RNA interference (RNAi) acts constitutively to silence the innate immune response, and innate immunity genes are misregulated in Dicer-deficient Caenorhabditis elegans. Here, we show that inhibition of Dicer expression by RNAi in human cells up-regulates major histocompatibility complex I-related molecules A and B (MICA and MICB). MICA and MICB are innate immune system ligands for the NKG2D receptor expressed by natural killer cells and activated CD8(+),T cells. We reveal that knockdown of Dicer elicits DNA damage. Up-regulation of MICA and MICB by Dicer knockdown is prevented by pharmacologic or genetic inhibition of DNA damage pathway components, including ataxia telangiectasia mutated (ATM) kinase, ATM- and Rad3-related kinase, or checkpoint kinase 1. Therefore we conclude that up-regulation of MICA and MICB is the result of DNA damage response activation caused by Dicer knockdown. Our results suggest that RNAi is indirectly linked to the human innate immune system via the DNA damage pathway.

Introduction

RNAi is important for regulation of heterochromatin structure and function (Bühler and Moazed, 2007; Locke and Martienssen, 2006). Loss of Dicer2, a key enzyme in the RNAi pathway, not only results in decondensation of heterochromatin but also leads to accumulation of extrachromosomal circular (ecc) repeated DNAs. Ligase IV, an essential regulator of nonhomologous end joining, and perhaps other DNA damage repair machinery, participate in ecc DNA formation (Peng and Karpen, 2007). This suggests that, in addition to increased accessibility of DNA repair and recombination proteins to repeated DNA caused by heterochromatin decondensation, activation of the DNA damage response may also contribute to the formation of ecc DNA in Dicer2 mutant cells. DNA replication timing is tightly regulated and correlates with chromatin state (Donaldson, 2005), and the timing of satellite DNA replication is misregulated in Dicer-deficient embryonic stem cells (Jørgensen et al., 2007). Stalled and collapsed replication forks elicit the DNA damage response (Sancar et al., 2004). In addition, RNAi is postulated to function as the genome’s immune system that defends against molecular parasites such as transposons and viruses (Plasterk, 2002; Fire, 2005), and loss of Dicer may activate transposons, which in turn leads to DNA damage (Gasior et al., 2006). These observations collectively suggest that DNA damage response may be elicited in Dicer-deficient cells.

Innate immunity genes are misregulated in Caenorhabditis elegans deficient in Dicer, RDE-4, or RDE-1 (Welker et al., 2007). Mouse and human NKG2D ligands are up-regulated in nontumor cell lines by genotoxic stress and stalled DNA replication, conditions known to activate a major DNA damage checkpoint pathway initiated by ataxia telangiectasia mutated (ATM) or ATM- and Rad3-related (ATR) protein kinases (Gasser et al., 2005). Based on these observations, we hypothesize that loss of Dicer elicits a DNA damage response, which in turn induces expression of NKG2D ligands.

Results and discussion

To test whether loss of Dicer causes DNA damage, we knocked down Dicer in HEK293T cells and human hepatoma HepG2...
cells using two different siRNAs. The frequency of DNA double-strand breaks (DSBs) was measured by immunostaining for the phosphorylated form of histone H2AX (γ-H2AX), a widely used marker for DSBs (Foster and Downs, 2005). Compared with mock-transfected or control siRNA-transfected cells, intense γ-H2AX staining was observed in Dicer knockdown HEK293T cells. Quantification of the data revealed an ~10-fold increase in the number of Dicer knockdown HEK293T cells positive for γ-H2AX compared with mock-transfected or control siRNA-transfected cells (Fig. 1A). These results suggest that DSBs accumulate in the absence of Dicer. Similar results were obtained with HepG2 cells. To confirm these results, we used immunofluorescence in Dicer knockdown, mock-transfected, and control siRNA-transfected cells to examine the distribution of replication protein A 70 (RPA70), a protein involved in DNA replication, recombination, and repair, that becomes phosphorylated and forms intranuclear foci upon exposure of cells to DNA damage (Zou et al., 2006). Consistent with γ-H2AX staining, a much higher percentage of Dicer knockdown cells also displayed intense RPA foci, further indicating the accumulation of DNA damage (Fig. 1A). Murchison et al. (2005) found that Dicer-deficient embryonic stem cells displayed only a slight
(Chk1) phosphorylation on S345, an event associated with DNA damage, was found in Dicer knockdown cells (Fig. 1 B). As a more direct assessment of DNA damage, comet assay revealed that knockdown of Dicer resulted in accumulation of DNA breaks, as indicated by formation of a comet-like tail after single-cell gel electrophoresis (Fig. 1 C). Upon exposure of cells to DNA damage, growth arrest – and DNA damage – inducible increase in G₁ and G₀ cells and a corresponding decrease in cells in G₂ and M phase. We also found that the cell cycle profile was not significantly affected by knocking down Dicer (Fig. S1, available at http://www.jcb.org/cgi/content/full/jcb.200801169/DC1), which excludes the possibility that increased γ-H2AX and RPA foci are simply the consequence of an increased percentage of cells in S phase. Furthermore, an increase in checkpoint kinase 1

Figure 2. Up-regulation of MICA and MICB in Dicer knockdown cells. (A) Up-regulation of MICA and MICB mRNAs determined by real-time RT-PCR. Cells treated with 4 μM aphidicolin for 16 h were used as positive control. (B) Transcription of MICA and MICB was monitored by RNAPol-ChIP. Data in A and B represent means ± SD from three independent experiments. (C) Cell surface expression of MICA and MICB measured by FACS. Dicer siRNA1-transfected (red) and Dicer siRNA2-transfected (blue) cells were compared with mock-transfected (black) and control siRNA-transfected (green) cells. Filled histograms indicate isotype control antibody staining. The x axis depicts staining intensity and the y axis depicts the relative number of cells. (D) Knockdown of Dicer sensitizes HepG2 and HEK293T cells to lysis by NKL cells. NKL cells were incubated with Dicer knockdown (squares) or control siRNA-transfected (circles) cells in the absence (closed) or presence (open) of anti-NKG2D antibody. The effector to target ratio (E:T) is indicated. Data represent means ± SD from three independent experiments.
and not depicted), which excludes the possibility that heterochromatin decondensation induced by Dicer knockdown leads to general up-regulation of transcription.

The DNA damage pathway regulates innate immune system ligands for the NKG2D receptor, and human NKG2D ligands are up-regulated by genotoxic stress and stalled DNA replication, conditions known to activate a major DNA damage checkpoint pathway (Gasser et al., 2005). Therefore, we tested whether NKG2D ligands were up-regulated in Dicer knockdown cells. Quantitative RT-PCR revealed markedly increased levels of major histocompatibility complex class I–related molecules A and B (MICA and MICB) mRNAs in Dicer knockdown cells compared with mock-transfected or control siRNA-transfected cells (Fig. 2A), whereas the levels of ULBP1, -2, and -3 mRNAs were not significantly regulated by inhibiting the expression of Dicer (not depicted). Up-regulation of MICA and MICB was confirmed by flow cytometry (Fig. 2C). In agreement with the up-regulation of MICA and MICB, Dicer knockdown cells exhibited greater sensitivity to lysis by NKL, a cell line derived from an aggressive form of human natural killer (NK) cell leukemia (Robertson et al., 1996). Lysis was partially inhibited by anti-NKG2D antibody, which indicated that up-regulated NKG2D ligands induce elevated lysis (Fig. 2D). This result suggests that Dicer-deficient cells may be cleared by NK or other immune cells.

DNA damage–induced up-regulation of NKG2D ligands can be prevented by pharmacologic or genetic inhibition of ATR,
ATM, or Chk1 (Gasser et al., 2005). The roles of ATR, ATM, and Chk1 in Dicer knockdown–induced MICA and MICB up-regulation were investigated. Up-regulation of MICA and MICB in response to Dicer knockdown was blocked by caffeine, an inhibitor of ATR and ATM, and by staurosporine, an inhibitor of Chk1 (Figs. 3 and S3 A, available at http://www.jcb.org/cgi/content/full/jcb.200801169/DC1). As a more specific test, expression of ATM, ATR, and Chk1 was repressed using siRNAs (Fig. S3, E and F). Up-regulation of MICA and MICB induced by Dicer knockdown was inhibited by cotransfection of Dicer siRNAs with ATR siRNA (Figs. 3 and S3 B). In contrast, cotransfection with control siRNA did not significantly affect Dicer knockdown–induced up-regulation of MICA and MICB (Fig. 3). Similarly, inhibition of ATM and Chk1 expression by siRNAs also blocked MICA and MICB up-regulation in response to Dicer knockdown (Figs. 3 and S3, C and D). In addition, we demonstrated that DNA damage progressed in parallel with the kinetics of up-regulation of MICA and MICB in Dicer knockdown cells (Fig. 4). These data suggest that up-regulation of MICA and MICB is a consequence of DNA damage response activation. Compared with ATR suppression, ATM suppression had larger effects on MICA and MICB expression (Figs. 3 and S3, B and C), which suggests that MICA and MICB up-regulation is predominantly in response to DSBs.

Some siRNAs are found to activate protein kinase R (PKR) and induce global up-regulation of IFN-stimulated genes (Sledz et al., 2003; Marques and Williams, 2005). This raises the question whether up-regulation of MICA and MICB is the consequence of nonspecific activation of the mammalian immune system by Dicer-specific siRNAs. To address this question, we checked the phosphorylation status of PKR. Western blotting demonstrated that there was no increase in PKR phosphorylation in Dicer knockdown cells compared with mock-transfected or control siRNA-transfected cells (Fig. S2 A). In addition, Dicer knockdown did not affect the expression of IFN-β1, stat1, ISG15, IFIT1, IFIT2, and OSA2 (Fig. S2 B), six genes nonspecifically induced by a glyceraldehyde 3-phosphate dehydrogenase (GAPDH) siRNA due to activation of the IFN system (Sledz et al., 2003). Therefore, it is unlikely that up-regulation of MICA and MICB was an indirect consequence of nonspecific activation of the mammalian immune system by Dicer siRNAs. Although RNAPol-ChIP indicated that the transcription of MICA and MICB was increased in Dicer knockdown cells (Fig. 2 B), further studies are necessary to determine whether up-regulation of MICA and MICB is also the consequence of increased stability due to reduction of miRNAs.

Collectively, our results demonstrate that suppression of Dicer expression leads to cellular clearance via DNA damage, and the subsequent DNA damage response up-regulates the expression of MICA and MICB, which in turn induces the NK-mediated destruction. RNAi constitutes a key component of the innate immune response to viral infection in both plants and invertebrate animals (Cullen, 2006) and has been postulated to act constitutively to silence the innate immune genes (Welker et al., 2007). Our study suggests that RNAi is indirectly linked to the human innate immune system via the DNA damage pathway.

We propose the following model for how DNA damage is elicited in Dicer knockdown cells. Dicer is essential for heterochromatin formation and restricts the accessibility of DNA repair and recombination proteins to repeated DNA. Loss of Dicer leads to decondensation of heterochromatin and causes ecc DNA formation (Peng and Karpen, 2007), which may activate the DNA damage response. Furthermore, heterochromatin decondensation results in misregulation of DNA replication timing (Jørgensen et al., 2007) and causes DNA replication stress, which elicits DNA damage responses. In addition, heterochromatin decondensation may activate transposons and cause DNA damage (Gasier et al., 2006).

DNA damage activates cell cycle checkpoints that prevent progression through the cell cycle. However, Murchison et al. (2005) and our study found that the cell cycle profile was not significantly changed in Dicer-deficient cells (Fig. S1). This conflict can be reconciled by the fact that Ago1 binds to 14-3-3 proteins and inhibits nuclear import of the mitosis-inducing phosphatase Cdc25 (Stoica et al., 2006). Because Ago1 interacts strongly with Dicer (Doi et al., 2003), the latter may also interact with 14-3-3 proteins and repress nuclear import of Cdc25. Therefore, knockdown of Dicer, on one hand, induces DNA...
damage and activates Chk1, which in turn phosphorylates Cdc25. 14-3-3 proteins bind to phosphorylated Cdc25 and induce export of this phosphatase from the nucleus (Lopez-Girona et al., 1999). Nuclear exclusion of Cdc25 correlates with an inability to enter mitosis because the phosphatase no longer has access to its substrate, the Cdc13–Cdc2 complex, which is located in the nucleus (Lopez-Girona et al., 1999). On the other hand, knockdown of Dicer may facilitate nuclear import of Cdc25 and induce cells to enter mitosis. This scenario may also explain why drcl mutant Schizosaccharomyces pombe cells are defective for the DNA damage–induced cell cycle checkpoint (Carmichael et al., 2004).

Materials and methods

Cell culture

HepG2 and HEK293T cells were cultured in RPMI 1640 medium supplemented with 10% FBS. All cultures were maintained at 37 °C in a moist atmosphere containing 5% CO₂ in air. The NKL cell line (provided by M. J. Robertson, Indiana University School of Medicine, Indianapolis, IN) was grown in RPMI 1640 with 15% FBS and 200 U/ml interleukin 2.

RNAi

siRNAs were prepared by in vitro transcription with the Silencer siRNA Construction kit (Ambion). Target sequences of siRNAs were as follows: Dicer siRNA1 (AAAGCTTACCTTCCAGGGGACTCTTTCCATGG), Dicer siRNA2 (AAATGGGCTTACCTTCCACGAGGCTACCTTTCCATGG), ATGCTTTTCCACTCTCTGTTGA, and control siRNA (AAATCTCCGACGCTGTCAGGTCA). Transfection was performed using siPORT NeoFX (Ambion) according to the manufacturer’s instructions. To maximally inhibit Dicer expression and keep the cells at optimal density, cells were transfected with two rounds of siRNAs. In brief, cells were split 2 d after the first round of Dicer siRNAs treatment and then treated again for another 2 d. To pharmacologically inhibit Chk1, ATR, or Cdc25, cells were treated with 2 μM caffeine (Alfa Aesar) or 8 μM staurosporine (Sigma-Aldrich) 24 h after the second round of Dicer siRNAs transfection. To genetically inhibit the DNA damage response, Dicer siRNAs were cotransfected with ATM, ATR, or Chk1 siRNAs, respectively.

Flow cytometry

Cell surface MICA and MICB were analyzed using mouse anti-human MICA and anti-MICB. In brief, cells were incubated with anti-MICA (MAB1300; R&D Systems), anti-MICB (MAB1599; R&D Systems), or the isotype control (MAB0041; R&D Systems) for 1 h at 4 °C. Then, the cells were washed three times with PBS and incubated with phycoerythrin-conjugated goat anti-mouse IgG (F0102; R&D Systems) for 30 min at 4 °C. Finally, the fluorescence was detected with FACSaria (BD Biosciences) and analyzed with WinMDI software (http://facs.scripps.edu/software.html). For cell cycle analysis, cells were fixed in cold ethanol, stained with 50 μg/ml propidium iodide, and analyzed by FACSaria.

Cellular cytotoxicity assay

HEK293T cells express several other activating ligands besides NKG2DL that are recognized by the various activating receptors on polyclonal NK cells (Welte et al., 2003). Therefore, we used the NKL cell line, which has been well characterized for its NKG2D expression and NKG2D-mediated effector functions, to study NKG2D-mediated recognition of Dicer knockdown cells. Target cells were labeled with 100 μCi Na2 51CrO4 (GE Healthcare) for 2 h at 37 °C and washed three times. In blocking experiments, anti-NKG2D (MAB139; R&D Systems) were added at 10 μg/ml to the target cells during the labeling procedure. Cells were washed, and effector cells were treated on the target cells and incubated for 4 h at 37 °C. Maximum release was determined from target cells lysed in 1% Triton X-100. The percentage of lysis was calculated as follows: 100 × [experimental release – spontaneous release]/(maximum release – spontaneous release). Experiments were performed in triplicate.

Western blotting

Cells were lysed in RIPA buffer. Total protein was measured using the Bradford protein assay. Samples were denatured at 100 °C for 5 min. Equal amounts of total protein were loaded to each well for electrophoresis in SDS-polyacrylamide gels and then transferred to polyvinylidene fluoride microporous membranes (Millipore). Membranes were then incubated with primary antibody followed by incubation with horseradish peroxidase-linked secondary antibodies. The primary antibodies included anti-Dicer (ab14601; Abcam), anti-phosphoPKR (Thr 451; Cell Signaling Technology), anti-phospho-Chk1 (Ser345) antibody (Cell Signaling Technology), anti-Chk1 (Cell Signaling Technology), and anti-GAPDH (KC-SG4; Kangchen Biotech).

Immunofluorescence microscopy

Cells were fixed and stained with anti-phospho-histone H2AX (S139) antibody (R&D Systems) and anti-GRP78 (Cell Signaling Technology). Images were acquired with identical exposure conditions and analyzed with a confocal microscope (TCS-SP5 AOS) using a 63× HCX PL APO 1.4 NA lens and LAS AF software (all from Leica); 100–300 cells were screened for each sample.

Quantitative real-time RT-PCR

Total RNA was prepared using TRIZOL (Invitrogen) and incubated with RNase-free DNase I (Fermentas) for 30 min. The DNA-free RNA was reverse transcribed using MMLV reverse transcription (TOYOBO Bio-Technology) according to the manufacturer’s instructions. Samples prepared without reverse transcription served as negative control templates. SYBR green PCR was performed in triplicate using the ABI PRISM 7300 Sequence Detection system (Applied Biosystems). All samples were normalized to the signal generated from GAPDH or 18S rRNA. Primer sequences (forward and reverse) were as follows: Dicer, TCCAGCGTCACAATACCAACCGG and GGGTTCTGCATTAGGCTGATGAG; ATM, TGATGACCTGATCTTGGTTG and CGAATGATTATCAAAAGTAAAGT; TCTGACCTGATCTTGGTTG and CGAATGATTATCAAAAGTAAAGT; TTGGCCTGAGACATAGGCTG and TCTGGACCTGATCTTGGTTG.

RNAPol-ChIP

Chromatin immunoprecipitation was performed as described by Sandoval et al. (2004). RNA pol II antibody (sc-899; Santa Cruz Biotechnology, Inc.) immunoprecipitated DNA was amplified with primer pairs in triplicate, and amplification was monitored using SYBR green chemistry on the ABI PRISM 7300 Sequence Detection system. Samples prepared without antibody served as negative controls. All samples were normalized to the signal generated from GAPDH or β-actin. Primers of GAPDH, ATF3, EGR1, BTG3, and NFIB for its real-time RTP-PCR were also used for RNAPol-Chip; other primer sequences (forward and reverse) were as follows: GADD45A, TCCACGAGTCACAATACCAACCGG and GGGTTCTGCATTAGGCTGATGAG; ATR, TCTGACCTGATCTTGGTTG and CGAATGATTATCAAAAGTAAAGT; ATM, TGATGACCTGATCTTGGTTG and CGAATGATTATCAAAAGTAAAGT; and 18S rRNA, CGCCTACCACTTCAAGAGAA and GCTGAGGAACTCAGTGAGAGA.

DNA damage was assessed for each sample.

Nuclear exclusion of Cdc25 correlates with an inability to enter mitosis because the phosphatase no longer has access to its substrate, the Cdc13–Cdc2 complex, which is located in the nucleus (Lopez-Girona et al., 1999). On the other hand, knockdown of Dicer may facilitate nuclear import of Cdc25 and induce cells to enter mitosis. This scenario may also explain why drcl mutant Schizosaccharomyces pombe cells are defective for the DNA damage–induced cell cycle checkpoint (Carmichael et al., 2004).
1 h in dark at 4°C. Cells were then covered in alkali solution (1 mmol/liter EDTA, 300 mmol/liter sodium hydroxide, pH > 13, and 10 μg/ml proteinase K) for 20 min followed by electrophoresis (300 mmol/liter NaCl, and 100 mmol/liter Tris, pH 9) in the dark at 25 V, 300 mA (1 V/cm) for 15 min. The slides were neutralized using 400 mmol/liter Tris, pH 7.5 and washed with double-distilled H2O twice before being staining with 20 μg/ml EB. Comet images were visualized by using a fluorescence microscope [Eclipse TE 2000-S; Nikon] and NIS-Elements 2.3 software [Nikon].

Online supplemental material
Fig. S2 shows that Dicer knockdown does not affect the cell cycle profile. Fig. S2 shows that up-regulation of MICA and MICB is not the consequence of non-specific activation of the mammalian immune system by Dicer-specific siRNAs. Fig. S3 shows that inhibition of the DNA damage response prevents MICA and MICB up-regulation in Dicer knockdown cells. Online supplemental material is available at http://www.jcb.org/cgi/content/full/jcb.200801169/DC1.
