1. INTRODUCTION

LS I +61 303 is a Be/X-ray binary with spectral type B0 Ve, a 26.5 day orbital period, and highly eccentric orbit (Grundstrom et al. 2007; Casares et al. 2005a). High-energy emission from LS I +61 303 was first detected 30 years ago (as γ-ray source CG 135+1) by the cosmic-ray satellite B (Hermsen et al. 1977). Shortly thereafter, NASA’s Einstein Observatory and ground based radio observations suggested that the system was no ordinary HMXB (Gregory & Taylor 1978; Bignami & Hermsen 1983). While the system has a relatively low X-ray luminosity based on recent red and blue optical spectra. Both systems have somewhat discrepant orbital solutions available in the literature, and our new measurements result in improved orbital elements and resolve the disagreements. The improved geometry of each orbit will aid in studies of the high-energy emission region near each source.

Key words: binaries: spectroscopic – stars: individual (LS 5039, LS I +61 303)

Online-only material: machine-readable table
Figure 1. Final mean spectrum of LS I +61 303, formed by shifting each spectrum to its rest velocity to remove orbital variations. The red spectrum reveals strong emission in the Hα line and weaker emission in the wings of the He I λ6678 line.

spectra were interpolated onto a log wavelength scale using a common heliocentric wavelength grid, and they were rectified to a unit continuum using line-free regions.

Our red spectra of LS I +61 303 include only two prominent stellar features, Hα and He I λ6678, shown in Figure 1. The Hα line is dominated by double-peaked emission from the circumstellar disk of the Be star. While the absorption trough does follow the orbital motion of the star, we did not use this line to measure the spectroscopic orbit since its radial velocity, \( V_r \), measurements may be strongly affected by changes in the disk structure. Weak emission is also present in the blue and red wings of the He I λ6678 line, but it is less affected by temporal changes in the disk. Therefore we measured radial velocities of LS I +61 303 using only this line.

We formed a reference spectrum of LS I +61 303 using the mean of all available spectra (without shifting to their rest velocity to avoid any prior assumptions about the orbit), and we measured the \( V_r \) of this mean spectrum using a parabolic fit of the He I λ6678 line core. Since we were concerned that the emission in the line wings (rather than the photospheric absorption component) might affect the relative velocities, we excised the emission on the blue and red wings of the reference spectrum to a unit continuum. We then performed a cross-correlation between each spectrum and this reference spectrum over the He I λ6678 line region to obtain the relative \( V_r \), which we added to the \( V_r \) of the reference spectrum to obtain the absolute \( V_r \). We also measured the cross-correlation velocity shift of the interstellar line at 6613 Å, \( \Delta V_{\text{ISM}} \), using the same method to monitor the stability of our measurements. After removing measurements with \( |V_{\text{ISM}}| > 5 \text{ km s}^{-1} \) and spectra in which the He I λ6678 line profile was strongly affected by cosmic rays, we present a total of 75 \( V_r \) measurements in Table 1.

The orbital period of LS I +61 303 is well known from radio flux observations (Gregory 2002), so we adopted the period 26.4960 ± 0.0028 d from that work. Many recent papers also use an arbitrary orbital phase, \( \phi(TG) \), defined to be zero at HJD 2,443,366.775 (Taylor & Gregory 1982), which we adopt as well. Our \( V_r \) agree well with Casares et al. (2005a), but measurements from Grundstrom et al. (2007) are systematically lower by 8.8 km s\(^{-1}\) (based on the difference in the center of mass velocity, \( \gamma \), using each data set separately). This difference is likely due to a small difference in the rest wavelength of that line; we used 6678.15 Å as given by the NIST Atomic Spectra Database (Ralchenko et al. 2008). Therefore we offset their \( V_r \) by this amount to determine the orbital elements of LS I +61 303, and we excluded their points with discrepant \( V_{\text{ISM}} \) values as well. Using this edited set of \( V_r \) from Casares et al. (2005a), Grundstrom et al. (2007), and this work, we determined the orbital elements using the nonlinear, least-squares fitting program of Morbey & Brosterhus (1974). There are several points with large scatter and a systematic trend in the \( V_r \) curve (discussed in Section 4), so we assigned zero weight to points with \( |O–C| > 2 \sigma \) and refit the orbit for the final orbital solution.

The resulting time of periastron, \( T_0 \), eccentricity, \( e \), angle of the line of nodes, \( \omega \), velocity semiamplitude, \( K_1 \), center of mass velocity, \( \gamma \), mass function, \( f(m) \), projected separation, \( a_1 \sin i \), and the standard deviation of the fit, \( \sigma \), are listed in Column 2 of Table 2. The final \( V_r \) curve is shown in Figure 2, and the orbital phases (relative to Taylor & Gregory 1982) and observed minus corrected errors (\( O–C \)) are included in Table 1. With our new orbital fit, the orbital phase of periastron is \( \phi(TG) = 0.275 \).

The geometry of the orbit is illustrated in Figure 3, assuming a Be star mass of 12.5 \( M_\odot \) (Casares et al. 2005a) with either a neutron star (1.4 \( M_\odot \)) or a black hole (4 \( M_\odot \)) companion. Except for \( \gamma \), each orbital element agrees very well with the values found by Grundstrom et al. (2007). Because our spectra of LS I +61 303 were obtained over 35 consecutive nights,
Figure 2. Radial velocity curve of LS I +61 303. Periastron corresponds to $\phi(TG) = 0.275$ and is marked as a dotted line in this plot. The points plotted as open diamonds are from Grundstrom et al. (2007), crosses are from Casares et al. (2005a), and filled circles are from this work.

Figure 3. Orbital geometry of LS I +61 303, looking down on the orbital plane, showing the relative orbits ($r/a$) of the optical star ($12.5 \, M_\odot$; Casares et al. 2005a) and its compact companion of unknown mass. The relative orbit of the compact object is shown as a solid line, while the Be star’s relative orbit depends greatly on the mass of the companion. The dashed line indicates the Be star’s orbit assuming a 4 $M_\odot$ black hole, while the dotted line assumes a 1.4 $M_\odot$ neutron star. The relevant phases of periastron, apastron, and conjunctions are marked along the orbit of the compact companion. The center of mass is indicated with a cross, and the thin solid line is the orbital major axis.

our $V_r$ measurements provide excellent coverage of the orbit with no large gaps in orbital phase, and the errors in our fit are slightly lower than those of Grundstrom et al. (2007) and significantly lower than those of Casares et al. (2005a). We also emphasize that our final orbital solution relies upon the fixed $P$ from Gregory (2002), but we found very similar values for each orbital element when we allowed $P$ to vary. We found $P = 26.4982 \pm 0.0076$ d using the fitting program of Morbey & Brosterhus (1974) with the combined $V_r$ data, which is not an improvement over Gregory (2002).

3. OBSERVATIONS AND RADIAL VELOCITY MEASUREMENTS OF LS 5039

Spectra of LS 5039 were taken at the CTIO 1.5 m telescope between 2007 August and 2008 April in service mode. We used grating 47 in the second order, a 200 $\mu$m slit, the B399 filter, and the Loral 1K CCD detector. Spectra were wavelength-calibrated using He–Ar comparison lamp spectra generally taken before and after each exposure. The observed wavelength region was therefore about 4050–4700 Å, with 2500 $< R < 3150$ across the chip.

For each night that we had service time available in fall 2007, we obtained four to six spectra, each with an exposure time of 30 minutes. During the spring of 2008, we obtained two spectra each night of observations, each of 22 minutes duration. Thus we obtained a total of 98 blue spectra of LS 5039. The images were zero-corrected, flat-fielded, and wavelength-calibrated onto a log wavelength scale using standard procedures in IRAF, and all spectra were interpolated onto a common heliocentric wavelength grid. The spectra were rectified to a unit continuum using line-free regions.

Since the signal-to-noise ratio was somewhat low, we chose to coadd pairs of consecutive spectra from each night. The total elapsed time during two consecutive observations is only one hour, about 1% of the orbital period, so coadding the spectra does not significantly affect the measured $V_r$. On two nights we collected an odd number of spectra, and in these cases the last spectrum of each set was examined individually. Therefore, we had 50 new spectra from which to obtain $V_r$ measurements and improve the orbital elements.

The spectra from 2007 August 29, were taken near the time of inferior conjunction and thus showed the least variation in $V_r$, so we chose to average these six spectra to produce a reference spectrum. This reference spectrum is plotted in Figure 4. Five lines were examined in each spectrum: H$\gamma$, H$\delta$, He$\ii$ $\lambda 4200$, 4542, and He $\i$ $\lambda 4471$. The spectra also recorded the strong He$\ii$ $\lambda 4686$ line, but a bad column on the chip interfered with measuring reliable $V_r$ from this line. We performed a cross-correlation between each spectrum and the reference spectrum to obtain its relative $V_r$, and then we used the mean $V_r$ from a parabolic fit of the line cores in the reference spectrum to find its absolute $V_r$.

The period of the system was obtained using the discrete Fourier transform and CLEAN deconvolution program of Roberts et al. (1987) (written in IDL7 by A. W. Fullerton). The $V_r$ from our observations were combined with the mean values from all lines measured by McSwain et al. (2001), McSwain et al. (2004), and Casares et al. (2005b). The $V_r$ measurements of Casares et al. (2005b) indicate a value of $\gamma$ that is systematically higher than our data sets by 7.0 km s$^{-1}$, so we subtracted this value from their measurements. No significant difference was found between the $V_r$ data presented here and past measurements obtained by our group. We used all of the available $V_r$ with the CLEAN algorithm, which found a strong peak at $P = 3.9060263$ d (which was improved slightly with the later orbital fit), nearly identical to the period found by Casares et al. (2005b). Our group has previously found $P = 4.1$ d (McSwain et al. 2001) and $P = 4.4$ d (McSwain et al. 2004) for LS 5039, due to the very high scatter in its $V_r$ curve, which has lead to considerable confusion about the correct orbital period of this system. We note that our period search also resulted in $P = 3.906$ d when we excluded the data of Casares et al.

THE ORBITS OF THE $\gamma$-RAY BINARIES LS I +61 303 AND LS 5039

Figure 4. Mean spectrum of LS 5039 from the night of 2007 August 29, taken near the time of inferior conjunction of the optical star. We used this mean spectrum as a reference to determine the relative $V_r$ by cross-correlation with each spectrum of LS 5039.

Figure 5. Radial velocity curve of LS 5039. Periastron corresponds to $\phi = 0$ in this plot. The points plotted as open diamonds are from McSwain et al. (2001, 2004), crosses are from Casares et al. (2005b), and filled circles are from this work.

For our new orbital fit of LS 5039, the geometry is illustrated in Figure 6. In this figure, we show the relative orbit of the optical star with 23 $M_\odot$ (Casares et al. 2005b) and a compact companion. Casares et al. (2005b) have proposed a 3.7 $M_\odot$ black hole in the system, although Dubus (2006) favors a neutron star (1.4 $M_\odot$) companion. Our orbital solution is not very different from the fit found by Casares et al. (2005b) using all available H, He i, and He ii lines. However, they adopt a final solution found using only the He ii lines, which results in a slightly higher $e$, $\gamma$, and $K_1$ than our result. Their argument that wind emission in the O star may affect the line species differently, whereas the He ii line is formed in the photosphere and is less contaminated by the wind, is very reasonable. However, we did not observe systematic line-to-line differences in our spectra, and the scatter for all lines is equally large. Therefore we favor using the mean of all available lines for the orbital solution of LS 5039.

4. DISCUSSION

Both LS I +61 303 and LS 5039 have previously published orbital solutions in the literature with large disagreements in the orbital elements (McSwain et al. 2001, 2004; Casares et al. 2005a, 2005b; Grundstrom et al. 2007). The need for an improved system geometry, especially in LS I +61 303, was highlighted recently by Sierpowska-Bartosik & Torres (2008) because the stellar separation and wind density play a significant role in the location of the $\gamma$-ray emission region (Dubus 2006) and opacities in a pulsar wind zone model. In fact, they found that a putative wind shock region in LS I +61 303 could lie unphysically close to the optical star using the orbital solution of Casares et al. (2005a) along with several assumptions about the stellar and pulsar wind strengths. Our new solution for LS I +61 303 results in a larger separation distance at periastron, so the stand-off distance of the shock region will be correspondingly farther from the star for the same wind parameters. Since the $\gamma$-ray production and its opacities are very sensitive to the orbital geometry, our spectroscopic orbital solutions of LS I +61 303 and LS 5039 may be further improved and the system inclinations constrained using their MeV–TeV light curves.

We note that the radial velocity curves of both LS I +61 303 and LS 5039 reveal a large number of spurious $V_r$ points near apastron. In the case of LS I +61 303, Figure 2 indicates a...
Thus the much more pronounced in the $V_r$ line core (not included in our $R$ both the red ($V_r$ secondary maximum in the plot of the gray-scale spectra is not included in our 35 nights of observation, sorted by HJD and smoothed for clarity, Figure 7. The intensity at each velocity in the gray-scale image is assigned one of 16 gray curve solution.

Figure 7. Upper plot shows the He $i$ λ6678 line profile of LS 1+61 303 over our continuous 35 nights of observation, sorted by HJD and smoothed for clarity, and the lower plot shows a gray-scale image of the same line. Note that the lower plot of the gray-scale spectra is not folded by orbital phase but is placed in the same chronological order as the upper plot, with the orbital phases indicated. The intensity at each velocity in the gray-scale image is assigned one of 16 gray levels based on its value between the minimum (dark) and maximum (bright) observed values. The intensity between observed spectra is calculated by a linear interpolation between the closest observed phases. The solid white line shows the theoretical $V_r$ curve solution.

secondary maximum in the $V_r$ curve near $\phi \sim 0.8$ which appears both in our observations and those of Grundstrom et al. (2007). To examine this behavior more carefully, we show in Figure 7 the He $i$ λ6678 line profiles and a gray-scale image of this line over our 35 consecutive nights of observation. Some glitches that do not affect the absorption line profile have been removed for clarity. Note that neither the line profiles nor the gray-scale plots are folded by orbital phase, but rather they reveal true chronological variations in the line profile behavior as a function of HJD and the corresponding orbital phase. Our spectra between $0.6 \lesssim \phi(TG) \lesssim 0.7$ reveal a slight increase in both the red ($R$) and violet ($V$) emission peaks, followed by a decline in emission between $0.7 \lesssim \phi(TG) \lesssim 0.9$. The effect is much more pronounced in the $H\alpha$ line profile and was also noted by Grundstrom et al. (2007). Thus the $V$ and $R$ variations appear to be related to cyclic orbital variations rather than an isolated event. Although one spectrum does contain a sharp glitch in the line core (not included in our $V_r$ measurements), the secondary $V_r$ increase near $\phi(TG) \sim 0.8$ is due to the decrease in emission strength and the corresponding broadening of the absorption-line profile.

In LS 5039, most of the spurious points in the $V_r$ curve occur between $0.4 \lesssim \phi \lesssim 0.6$, and they have been observed by other authors as well (McSwain et al. 2001, 2004; Casares et al. 2005b). In fact, the frequent deviations in $V_r$ are the main source of confusion in the orbital elements published by these authors. Our low spectral resolution does not permit a detailed analysis of the line behavior at this time, but higher-resolution spectra may provide evidence of systematic line profile changes in the system.

We gratefully acknowledge the anonymous referee for helpful comments about this manuscript as well as Jorge Casares for sharing his radial velocity measurements of LS 5039. We also thank Di Harmer and the staff at KPNO, as well as Fred Walter and the SMARTS service observers, for their hard work to schedule and support these observations. This work is supported by NASA DPR numbers NNX08AV70G, NNX08AX79G, and NNG08E1671 and an institutional grant from Lehigh University.
