ik)} - \mu_x^{(ik)} \in \text{Im}(\Sigma_x^{(ik)} + \Sigma_x^{(jf)}) = \text{Im}(\Sigma_x^{(ik)}),
\]

then the misclassification probability is not guaranteed to approach zero in the low-noise regime. However, on using the law of total probability and the definition of MSE, we can notice that the argument of the limit in (166) is upper bounded by \( E \left[ \|x_1 - W_{x}^{(jf)}(y)\|^2 | C_1 = i, C_2 = k \right] \) and that

\[
E \left[ \|x_1 - W_{x}^{(jf)}(y)\|^2 | C_1 = i, C_2 = k \right] \leq E \left[ \|x - W_{x}^{(jf)}(y)\|^2 | C_1 = i, C_2 = k \right],
\]

where

\[
W_{x}^{(jf)}(y) = \mu_x^{(jf)} + W_x^{(jf)} (y - \Phi \mu_x^{(jf)})
\]

and

\[
W_x^{(jf)} = \Sigma_x^{(jf)} \Phi^T (\sigma^2 I + \Phi \Sigma_x^{(jf)} \Phi^T)^{-1}.
\]

Then, we can show that the right hand side of (170) approaches zero when \( \sigma^2 \to 0 \) by using steps similar to those in [64, Appendix C-B]. This reflects the fact that the mismatched MSE for Gaussian sources reaches zero in the low-noise regime, provided that the estimated input covariance has the same range space than the true input covariance. In particular, on denoting by \( \Sigma_y^{(ik)} = \sigma^2 I + \Phi \Sigma_x^{(ik)} \Phi^T \) the covariance matrix of \( y \) conditioned on \((C_1, C_2) = (i, k)\), and on introducing the symbol \( M^{(ik,jf)} = (\mu_x^{(ik)} - \mu_x^{(jf)}) (\mu_x^{(ik)} - \mu_x^{(jf)})^T \), we can write

\[
\text{MSE}^{(ik,jf)}(\sigma^2) = E \left[ \|x - W_x^{(jf)}(y)\|^2 | C_1 = i, C_2 = k \right]
\]

\[
= E \left[ \text{tr} \left( (x - W_x^{(jf)}(y)) (x - W_x^{(jf)}(y))^T \right) | C_1 = i, C_2 = k \right]
\]

\[
= \text{tr} \left( \Sigma_x^{(ik)} \right) - 2 \text{tr} \left( W_x^{(ik)} \Sigma_y^{(ik)} (W_x^{(ik)})^T \right) + \text{tr} \left( W_x^{(jf)} \Sigma_y^{(ik)} (W_x^{(jf)})^T \right) + \text{tr} \left( M^{(ik,jf)} \right)
\]

\[
- 2 \text{tr} \left( M^{(ik,jf)} \Phi^T (W_x^{(jf)})^T \right) + \text{tr} \left( \Phi W_x^{(jf)} M^{(ik,jf)} (W_x^{(jf)})^T \right),
\]
and we can prove that
\[
\lim_{\sigma^2 \to 0} \tr \left( W_x^{(ik)} \Sigma_y^{(ik)} (W_x^{(j\ell)})^T \right) = \tr(\Sigma_x^{(ik)}); \tag{176}
\]
\[
\lim_{\sigma^2 \to 0} \tr \left( W_x^{(j\ell)} \Sigma_y^{(ik)} (W_x^{(j\ell)})^T \right) = \tr(\Sigma_x^{(ik)}); \tag{177}
\]
\[
\lim_{\sigma^2 \to 0} \tr \left( M^{(ik,j\ell)} (W_x^{(j\ell)})^T \right) = \tr \left( M^{(ik,j\ell)} \right); \tag{178}
\]
\[
\lim_{\sigma^2 \to 0} \tr \left( W_x^{(j\ell)} \Phi M^{(ik,j\ell)} \Phi^T (W_x^{(j\ell)})^T \right) = \tr \left( M^{(ik,j\ell)} \right). \tag{179}
\]

The proof is based on the use of the inversion Lemma \[79\]
\[
A(Ic^{-1} + BA)^{-1} B = I - (I + cAB)^{-1}, \tag{180}
\]
in which we choose \( A = \Phi^T \) and \( B = \Phi \Sigma_x^{(j\ell)} \) and we write
\[
\tr \left( W_x^{(ik)} \Sigma_y^{(ik)} (W_x^{(j\ell)})^T \right) = \tr \left( \Sigma_x^{(ik)} \Phi^T (Ic^2 + \Phi \Sigma_x^{(j\ell)} \Phi^T)^{-1} \Phi \Sigma_x^{(j\ell)} \right)
= \tr \left( \Sigma_x^{(ik)} \right) - \tr \left( \Sigma_x^{(ik)} (I + \frac{1}{\sigma^2} \Phi^T \Phi \Sigma_x^{(j\ell)})^{-1} \right). \tag{181}
\]

Then, on noting that the matrix \( \Phi^T \Phi \Sigma_x^{(j\ell)} \) is diagonalizable with probability 1, and by following steps similar to those adopted in the proof of Theorem \[3\] we are able to prove (176). Finally, also (177), (178) and (179) are proved by following a completely similar approach.
