(Received 7 December 2015; revised manuscript received 9 February 2016; published 7 March 2016)

We report neutron scattering and muon spin relaxation measurements ($\mu$SR) on the pyrochlore antiferromagnet Yb$_2$Ge$_2$O$_7$. Inelastic neutron scattering was used to probe the transitions between crystal electric field levels, allowing us to determine the eigenvalues and eigenvectors appropriate to the $J = \frac{3}{2}$ Yb$^{3+}$ ion in this environment. The crystal electric field ground state doublet in Yb$_2$Ge$_2$O$_7$ corresponds primarily to $m_J = \pm \frac{1}{2}$ with local XY anisotropy, consistent with an $S_{\text{eff}} = \frac{1}{2}$ description for the Yb moments. $\mu$SR measurements reveal the presence of an ordering transition at $T_N = 0.57$ K with persistent weak dynamics in the ordered state. Finally, we present neutron diffraction measurements that reveal a clear phase transition to the $k = (000)$ $\Gamma_2$ ground state with an ordered magnetic moment of $0.3(1) \mu_B$ per Yb ion. We compare and contrast this phenomenology with the low-temperature behavior of Yb$_2$Ti$_2$O$_7$ and Er$_2$Ti$_2$O$_7$, the prototypical $S_{\text{eff}} = \frac{1}{2}$ XY pyrochlore magnets.

I. INTRODUCTION

Magnetic frustration arises for systems in which the lattice geometry precludes the simultaneous satisfaction of all pairwise magnetic interactions. Cubic pyrochlore oxides, with the composition $A_2B_2O_7$, present exemplary three-dimensional realizations of lattices that can be subject to strong geometric magnetic frustration when either the $A$ or $B$ site is occupied by a magnetic cation [1]. The sublattices produced by the $A$ and $B$ site cations form two interpenetrating networks of corner-sharing tetrahedra. The topicality of the pyrochlore lattice for the study of magnetic frustration is, in part, due to the ease with which numerous magnetic and nonmagnetic cations can be substituted onto the $A$ and $B$ sites of the lattice [2]. As a result, a plethora of magnetic pyrochlores have been investigated, revealing a diverse array of exotic magnetic ground states.

Rare-earth titanates and stannates of the form $R_2B_2O_7$, where $R$ is a rare-earth ion and nonmagnetic $B$ is either Ti$^{4+}$ or Sn$^{4+}$, have been of great experimental interest. Both of these families can be synthesized using a wide range of rare-earth oxides. However, while it is straightforward to grow large single crystals of the titanate $R_2Ti_2O_7$ series, the stannate $R_2Sn_2O_7$ series exists only in powder form at present. More recently, the rare-earth germinate family, $R_2Ge_2O_7$, has presented a new avenue to investigate the physics of magnetic pyrochlores. The germinate family is relatively unexplored, as they can only be grown under high pressures, and have thus far only been obtained as small polycrystalline samples [3]. The germinate pyrochlores, due to the small ionic radius of Ge$^{4+}$, have contracted lattice parameters with respect to their titanium and tin analogs, and thus have so far been studied in the context of chemical pressure [3–5].

The diversity of magnetic ground states observed across the $R_2B_2O_7$ series, with $B = Ge$, Ti, or Sn, can be primarily attributed to two sources. First, the moment size and anisotropy differ significantly, depending upon which rare-earth element sits at the $A$ site. These single-ion properties are determined by the crystal field splitting of the $(2J + 1)$ multiplet arising from the partially filled $4f$ shell at the $R^{3+}$ site. Second, the relative strength and nature of the magnetic interactions that exist between the $R^{3+}$ moments can vary greatly. Furthermore, due to strong spin-orbit coupling in the $4f$ series, the exchange interactions between the $R^{3+}$ moments are anisotropic, and the form of these interactions is determined by the point group symmetry at the $R^{3+}$ site [6]. In simple terms, these combinations can generate ferromagnetically or antiferromagnetically coupled Ising, XY, or Heisenberg spins decorating a network of corner-sharing tetrahedra, and the diversity of ground states that these combinations imply.

While a range of magnetic ground states exist in the rare-earth pyrochlores, we limit ourselves henceforth to discussion of those rare-earth pyrochlores with XY anisotropy, specifically the Yb$^{3+}$ and Er$^{3+}$ pyrochlores. The crystal electric field states for Yb$_2$Ti$_2$O$_7$ are well understood [7–9], while those corresponding to Er$_2$Ti$_2$O$_7$ are less well determined [10,11]. However, it is clear that both the Yb$^{3+}$ and Er$^{3+}$ ions in $R_2Ti_2O_7$ give rise to XY-like magnetic anisotropy. This XY anisotropy implies that the eigenfunctions describing the ground state doublet have large contributions from $m_J = \pm \frac{1}{2}$. Provided that the ground state doublet is well separated from the first excited crystal field level, this results in an $S_{\text{eff}} = \frac{1}{2}$ quantum description for the magnetic degrees of freedom. Similarties in crystal structure and associated crystal field
effects suggest that the same should be true for all of Yb$_2$B$_2$O$_7$ and Er$_2$B$_2$O$_7$ with $B =$ Ge, Ti, and Sn.

Yb$_2$Ti$_2$O$_7$ and Yb$_2$Sn$_2$O$_7$ both possess Curie-Weiss constants that are ferromagnetic and weak [8,12,13]. These two materials have also both been found to order into a canted ferromagnetic state at low temperatures [13–16]. However, there are exotic characteristics to such states, at least in the case of Yb$_2$Ti$_2$O$_7$, for which single-crystal studies are required. For example in the "ordered" state of Yb$_2$Ti$_2$O$_7$ there is persistent anisotropic diffuse scattering [17,18] and no evidence of well-defined spin wave excitations in zero magnetic field [19,20]. Further single-crystal inelastic neutron scattering measurements of Yb$_2$Ti$_2$O$_7$ in its field-induced polarized state have been used to estimate its microscopic spin Hamiltonian [21,22]. Interestingly, the heat capacity anomalies in Yb$_2$Ti$_2$O$_7$ are known to be sample dependent, with sensitivity to the presence of weak quenched disorder at the 1% level [23,24]. This sample dependence also extends to the ground state properties, as observed with both $\mu$SR and neutron scattering [14,15,19,20,25,26].

Er$_2$Ti$_2$O$_7$ is an interesting contrast to the ytterbium systems. Er$_2$Ti$_2$O$_7$ is known to possess a relatively large, antiferromagnetic Curie-Weiss constant [10,12] and undergoes a continuous phase transition to a noncoplanar $\psi_2$ antiferromagnetic ordered state at $T_N = 1.2$ K [27–29]. However, in contrast to Yb$_2$Ti$_2$O$_7$, there are well-defined conventional spin wave excitations in Er$_2$Ti$_2$O$_7$ below $T_N$ [30]. Its microscopic spin Hamiltonian has also been estimated from inelastic neutron scattering [31], and the selection of the $\psi_2$ ground state is argued to arise due to an order-by-quadratic disorder mechanism [27,31–35]. The corresponding order-by-disorder spin wave gap has been measured with inelastic neutron scattering [36]. An alternate energetic argument for ground state selection of the $\psi_2$ state has also recently been made [37–38]. In striking contrast to Yb$_2$Ti$_2$O$_7$, the $\psi_2$ ground state in Er$_2$Ti$_2$O$_7$ is not obviously sensitive to quenched disorder and does not display sample dependence. It has even been shown to accommodate magnetic dilution consistent with three-dimensional percolation theory [39].

In this paper, we turn our attention to a member of the germanate pyrochlore family, Yb$_2$Ge$_2$O$_7$, wherein Ge$^{4+}$ on the $B$ site is nonmagnetic and the magnetism is carried by Yb$^{3+}$ on the $A$ site. We first present our inelastic neutron scattering measurements, which establish the eigenvalues and eigenfunctions for the crystal field levels appropriate to Yb$_2$Ge$_2$O$_7$. This firmly establishes the XY nature of the Yb$^{3+}$ moments in their $g$ tensor anisotropy. We next show $\mu$SR measurements that establish a phase transition at $T_N = 0.57$ K to a conventional long-range ordered state with weak dynamics. Finally we present elastic neutron scattering measurements which reveal the ordered state in Yb$_2$Ge$_2$O$_7$ to be the $K = (000)$ $\Gamma_5$ antiferromagnetic structure with an ordered moment of 0.3(1)$\mu_B$. As both Yb$_2$Ge$_2$O$_7$ and Er$_2$Ti$_2$O$_7$ are antiferromagnetically coupled systems with ordered states in the $\Gamma_5$ manifold, $S_{\text{eff}} = \frac{1}{2}$ degrees of freedom, and XY anisotropy, we compare and contrast these two pyrochlores.

II. EXPERIMENTAL METHODS

The cubic pyrochlore phase of Yb$_2$Ge$_2$O$_7$ cannot be stabilized at ambient pressure using conventional solid state synthesis. Thus, powder samples of Yb$_2$Ge$_2$O$_7$ were synthesized using a belt-type high pressure apparatus. Stoichiometric quantities of Yb$_2$O$_3$ and GeO$_2$, pre-reacted into the tetragonal pyrogermanate phase, were sealed in gold capsules and reacted at 1300 $^\circ$C under 6 GPa of pressure. The resulting product was thoroughly ground and powder x-ray diffraction was used to confirm the $Fd\bar{3}m$ pyrochlore structure for each 400 mg batch. Our Rietveld refinements of the x-ray patterns gave a lattice parameter of 9.8284(2) Å, in agreement with previous reports [5,40]. While scaling up materials synthesized under high pressure is cumbersome, such samples do present some inherent advantages. First, high pressure synthesis gives a high degree of control over the stoichiometry [4]. Furthermore, the large ionic radii difference between Yb$^{3+}$ and Ge$^{4+}$, which necessitates high-pressure synthesis, also significantly reduces the probability of site mixing [3]. This is particularly attractive in light of the sensitivity that the magnetism in some pyrochlores has shown to subtle variations in stoichiometry and so-called “stuffing” [23,41,42].

Muon spin relaxation ($\mu$SR) measurements on Yb$_2$Ge$_2$O$_7$ were carried out at the TRIUMF Laboratory. A 300 mg pressed pellet of Yb$_2$Ge$_2$O$_7$, mixed with 20% silver powder to improve thermalization, was attached to a silver coated cold finger with Aipelzon N-grease. Measurements between 25 mK and 2 K were carried out in a dilution refrigerator, both with zero external field and in fields up to 0.5 T. In $\mu$SR measurements, 100% spin polarized muons are implanted one at a time in a sample, where the muon spins evolve in the local magnetic environment. As the muons decay, with an average lifetime of 2.2 $\mu$s, they emit a positron preferentially in the direction of the muon spin. Two opposing sets of detectors, in the forward and backward direction from the sample relative to the muon beam, detect the emitted positrons. The asymmetry spectrum, which is directly proportional to the muon polarization, is described by $A(i) = [F(i) - B(i)]/[F(i) + B(i)]$, where $F(i)$ and $B(i)$ are the numbers of positrons detected in the forward and backward directions respectively, scaled by their counting efficiencies. Fits to the $\mu$SR data were performed using MUSRFIT [43].

The inelastic neutron scattering measurements on Yb$_2$Ge$_2$O$_7$ were performed on the SEQUOIA spectrometer at the Spallation Neutron Source at Oak Ridge National Laboratory. A 2.7 gram powder sample of Yb$_2$Ge$_2$O$_7$ was sealed in an aluminum sample can under a helium atmosphere. Using a standard orange Institut Laue-Langevin (ILL) cryostat, measurements were performed at 2 K with an incident energy of 150 meV, giving an elastic energy resolution of $\pm$2.8 meV. The energy resolution improves at higher energies and is approximately 1.4 meV for energy transfers of 80 meV and 1 meV for energy transfers of 120 meV. This configuration was also used for measurements on an identical empty can, which serves as a background.

Magnetic neutron diffraction measurements on Yb$_2$Ge$_2$O$_7$ were carried out with the fixed incident energy triple axis spectrometer HB1A at the High Flux Isotope Reactor at Oak Ridge National Laboratory. The same 2.7 gram sample of Yb$_2$Ge$_2$O$_7$ was mounted in an oxygen free copper sample can under a helium atmosphere. The incident neutron beam has a wavelength of 2.37 Å, which is selected by a double pyrolitic graphite monochromator. Energy analysis of the scattered
beam employs a pyrolitic graphite analyzer crystal, giving an elastic energy resolution of approximately 1 meV. Elastic diffraction measurements were carried out using both a $^3$He insert and a dilution insert, with base temperatures of 300 and 50 mK, respectively, and a maximum temperature of 10 K. Representational analysis of the diffracted intensities were performed using SARAH REFINE [44] and FULLPROF [45].

III. RESULTS AND DISCUSSION

A. Determination of the crystal electric field eigenvalues and eigenfunctions via inelastic neutron scattering

Figure 1(a) shows the inelastic neutron scattering spectrum for Yb$_2$Ge$_2$O$_7$ collected at 2 K for energy transfers up to 150 meV. The excitations corresponding to transitions between crystal electric field (CEF) levels can be assigned based on two criteria: (i) They should be dispersionless, i.e., without $Q$ dependence, and (ii) their intensity should be maximal at the lowest $Q$ values and should fall off according to the magnetic form factor of Yb$^{3+}$. Following these criteria, three crystal field excitations can be identified in Fig. 1(a) at 80.7, 84.2, and 123.3 meV. The $Q$ dependence for the first two transitions is shown in Fig. 2 and is consistent with the Yb$^{3+}$ magnetic form factor. The valence shell of Yb$^{3+}$ contains 13 $f$ electrons which, following Hund’s rules, gives a spin orbit ground state with total angular momentum $J = \frac{7}{2}$ and a $2J + 1 = 8$ fold degeneracy. The local oxygen environment surrounding each Yb$^{3+}$ cation produces a crystal electric field that lifts the ground state degeneracy. However, from its odd electron count, it follows that Yb$^{3+}$ is subject to Kramer’s theorem and, consequently, the crystal electric field can produce at most four doublets. Thus, the three crystal field doublets observed in Fig. 1(a) and the ground state doublet account for the full manifold of the Yb$^{3+}$ crystal electric field transitions.

The eight oxygens that surround each Yb$^{3+}$ cation form a cube that is distorted along one of its body diagonals, where this direction forms the local [111] axis. Defining the $\hat{z}$ axis along this [111] local axis, the local environment has a threefold symmetry, as well as an inversion symmetry, giving a point group symmetry $D_{3d}$. Following the Stevens’ operator formalism, we use the following Hamiltonian to approximate the Coulomb potential generated by the crystal electric field due to the neighboring oxygen atoms [46–48]:

$$H_{\text{CEF}} = B_2^0 \hat{O}_2^0 + B_4^0 \hat{O}_4^0 + B_6^0 \hat{O}_6^0 + B_2^3 \hat{O}_2^3 + B_4^3 \hat{O}_4^3 + B_6^3 \hat{O}_6^3,$$

(1)

where the CEF parameters, $B_m^n$, have been fit using our inelastic neutron scattering data of Fig. 1(a). To do so, the scattered intensity is computed in the same way as in Ref. [7] using the CEF parameters of Yb$_2$Ti$_2$O$_7$ as an initial guess. This calculation is compared by a least squares refinement
TABLE I. The crystal electric field (CEF) eigenvalues and eigenvectors for Yb$^{3+}$ at the A site of Yb$_2$Ge$_2$O$_7$. The first column displays the CEF eigenvalues of the system, while the corresponding eigenvectors are given in each row in terms of the $m_J$ basis.

At sufficiently high temperatures, when a system is in its paramagnetic regime, there will only be a small relaxation due to nuclear dipole moments; at such temperatures, the spins in the sample are rapidly fluctuating and the dynamics are faster than the muon time window. In Yb$_2$Ge$_2$O$_7$ we see that at 2 K the asymmetry is only weakly relaxing, indicating that the
sample is within its paramagnetic regime. At 1 K, there is a slight increase in the relaxation, indicating that electronic spin correlations are beginning to develop. Upon cooling towards the Néel temperature, the relaxation further increases due to slowing fluctuations as the electronic correlations grow stronger [Fig. 3(a)]. As Yb$_2$Ge$_2$O$_7$ is cooled below the Néel temperature, the asymmetry takes on a two-component form, with a sharp drop in the early time asymmetry followed by a slow relaxation at longer times.

The data at all temperatures are well described in terms of a dynamical Lorentzian Kubo-Toyabe function [49]. This function, which is appropriate for a system with a Lorentzian distribution of internal fields, $a$, appropriately captures the physics in a system with slow or fast dynamics. The temperature evolution of $a$, as shown in Fig. 3(c), provides a clear order parameter corresponding well with the observed Néel temperature from ac susceptibility and heat capacity, $T_N = 0.57$ K [5]. The internal field distribution plateaus below 200 mK at approximately 12 $\mu$s$^{-1}$, which corresponds to 0.1 T.

The asymmetry spectra for Yb$_2$Ge$_2$O$_7$ differs from the canonical spectra for a system with static magnetic order in two key aspects. First, the long-time component is not fully time independent, but instead has a weak exponential relaxation. This indicates that, below the Néel temperature, Yb$_2$Ge$_2$O$_7$ remains weakly dynamic. A persistent relaxing signal, while not fully understood, is a common feature of magnetically frustrated systems [50]. Second, no long-lived precessing signal could be resolved in the asymmetry spectra. However, a lack of oscillations does not preclude static magnetic order. In fact, the absence of oscillations is frequently observed for pyrochlores with long range magnetic order, such as Er$_2$Ti$_2$O$_7$ [51] and Tb$_2$Sn$_2$O$_7$ [52,53]. A lack of oscillations can be attributed to an inhomogeneous internal field distribution, which can, in part, be explained by having multiple muon stopping sites. Similarly, the minimum in Kubo Toyabe function can be “wiped out” by multiple field distributions, as would be expected for multiple muon stopping sites [54]. As the pyrochlore structure contains two inequivalent oxygen sites, and positively charged muons stop at the most electronegative positions, at least two inequivalent stopping sites can be expected in Yb$_2$Ge$_2$O$_7$.

We also performed $\mu$SR measurements on Yb$_2$Ge$_2$O$_7$ with an externally applied magnetic field. In our measurements, the external field is applied parallel to the initial muon polarization direction, i.e., longitudinal geometry. In the case of static (or quasistatic) magnetism, the external field can be increased until it overwhelms the static internal fields produced by the sample. When this happens, the muon spins will respond more strongly to the external field and become effectively “decoupled” from the sample, resulting in a reduced relaxation rate. For Yb$_2$Ge$_2$O$_7$, at 25 mK in fields between 0.01 and 0.5 T, the asymmetry decouples in the expected manner for a dynamic Lorentzian Kubo-Toyabe, with the magnitude of the external field imposed as a constraint [Fig. 3(b)]. While applying a longitudinal field effectively decouples the majority of the relaxation, as in the zero field case, there remains a weak long time relaxation, so-called persistent spin dynamics. Thus, both the zero field and longitudinal field measurements on Yb$_2$Ge$_2$O$_7$ are consistent with quasi static magnetic order on the muon timescale.

### C. Measurement of the magnetic structure
by elastic neutron diffraction

Magnetic neutron diffraction was employed to determine the magnetic ground state of Yb$_2$Ge$_2$O$_7$. Our initial measurements surveyed a broad region of $Q$-space between 0.5 and 2.5 Å$^{-1}$. Comparison of data sets collected at 50 and 900 mK revealed the formation of magnetic Bragg peaks on cooling into the ordered phase. All magnetic Bragg peaks were observed to form on allowed positions for nuclear reflections in the pyrochlore lattice. Figure 4 shows four of the measured Bragg positions at 50 and 900 mK. In each case, the peak has been fit to a Lorentzian peak shape function where the only independent adjustable parameter between 50 and 900 mK is the peak area. The intensity gain from 900 to 50 mK, in arbitrary units of counts normalized by monitor, is $3.1 \pm 0.7$. The (002) position, which does not contain a nuclear reflection, is also devoid of a magnetic reflection [Fig. 4(b)]. The next magnetic reflections occur at (220) and (113), which have intensity gains of $1.8 \pm 1.0$.
TABLE II. Powder averaged magnetic Bragg intensities for each of the irreducible representations allowed for Yb$^{3+}$ on the 16d site of the $Fd\bar{3}m$ pyrochlore lattice with a propagation vector of $k = (000)$. Despite having multiple basis vectors, $\Gamma_5$ and $\Gamma_7$ have only one entry because the powder diffraction patterns are identical for each of their basis vectors. The six basis vectors of $\Gamma_9$ likewise produce only two unique powder patterns. We also consider an optimized linear combination of $\Gamma_9$. The final row gives the experimentally observed magnetic intensities. In all cases, the intensities have been normalized relative to the most intense reflection in that pattern.

|           | (111) | (002) | (220) | (113) | (222) | (004) |
|-----------|--------|--------|--------|--------|--------|--------|
| $\Gamma_5(\psi_1)$ | 0      | 0      | 0.99   | 1      | 0      | 0      |
| $\Gamma_5(\psi_{2,3})$ | 1      | 0      | 0.68   | 0.37   | 0      | 0      |
| $\Gamma_7(\psi_{4,5,6})$ | 1      | 0.74   | 0.34   | 0.37   | 0      | 0      |

| $\Gamma_9$ (L.C.) | 1      | 0.22   | 0.10   | 0.37   | 0      | 0.40   |

Experiment $1 \pm 0.2$ $0 \pm 0.6 \pm 0.3$ $0.4 \pm 0.3$ $0 \pm 0$

and $1.3 \pm 0.9$, respectively [Figs. 4(c) and 4(d)]. The (113) Bragg peak, which is centered at 2.13 Å$^{-1}$ has a large sloping background because it is immediately adjacent to the large (222) nuclear reflection, centered at 2.23 Å$^{-1}$. The (222) and (004) positions were also carefully measured and showed no intensity gain below the Néel temperature. A summary of the experimental intensities, given as a fraction of the intensity of (111), is shown in Table II.

Magnetic Bragg peaks were only found on positions allowed for nuclear scattering by the pyrochlore lattice. Thus, the magnetic reflections in Yb$_2$Ge$_2$O$_7$ can be indexed with a propagation vector of $k = (000)$. The possible magnetic structures for Yb$^{3+}$ on the 16d site of the $Fd\bar{3}m$ pyrochlore lattice, with propagation vector $k = (000)$, can be described by four possible irreducible magnetic representations: $\Gamma_{Mag} = \Gamma_1 + \Gamma_3 + \Gamma_5 + \Gamma_9$ [55,56]. These irreducible representations can be expressed in terms of their basis vectors ($\psi_1, \psi_2, \ldots, \psi_{12}$).

The $\Gamma_1$ ($\psi_1$) structure is the so-called “all-in, all-out” state, a noncoplanar antiferromagnetic structure in which the moments are oriented along their local (111) axes. The $\Gamma_3$ ($\psi_3$) structure was first experimentally realized in FeF$_3$ [57] and has subsequently been found in various other systems [58–60]. The $\Gamma_5$ manifold has two basis vectors, $\psi_5$ and $\psi_7$, and has been observed in the XY antiferromagnets Er$_2$Ti$_2$O$_7$ and Er$_2$Ge$_2$O$_7$ [27,61]. Linear combinations of the $\Gamma_7$ manifold, composed of $\psi_4, \psi_5,$ and $\psi_6$, are often referred to as the Palmer-Chalker ground state [62]. The Palmer-Chalker ground state is found in Gd$_2$Sn$_2$O$_7$, which is a realization of a Heisenberg pyrochlore antiferromagnet with dipolar interactions [56]. There are six basis vectors that make up the $\Gamma_9$ manifold. Linear combinations of these six basis vectors can give noncollinear ferromagnetic structures related to the spin ice state, such as the splayed ferromagnetic state found in Yb$_2$Sn$_2$O$_7$ [13].

The simulated relative intensities for each of these representations are listed in Table II. In the case of $\Gamma_5$ and $\Gamma_7$, the powder diffraction patterns for their specific basis vectors are, in general, identical. Thus, we do not distinguish between $\psi_2$ and $\psi_3$, nor do we distinguish between $\psi_4, \psi_5, \psi_6$. The six basis vectors that make up $\Gamma_9$ produce two distinct powder diffraction patterns, as indicated in the table. Finally, a linear combination of the $\Gamma_9$ basis vectors can also be considered. While there is poor agreement between $\Gamma_5$ and the experimental data, the linear combination presented in Table II is the one that most closely fits the experimental data: $\Gamma_{Mag} = 0.038(\psi_{7,9,11}) + 0.021(\psi_{8,10,12})$. Inspection of this table reveals excellent agreement between the experimental results and the $\Gamma_5$ manifold.

Rietveld refinement of all measured Bragg reflections, as summarized in Table II, was used to determine the size of the ordered moment in Yb$_2$Ge$_2$O$_7$. All structural parameters for the pyrochlore $Fd\bar{3}m$ lattice and the scaling factor were determined from a refinement of the 900 mK data set, which is well above $T_N$. The 50 mK data set was then refined with a $\Gamma_5$ magnetic structure where only the magnitude of the ordered moment was allowed to freely vary. The $\psi_2$ and $\psi_3$ basis vectors which comprise $\Gamma_5$ generate identical powder neutron diffraction patterns and identical magnetic moment sizes, and thus we do not distinguish between the two within our Rietveld refinement. The resultant Rietveld refinement for Yb$_2$Ge$_2$O$_7$ at 50 mK is shown in Fig. 5(a). The best agreement with the measured data, as indicated by a minimization of $\chi^2_{\text{bragg}}$, was obtained for an ordered moment of 0.3(1) $\mu_B$ [Fig. 5(b)].

In order to obtain a measurement of the order parameter in Yb$_2$Ge$_2$O$_7$, we tracked the (111) Bragg peak, which is the largest magnetic reflection. Figure 6 shows the intensity of (111) as a function of temperature, where the zero has been set by the average intensity between 1 and 5 K, well above the Néel temperature. The order parameter in Yb$_2$Ge$_2$O$_7$ correlates directly with the sharp anomaly in the heat capacity, which is peaked at $T_N = 0.57$ K. While the order parameter in Yb$_2$Ge$_2$O$_7$ appears quite conventional, this is not generally true in the ytterbium pyrochlores. The order parameter in Yb$_2$Ti$_2$O$_7$, which plateaus below $T_c = 240$ mK, continually decreases well above $T_c$, to at least 700 mK [16].

D. Comparison to relevant XY pyrochlore magnets

The antiferromagnetic $\Gamma_5$ structure we have determined for Yb$_2$Ge$_2$O$_7$ below $T_N = 0.57$ K belongs to the same ground state manifold as Er$_2$Ti$_2$O$_7$ below its $T_N = 1.2$ K transition. However, Er$_2$Ti$_2$O$_7$ was identified as uniquely displaying the $\psi_3$ state, with a rather large ordered moment of $\mu_{ord} = 3.01\mu_B$ [27]. For our powder sample of Yb$_2$Ge$_2$O$_7$, we cannot distinguish $\psi_2$ from $\psi_3$ within $\Gamma_5$ [inset of Fig. 5(b)], and the ordered moment within this structure at low temperatures is small, $\mu_{ord} = 0.3(1)\mu_B$. We note that a large ordered moment of 1.06(7)$\mu_B$ has recently been reported for the antiferromagnetic ground state of Yb$_2$Ge$_2$O$_7$ [61], but this estimate arose from measurements on a much smaller volume of sample, and no net magnetic scattering (i.e., difference between high and low temperature) is shown for the strongest magnetic Bragg peak, (111). In any case, this large ordered moment estimate for Yb$_2$Ge$_2$O$_7$ is inconsistent with our results [Fig. 5(b)].

Order-by-quantum disorder has been proposed as the mechanism for the selection of the $\psi_3$ ground state for Er$_2$Ti$_2$O$_7$ [27,31–35], based on understanding the microscopic spin Hamiltonian derived from spin wave measurements [31].
This mechanism predicts a gap in the spin wave spectrum due to breaking the continuous symmetry which exists between the $\psi_2$ and $\psi_3$ ground states within $\Gamma_5$. Indeed, this spin wave gap has been measured in Er$_2$Ti$_2$O$_7$ [36]. However, an alternative mechanism for ground state selection based on virtual transitions to excited crystal field levels has also been proposed for Er$_2$Ti$_2$O$_7$ [35,37,38]. This alternative mechanism relies on the presence of low energy crystal field levels, as the probability for such virtual transitions go as the inverse square of the energy required for the transitions out of the ground state. This is a plausible scenario for Er$_2$Ti$_2$O$_7$ [27]. However, it is not a plausible scenario for Yb$_2$Ge$_2$O$_7$, as we have just determined that the lowest crystal field transition occurs at 80.7 meV, more than an order of magnitude higher in energy than was the case for Er$_2$Ti$_2$O$_7$. In this regard, Yb$_2$Ge$_2$O$_7$ is a stronger candidate for exhibiting an ordered state selected by a thermal or quantum order-by-disorder mechanism.

We emphasize that it does not follow that the $\Gamma_5$ antiferromagnetic ground state we observe in Yb$_2$Ge$_2$O$_7$ arises from an order-by-disorder mechanism. It has been shown that a $\Gamma_5$ state in Yb$_2$Ge$_2$O$_7$ could be predicted purely on the basis of the phase diagram for Yb$_2$Ti$_2$O$_7$ obtained from its anisotropic spin exchange Hamiltonian [63]. Indeed, as $\Gamma_5$ is constituted by both $\psi_2$ and $\psi_3$, it is not clear that a selection is even being made, which would necessitate an order-by-disorder scenario. Dun et al. claim that fits to the heat capacity below $T_N = 0.57$ K are consistent with the presence of an emerging spin wave gap of 24 $\mu$eV, but no such gap has been directly measured. Nonetheless, the absence of low lying crystal field excitations in Yb$_2$Ge$_2$O$_7$ implies that there could be significant differences between the antiferromagnetic ground states in Yb$_2$Ge$_2$O$_7$ and Er$_2$Ti$_2$O$_7$, despite their similarities.

IV. CONCLUSIONS

To conclude, we have synthesized relatively large volumes of the pyrochlore magnet Yb$_2$Ge$_2$O$_7$ using high-pressure synthesis techniques. This has enabled studies of both the crystal field excitations of Yb$_2$Ge$_2$O$_7$, using inelastic neutron scattering, and the low-temperature ground state of this system, using magnetic neutron diffraction and $\mu$SR techniques. Our inelastic neutron scattering measurements allow us to determine the eigenvalues and eigenfunctions associated with the splitting of the $(2J+1)$ manifold of states appropriate to Yb$^{3+}$ in the Yb$_2$Ge$_2$O$_7$ environment. We find an XY nature to the single-ion ground state wave function, as expressed in $g_{\perp}/g_z = 1.7(2)$, and a large 80.7 meV gap to the first excited state. The ground state doublet is primarily comprised of $m_J = \pm \frac{1}{2}$, supporting a picture of $S_{eff} = \frac{1}{2}$ Yb$^{3+}$ moments.

$\mu$SR measurements show quasistatic magnetic order on the muon time scale to set in below $T_N = 0.57$ K. Our elastic
neutron scattering measurements show the ground state to be a $\Gamma_5$, $k = (000)$, antiferromagnetic state, with a relatively small ordered moment of $0.3(1)\mu_B$ at low temperatures. We hope that this characterization of the single ion and ground state properties of Yb$_2$Ge$_2$O$_7$ motivates a full understanding of the structure and dynamics of this exotic pyrochlore magnet, and helps guide a thorough understanding of its fascinating phase behavior.

ACKNOWLEDGMENTS
