**Abstract** To explore the metabolic responses of marine-derived *Trichoderma* fungi to environmental stresses, the survivability, metabolism, and antagonism of ten marine isolates have been examined. Their survival in both freshwater and seawater indicates them to be facultative marine fungi, but they are more adaptable to marine environment. Most of them feature strain-specific and positive metabolic responses to seawater, which also usually result in the higher proportions of heteroatom-bearing and unsaturated units in mycelial constituents. Seawater factors can promote many strains to produce bioactive metabolites, including plant pathogen- and marine phytoplankton-inhibitory and marine animal-toxic ones, but the effects of NaCl are often weak or negative. The inhibition of marine phytoplankton corresponds to the intracellular accumulation of heteroatom-bearing and unsaturated units under seawater condition, and the varied toxicities to marine animals further signify the divergences of lipophilic exudates under different conditions. The results may contribute to further understanding and mining the structural diversity and biological activity of secondary metabolites from marine-derived *Trichoderma* fungi.

**Keyword:** *Trichoderma*; fungus; metabolic response; seawater; antagonistic potential

1 INTRODUCTION

*Trichoderma* species are widespread as free-living fungi, mycoparasites, or opportunistic plant symbionts (Harman et al., 2004). As promising biocontrol agents in agriculture, those of terrestrial origin have been investigated for over 80 years and achieved great success especially to suppress phytopathogenic fungi (Papavizas, 1985). Following the pioneering work of Weindling (1932, 1934), a number of *Trichoderma* species with the biocontrol potential have been characterized, and some strains are officially registered or even commercially available as microbicides, such as *T. harzianum* T22 and KRL-AG2, *T. asperellum* T34 and T211, *T. atroviride* I-1237, and *T. virens* G-41. Their interactions with pathogens and plants seem complex, and the production of antibiotic secondary metabolites is regarded as one of the key antagonistic mechanisms (Vinale et al., 2008). Up to now, a plethora of structurally diverse compounds have been isolated and identified therein, of which some are responsible for the ability of *Trichoderma* to attack or inhibit pathogenic fungi and other targets, such as bacteria and weeds (Ghisalberti and Sivasithamparam, 1991; Reino et al., 2008; Keswani et al., 2014).

Even though *Trichoderma* is normally considered as a terrestrial genus, halotolerant strains have been continuously discovered from marine sediments, invertebrates, and algae (Ji and Wang, 2016; Blunt et al., 2018). Marine isolates of *Trichoderma* species also produced multifarious new structures, such as polyketides (Sun et al., 2008; Song et al., 2010), terpenes (Miao et al., 2012), and peptides (Garo et al., 2003; Ren et al., 2009; Chen et al., 2013), but most

bioassays were focused on pharmaceutical activity rather than ecological function toward phytopathogenic fungi and marine organisms. It is worth to mention that the secondary metabolism of marine-derived fungi appears sensitive to seawater concentration (Bugni and Ireland, 2004). However, little attention has been paid to the effects of seawater factors on the secondary metabolite production of marine-derived Trichoderma strains and their applications in agriculture and mariculture.

In order to gain a view of the survivability, metabolism, and antagonism of marine-derived Trichoderma fungi responding to environmental stresses, the effects of NaCl, NaBr, pH, and natural seawater (SW) on ten Trichoderma strains, including Trichoderma sp. dl8, T. pseudokoningii dl11, T. asperellum dl34 and dl48, T. harzianum dl36 and lyg12, T. longibrachiatum dl44 and cf11, and T. koningii dl49 and yt6, have been examined by analysis of the biomasses, production and NMR signals of lipophilic metabolites, and their bioactivities against some phytopathogenic fungi and marine organisms.

2 MATERIAL AND METHOD

2.1 Trichoderma strains

Following a previous procedure (Wang et al., 2006), ten marine-derived Trichoderma strains, including Trichoderma sp. dl8, T. pseudokoningii dl11, T. asperellum dl34 and dl48, T. harzianum dl36 and lyg12, T. longibrachiatum dl44 and cf11, T. koningii dl49 and yt6, were isolated from the inner tissue of the surface-sterilized marine macroalgae collected off the coasts of Dalian, Yantai, and Lianyungang of China. They were identified by morphological observation and by analysis of ITS regions for dl34 (GenBank accession number KR023953), dl36 (KX235318), dl44 (KX235319), dl48 (KX235320), and cf11 (JX089966) and 18S rDNA for dl8 (KX235317), dl11 (KX235313), dl49 (KX235314), lyg12 (KX235315), and yt6 (KX235316), which are preserved at the Yantai Institute of Coastal Zone Research, Chinese Academy of Sciences.

2.2 Fermentation

Fresh mycelia of ten Trichoderma strains were grown on the agar plates, and then they were cut into small segments and aseptically inoculated into Erlenmeyer flasks (1 L), each containing 150 mL freshwater (distilled water)-based media (glucose 20 g/L, peptone 5 g/L, yeast powder 2 g/L, K$_2$HPO$_4$ 1 g/L, MgSO$_4$ 0.5 g/L, and pH 7.0) as the control. To examine the effects of marine environmental factors, the media with 30.0 g/L NaCl, 86.3 mg/L NaBr, pH 8.0, or 100% natural seawater (salinity 3.0% and pH 8.0) were also used respectively for all the strains. Static fermentations were performed at 28°C for 30 days, with two replicates for each condition.

2.3 Extraction

The lipophilic metabolites in mycelia and broths of ten Trichoderma strains were extracted using ethyl acetate (EtOAc). Each culture was filtered to separate mycelia from broth, and the dried mycelia were weighted and then extracted with mixed CH$_2$Cl$_2$ and MeOH (1:1, v/v). The crude extract was further partitioned between EtOAc and H$_2$O to give the EtOAc-soluble extract. On the other hand, the broth was directly extracted with EtOAc. The extracting and partitioning procedures were repeated for three times, and the EtOAc extracts of mycelia and broth were evaporated at 40°C under reduced pressure and then weighted.

2.4 $^1$H NMR determination

10.0 mg sample of each extract was dissolved in 0.5 mL DMSO-$d_6$, and then subjected to the $^1$H NMR determination by a Bruker Avance III 500 NMR spectrometer (equipped with 5 mm probe) at 298 K. Chemical shifts ($\delta_H$) in ×10$^{-6}$ are referenced to tetramethylsilane (TMS), and signals in the upfield ($\delta_H$ (0.5–2.0)×10$^{-6}$, US), midfield ($\delta_H$ (3.5–5.0)×10$^{-6}$, MS), and downfield ($\delta_H$ (5.0–8.0)×10$^{-6}$, DS) were integrated, respectively. The integral ratios of midfield or downfield signals to upfield ones of mycelium and broth extracts of ten Trichoderma strains under different conditions were calculated.

2.5 Statistical analysis

The data were processed using the Microsoft Excel 2010 software, and the error bars were obtained through the STDEV function. The bioassay results were calculated based on three independent experiments. Mycelial weights, weights of extracts, and integral ratios of signals in the $^1$H NMR spectra retained two effective repetitions.

2.6 Bioassays

Antifungal activity against Fusarium oxysporum f. sp. cubense and F. oxysporum f. sp. cucumerinum was tested at 75 μg/disk using the disk diffusion method (Schulz et al., 1995), with amphotericin B
(inhibition zone 12.0 mm for \textit{F. oxysporum} f. sp. \textit{cubense} and 15.0 mm for \textit{F. oxysporum} f. sp. \textit{cucumerinum}) and DMSO as positive and negative controls, respectively. Briefly, each fungus tested was incubated in PDA medium for four days, and then its spores were rinsed and suspended by 4 mL sterile 0.85% NaCl solution (including 0.25% Tween 20). Inoculum suspension was adjusted to match the 0.5 McFarland turbidity standard and further diluted to 5×10^5 CFU/mL. On the other hand, each extract was dissolved in DMSO to a concentration of 15 mg/mL as the stock solution, and then 5 μL was pipetted onto a sterile filter disk (5.0 mm diameter). Subsequently, eight disks were dispersedly placed onto a PDA plate, which was precoated uniformly with 200 μL seawater. Three parallel tests were set for each sample, and the diameters of inhibition zones were measured and recorded in millimeter after the incubation at 28°C for 72 h.

The marine phytoplankton (microalgae) \textit{Proorocentrum donghaiense} and \textit{Heterosigma akashiwo} were used for antimicroalgal test, according to the procedure described previously (Chen et al., 1996). Firstly, each microalgae was inoculated for four days using the sterilized f/2 medium at 20°C in an incubator with the 14 h:10 h light-dark cycle (2 000 lux light). The culture at exponential growth phase was inoculated into the sterilized f/2 medium at 20°C and 196 μL seawater containing about 15 larvae was pipetted into each well of a 96-well microplate. Subsequently, 3.3 μL sample solution (0.5 mg/mL) was pipetted into each well and treated by gradually decreasing the concentrations. Culture filtrate was used as a blank, which was treated synchronously. The OD values were recorded at 450 nm, and inhibition rates were calculated by the following equation.

\[
\text{Inhibition rate} = \frac{(\text{OD}_{\text{sample}} - \text{OD}_{\text{blank}}) - (\text{OD}_{\text{blank}} - \text{OD}_{\text{DMSO}})}{\text{OD}_{\text{DMSO}}} \times 100\%.
\]

Brine shrimp (\textit{Artemia salina}) lethality assay followed the microplate method (Solis et al., 1993). Briefly, brine shrimp eggs were hatched in natural seawater for 48 h at 28°C under natural light, and then some 15 brine shrimp larvae along with 196.7 μL seawater were placed into each well of a 96-well microplate. Subsequently, 3.3 μL sample solution (15 mg/mL) was pipetted into each well and treated for 24 h. K_2CrO_7 (lethality rate 100%) and DMSO were used as positive and negative controls, respectively, and three replicates were set. Died larvae were identified and recorded with the aid of an anatomical lens. For the samples with lethal rates exceeding 50%, their LC_{50} values were also determined by gradually decreasing the concentrations.

Marine mollusc \textit{Littorina brevicula} larvae were used for the periwinkle-lethal assay. In spring, the adult \textit{L. brevicula} was obtained from the coast of Yantai and cultured with \textit{Ulva pertusa} in natural seawater. The released eggs were deposited on the vessel bottom, which were collected and further incubated for a week to afford the larvae tested. Then, 196 μL seawater containing about 15 larvae was gently pipetted into each well of a 96-well microplate, followed by the addition of 4 μL sample solution (0.5 mg/mL). Three replicates were used for each sample, and DMSO was taken as a negative control. Treated for 12 h, the larvae were checked through an anatomical lens, and the dead ones were counted for the calculation of lethal rates.

3 RESULT

3.1 Effect on biomasses

Prior to examining metabolic responses, the survivability of ten marine-derived \textit{Trichoderma} strains was investigated. All of them grew well under freshwater (control) and seawater conditions, but the latter increased the biomasses by 54%–125% cultured for 30 days (Fig.1). \textit{T. asperellum} dl34 with the biomass increased by 125% appeared the most sensitive to seawater, which along with \textit{Trichoderma} sp. dl8, \textit{T. longibrachiatum} dl44, and \textit{T. koningii} yt6, was synchronously promoted by NaCl (30.0 g/L), NaBr (86.3 mg/L), and pH 8.0. Among these three factors, NaCl was predominant in the promotion of \textit{Trichoderma} sp. dl8, \textit{T. harzianum} lyg12, \textit{T. asperellum} dl34 and dl48, whereas pH 8.0 exceeded
the others to affect the growth of *T. longibrachiatum* dl44. NaBr outstood to increase the mycelium yields of *T. pseudokoningii* dl11 and *T. longibrachiatum* cf11, but they were inhibited by NaCl. Additionally, the proliferation of *T. koningii* dl49 only slightly (≤10%) responded to these three factors.

### 3.2 Production of lipophilic metabolites

Except for *Trichoderma* sp. dl8 and *T. asperellum* dl48, the strains in seawater-based media afforded 22%–217% more lipophilic metabolites in mycelia than controls (Fig.2). The yields were improved 113% for *T. asperellum* dl34 and reduced 45% for *T. pseudokoningii* dl11 by NaCl (30.0 g/L), though it appeared weak to affect the other strains. Moreover, NaBr (86.3 mg/L) increased the production of mycelial constituents by 63%–85% for *T. pseudokoningii* dl11, *T. asperellum* dl34, *T. harzianum* dl36, and *T. longibrachiatum* dl44 and >200% for *T. longibrachiatum* cf11 and *T. koningii* dl49. The positive effect of pH 8.0 on each strain was dwarfed by NaCl or NaBr. On the other hand, most of the strains gave less broth extracts than mycelium dwarfed by NaCl or NaBr. On the other hand, most of the strains gave less broth extracts than mycelium ones (Fig.2). The lipophilic exudates of *T. asperellum* dl48, *T. longibrachiatum* cf11, *T. harzianum* lyg12, *T. koningii* dl49 and yt6 were improved over 30% under seawater condition. NaBr and/or pH 8.0 appeared effective to raise the production of exudates for most of the strains, which even exceeded seawater.

To characterize these intra- and extracellular metabolites, their proton nuclear magnetic resonance (‘H NMR) spectra were determined. The signals were divided into upfield (δH (0.5–2.0)×10⁻⁴, US), midfield (δH (3.5–5.0)×10⁻⁴, MS), and downfield (δH (5.0–8.0)×10⁻⁴, DS) ones, mainly corresponding to the protons of saturated (alkyl), heteroatom (oxygen, nitrogen, or halogen)-bearing, and unsaturated (vinyl or aryl) units, respectively. Their integral ratios (MS/US and DS/US) preliminarily indicated the structural characteristics of lipophilic metabolites (Fig.3). More heteroatom-bearing and unsaturated units were accumulated in mycelia of eight strains under seawater condition, especially in those of *T. longibrachiatum* dl44 and *T. asperellum* dl48. On the contrary, their yields in *T. koningii* yt6 were dramatically decreased by seawater. NaBr promoted the production of both heteroatom-bearing and unsaturated units in mycelia of *Trichoderma* sp. dl8, *T. harzianum* dl36, *T. longibrachiatum* dl44, *T. asperellum* dl34 and dl48. The MS/US of mycelial constituents was improved about three times for *T. harzianum* lyg12 under pH 8.0 condition, which also exceeded the others to promote the production of unsaturated units by *Trichoderma* sp. dl8, *T. pseudokoningii* dl11, *T. longibrachiatum* dl44, and *T. koningii* dl49. However, seawater was almost incapable of inducing the extracellular secretion of heteroatom-bearing and unsaturated units, and single factor (NaCl, NaBr, or pH 8.0) was also weak or negative to increase their exudation.

### 3.3 Inhibition of phytopathogenic fungi

The lipophilic metabolites of ten *Trichoderma* strains cultured under different conditions were evaluated for antifungal activity against two plant pathogens, *Fusarium oxysporum* f. sp. *cubense* and *F. oxysporum* f. sp. *cucumerinum*. Only several exhibited inhibitory activity against these two pathogenic fungi at 75 μg/disk, as shown in Tables 1 and 2. The results were ranked by comparison with those of positive control (weak ≤1/3, moderate >1/3 and ≤2/3, and strong >2/3 of the inhibition zone of amphotericin B). Both *F. oxysporum* f. sp. *cubense* and *F. oxysporum* f. sp. *cucumerinum* could be inhibited by the lipophilic metabolites of *Trichoderma* sp. dl8, *T. harzianum* dl36, and *T. asperellum* dl48, but only the latter responded to those of *T. pseudokoningii* dl11, *T. asperellum* dl34, *T. koningii* dl49 and yt6. Among...
them, *T. harzianum* dl36 represented the most potent strain, which in freshwater-based media produced intra- and extracellular metabolites with strong inhibitory activity against *F. oxysporum* f. sp. *cucumerinum*. This inhibition was slightly affected by NaCl (30.0 g/L) but reduced or even removed by the other factors tested. Additionally, all the other active extracts are moderate to inhibit *F. oxysporum* f. sp. *cubense* and/or *F. oxysporum* f. sp. *cucumerinum*.

### 3.4 Inhibition of marine phytoplankton

Most mycelium extracts of ten *Trichoderma* strains cultured in seawater-based media exhibited more or less inhibition of the marine phytoplankton *Prorocentrum donghaiense* and *Heterosigma akashiwo* at 220 μg/mL, but it was interesting that NaCl (30.0 g/L) often prevented the production of
inhibitory metabolites (Fig.4). The mycelial constituents of *T. longibrachiatum* dl44 under freshwater condition could promote the proliferation of *P. donghaiense*, which was remarkably accelerated by NaCl. Moreover, the proliferation of *H. akashiwo* greatly profited from the mycelial constituents of *T. longibrachiatum* dl44 under all the conditions. On the other hand, some half of the strains positively responded to seawater in producing extracellular exudates with inhibition of *P. donghaiense* or *H. akashiwo*. Seawater condition effectively stimulated *T. harzianum* lyg12 to secrete inhibitory metabolites, while NaCl significantly reduced the inhibitory activity of *T. longibrachiatum* dl44 exudates.

### 3.5 Toxicity to marine animals

All the mycelium and broth extracts of ten *Trichoderma* strains cultured in seawater-based media exhibited over 70% lethal rates against the marine zooplankton *Artemia salina* at 250 μg/mL, but several were less toxic under other conditions (Fig.5). The extracellular exudates, except for those of *T. koningii* dl49, under NaBr (86.3 mg/L), pH 8.0, and seawater conditions were extremely lethal to *A. salina*, with LC50 values ranging from 5.4 to 57.8 μg/mL. However, those under freshwater and NaCl (30.0 g/L) conditions were less toxic. Due to the high toxicity of the exudates of *T. harzianum* dl36, *T. koningii* yt6, *T. asperellum* dl34 and dl48, they were further assessed for the lethal effect on the mollusc *Littorina brevicula* (Fig.6) that feeds on marine macroalgae (Xue, 1992). *T. asperellum* dl48 produced exudates with significant lethality against *L. brevicula* larvae under three conditions, but the high lethality of *T. asperellum* dl34 relied on NaBr. Moreover, pH 8.0 increased the toxicity of *T. harzianum* dl36 and *T. koningii* yt6 exudates.

### 4 DISCUSSION

Fungi in the marine ecosystem have been divided into obligate and facultative ones according to the necessity of seawater during their growth and sporulation (Bugni and Ireland, 2004). The survival in both freshwater- and seawater-based media suggests ten *Trichoderma* strains tested to be facultative marine fungi rather than obligate ones. The larger biomasses under seawater condition imply that these strains prefer to propagate in marine environment, though they are possibly terrigenous. In contrast, the true terrestrial-derived *Trichoderma* strains tend to be
inhibited by high-level salt and pH (Lejeune et al., 1995; Yin et al., 2013). *Trichoderma* fungi tested adapt well to seawater, but the influences of seawater factors on their growth vary with species and strains. Although the effects of halides (30.0 g/L NaCl and 86.3 mg/L NaBr) and/or pH (8.0) of seawater are not always positive, each strain enjoys at least one of them. There are other constituents in seawater, such as metal ions (Cacciola et al., 2015), which may also contribute more or less to the growth. Based on the low or negative effects of NaCl, NaBr, and pH 8.0 on *T. harzianum* dl36 and *T. koningii* dl49, their extra biomasses are deduced to be even dominated by the other factors. The competition for space and nutrients is one of the key antagonistic mechanisms of *Trichoderma* species (Vinale et al., 2008), which undoubtedly profits from the rapid proliferation to some extent. Thus, marine isolates of *Trichoderma* seem suitable for the biocontrol in agriculture at the saline lands of coastal zones.

Fungal lipophilic metabolites are mainly produced through secondary metabolism, and those of *Trichoderma* origin exhibit high structural diversity and various biological activities (Reino et al., 2008). Marine environment has added the diversity to some extent (Blunt et al., 2018), but its roles need to be further cleared. It is notable that the effects of NaCl (30.0 g/L), NaBr (86.3 mg/L), pH 8.0, and seawater on the yields of lipophilic metabolites of *Trichoderma* strains tested are not always parallel to those on biomasses. Most of them feature positive metabolic responses to seawater, producing more intra- and extracellular lipophilic metabolites. Although NaCl and pH 8.0 outstand to influence several strains, they are less common than NaBr to effectively promote the production of lipophilic metabolites. Single factor tested often exceeds seawater to increase the yields, which suggests that other components in seawater...
may play a negative role. Seawater tends to increase the production of heteroatom-bearing and unsaturated units in mycelia, which often profits from NaBr and/or pH 8.0. *Trichoderma* species feature the ability to produce halogenated compounds in seawater-based media (Garo et al., 2003; Yamazaki et al., 2015), which probably contribute to the large portions of heteroatom-bearing units. Those can also be improved by polyols and amino compounds that have been indicated to respond to the high osmotic pressure (Bugni and Ireland, 2004). Alkaline condition (pH 8.0) has been evidenced to benefit the enzyme activity of some fungal dehydrogenases (Liu et al., 2006), which may help these *Trichoderma* strains to produce unsaturated units. It has been demonstrated that metal ions are able to induce the gene expression of *Trichoderma* (Puglisi et al., 2012; Cacciola et al., 2015), which likely promote the production of heteroatom-bearing units in *T. harzianum* dl36 and *T. longibrachiatum* cf11 in view of the weak or negative contribution of NaCl, NaBr, and pH 8.0. Despite the improved production of heteroatom-bearing and unsaturated units in mycelia under the seawater condition, their exudation seems restricted, which may be partially caused by the high osmotic pressure of seawater.

The bioactivities of lipophilic metabolites of *Trichoderma* strains tested also vary with culture conditions, as is the case with other marine-derived fungi (Masuma et al., 2001; Tarman et al., 2011). Many strains play a fungicidal role depending on NaCl (30.0 g/L), NaBr (86.3 mg/L), pH 8.0, or seawater condition, and their effects differ slightly from each other. *T. harzianum* represents one of the most effective fungicides in agriculture (Ghisalberti and Sivasithamparam, 1991), but marine-derived strains remain less explored. Although *T. harzianum* dl36 and lyg12 belong to the same species, only the former is active to plant pathogens tested. Especially, its activities rely more greatly on culture conditions and exhibit higher strain-specific property than the others. The majority of extracellular exudates are more active to inhibit the proliferation of marine phytoplankton tested than mycelial constituents, which demonstrates the differences between intracellular metabolites and extracellular exudates. For most mycelial constituents produced in seawater, their higher inhibition of marine phytoplankton than those produced in freshwater is deduced to correlate with the larger portions of heteroatom-bearing and unsaturated units (Fig.3). On the other hand, NaBr, pH 8.0, and seawater, rather than NaCl, permit the production of highly marine animal-toxic exudates, but it is not the common case with intracellular metabolites. The differences in toxicity also suggest varied components of exudates responding to seawater factors, which are not obviously reflected by ^1^H NMR (Fig.3). Moreover, the extra heteroatom-bearing and unsaturated units in mycelial constituents produced under the seawater condition appear not highly toxic to marine animals. All *Trichoderma* strains tested were isolated from marine macroalgae, which live in the ocean faced with pathogenic fungi (Kubanek et al., 2003), feeding herbivores (Xue, 1992), and phytoplankton competition for space and nutrients (Nan and Dong, 2004). Their interactions with macroalgae remain little understood, but the algalcolous *Trichoderma* strains that are antagonistic to pathogenic fungi, phytoplankton, and marine animals probably contribute to the survival of host macroalgae. Marine phytoplankton, represented by *P. donghaiense* and *H. akashiwo* (Tyrrell et al., 2002; Lu et al., 2005), have often resulted in harmful algal blooms that damage marine fisheries, and some *Trichoderma* strains may be developed as the effective agents to control them.

5 CONCLUSION

Overall, ten marine isolates of *Trichoderma* grow positively responding to seawater, which suggests they are more adaptable to marine environment. High yields of lipophilic metabolites often match the large biomasses, but heteroatom-bearing and unsaturated units tend to be accumulated in mycelia in response to the seawater condition. Single factor, NaCl, NaBr, or pH of seawater, may play a positive or negative role in the growth of mycelia and production of lipophilic metabolites, and one of them often exceeds seawater to increase the metabolism. Seawater factors can promote many strains to produce bioactive metabolites, but the effects of NaCl are often weak or negative. The larger portions of intracellular heteroatom-bearing and unsaturated units produced in seawater may be responsible for the inhibition of marine phytoplankton rather than toxicity to marine animals, and the varied toxicities to marine animals further signify the divergences of extracellular exudates produced under different conditions. Although four pairs of the strains are regarded as the same species, respectively, from a mycological perspective, those in each pair feature different
chemical and bioactive profiles. Considering the wide distribution of Trichoderma fungi in marine environment, the results may greatly contribute to further understanding and mining the structural diversity and biological activity of their secondary metabolites.
