Weather Variability, Socioeconomic Factors, and Pneumonia in Children Under Five-Years Old — Bangladesh, 2012–2016

Mohammad Zahid Hossain1,2; Shilu Tong1,3,4; Hilary Bambrick1; Md Alfazal Khan6; Wenbiao Hu1,*

Summary

What is already known on this topic?
Different socioecological factors were associated with childhood pneumonia in Bangladesh. However, previous studies did not assess spatial patterns, and socioecological factors and spatial variation have the potential to improve the accuracy and predictive ability of existing models.

What is added by this report?
The spatial random effects were present at the district level and were heterogeneous. Average temperature, temperature variation, and population density may influence the spatial pattern of childhood pneumonia in Bangladesh.

What are the implications for public health practice?
The study results will help policymakers and health managers to identify the vulnerable districts, plan further investigations, help to improve proper resource allocation, and improve health interventions.

Pneumonia is one of the leading causes of mortality and morbidity in children aged under five years in Bangladesh. This study aimed to identify the association between weather, social factors and childhood pneumonia and identify the spatial variation of the disease. A Bayesian spatial Poisson regression model with a conditional autoregressive prior structure was developed to quantify the association between childhood pneumonia and socioecological factors and identify the spatial variation. The study results suggested that a 1 °C increase in monthly temperature and monthly temperature variation may increase the monthly associated log relative risk (RR) of childhood pneumonia by 1.161 [95% credible interval (CrI): 1.013–1.429] and 1.463 (95% CrI: 1.170–1.839), respectively. However, the population density was inversely related with pneumonia risk (RR: 0.996, CrI: 0.994–0.998). Socioecological factors may influence the spatial pattern of childhood pneumonia, and the spatial random effects were heterogeneous.

Prior to this analysis, we examined multicollinearity among the different covariates but did not find sufficiently strong associations to warrant exclusion or other treatment of any variables (Supplementary Table S1, available in http://weekly.chinacdc.cn). As a consequence, a total of 6 models were developed.
(Supplementary Material, available in http://weekly.chinacdc.cn). The model which incorporated all socioecological covariates with both structured and unstructured random effects were selected for the final analysis.

The expected log relative risk $\theta_k$ was represented as follows:

$$
\theta_k = \alpha + (\text{Temp}_k) \beta_1 + (\text{Tempva}_k) \beta_2 + (\text{Rain}_k) \beta_3 + (\text{Edu}_k) \beta_4 + (\text{Int}_k) \beta_5 + (\text{povi}_k) \beta_6 + (\text{pop}_k) \beta_7 + u_k + v_k
$$

where $\alpha$ is a constant; $\beta$, is the coefficient for temperature, $\beta_3$ is the coefficient for temperature variation, $\beta_4$ is the coefficient for rainfall, $\beta_5$ is the coefficient for percentage of education at the district level, $\beta_6$ is the coefficient for percentage of internet user at the district level, $\beta_7$ is percentage of poverty at the district level, and $\beta_8$ is the population density per square kilometer; $v_i$ is a spatially unstructured random effect that is assumed to be normally distributed with mean zero and variance $\sigma_v^2$ and $u_i$ is the spatially structured random effect that was modeled using a conditional autoregressive (CAR) prior $u_k \sim N(\bar{u}_k, \sigma_u^2/n_k)$, where $-k$ denotes the neighbors of the $k$th district based on a simple adjacency matrix and $n_k$ is the corresponding number of neighbors (7).

WinBUGS software (version 1.4.3, MRC Biostatistics Unit, Cambridge, and Imperial College School of Medicine, London) was used to fit the Bayesian Poisson regression models. In the Markov chain Monte Carlo analysis, a 30,000 iteration “burn-in” was followed by 100,000 iteration sample collection. In every case, the Monte Carlo error was <5% of the overall standard deviation, indicating sufficient iterations of the model had been run after convergence. Model comparison was performed using the Deviance Information Criterion (DIC). Best fitted models were indicated by smaller DIC values (8).

The mean monthly number of pneumonia cases in children <5 years was 747.82. The mean monthly temperature, temperature variation, and rainfall were 30.97 °C, 3.63 °C, and 164.54 mm, respectively. Among the social factors, the mean percentages of education, internet use, poverty (per 100 population) and <5 years children density (per square kilometer) were 54.66%, 0.62%, 24.45%, and 117.72, respectively, at the district level (Supplementary Table S2, available in http://weekly.chinacdc.cn). The average monthly temperature was higher in the western region, while the monthly temperature variation was higher in most of the hilly areas located in the southern part of the country and two districts (Bhola and Pirojpur) of the coastal region of Bangladesh. The distributions of higher monthly average rainfall were scattered in different regions. Inclusion of spatial autorecorrelation in the model was important. The model which included both structured and unstructured random effects had the smallest DIC (665.47 and 13,773.00 for models with and without random effects, respectively) (Supplementary Table S3, available in http://weekly.chinacdc.cn). The highest RRs were observed in the southeastern part (Rangamati district) and southern part (Pirojpur district) of the country (Figure 1). Supplementary Table S4 (available in http://weekly.chinacdc.cn) shows the list of districts with the higher RR.

Figure 2 depicts the distribution of spatial random effects (structured heterogeneity) of pneumonia in Bangladesh. The districts with darker color (red color) had relatively high spatial variation. These districts with high spatial variation might have some unknown factors that may have had effects on the incidence of childhood pneumonia but that we did not consider in the models (e.g., incomplete measurement of variables, lack of geocoding, and generalization of geographic features).

Our study results suggested that a rise of 1 °C average monthly temperature and temperature
variation was associated with RR estimates of childhood pneumonia of 1.161 (95% CrI: 1.012–1.428) and 1.463 (95% CrI: 1.169–1.838), respectively. The density of children under five years in population was negatively associated with pneumonia (RR: 0.996, 95% CrI: 0.994–0.998) (Table 1).

Additionally, no significant associations were found between childhood pneumonia and rainfall, education, internet use, or poverty since the corresponding 95% CrIs for the RR of each factor included 1.

**DISCUSSION**

In young children, the thermoregulation system is not yet matured and makes the children more vulnerable to temperature variation. This study describes the spatial pattern of childhood pneumonia and their socioecological factors in Bangladesh. Identifying the spatial variation of childhood pneumonia and important socioecological determinants can help target high-risk communities with evidence-based effective preventative measures.

Mapping of the spatially structured random effects indicated the spatial variation after controlling socioecological factors and spatial autocorrelation in the model. The Bayesian CAR model included unknown parameters as random effects, which incorporated the spatially correlated random effects (9). This approach can account for the residual variability resulting from spatial variation in effects that were not included in the models. The districts containing higher spatial random effects or variation may have some other risk factors remaining after adjustment of socioecological factors and spatial correlation.

**TABLE 1.** Crude and adjusted RR of different socioecological factors in Children Under Five-Years Old — Bangladesh, 2012–2016.

| Variables           | Crude RR (95% CrI)          | Adjusted RR (95% CrI)          |
|---------------------|----------------------------|-------------------------------|
| Temperature*        | 1.146 (0.929–1.432)        | 1.161 (1.013–1.429)           |
| Temperature†        | 1.730 (1.694–1.763)        | 1.529 (1.503–1.555)           |
| Temperature variability* | 1.821 (1.376–2.491)    | 1.463 (1.170–1.839)           |
| Temperature variability† | 1.623 (1.596–1.649)    | 1.421 (1.395–1.447)           |

| Internet†           | 0.874 (0.862–0.885)        | 0.929 (0.916–0.942)           |

Abbreviations: RR=relative risk; CrI=credible interval.
* with heterogeneity (u and v).
† without heterogeneity (u and v).
This study was subject to some limitations. First, in this study, we used data from monthly reports of the DGHS. This represented the number of patients that attended different levels of health facilities in Bangladesh for pneumonia treatment. However, there might be some patients in the community who did not attend any health facilities and who received treatment from village doctors or spiritual healers, especially in the rural areas. Therefore, there was a chance of measurement and information biases. Second, the unit of analysis was at the group level rather than at the individual level, so the results may be prone to the ecological fallacy.

The findings of this study could help policymakers better understand that childhood pneumonia has a heterogeneous spatial pattern and that socioecological factors may play a significant role in describing this pattern.

Statistical models
As a consequence, a total of 6 models were developed. Model I included only ecological measures (temperature, temperature variation, and rainfall) as explanatory variables; Model II included only social factors (education, internet use, population density, and poverty) as covariates; Model III included both ecological and social factors as explanatory variables; Model IV incorporated spatially structured random effects with all socioecological covariates; Model V incorporated spatially unstructured random effects with all socioecological covariates; Model VI incorporated both structured and unstructured random effects with all socioecological covariates.

The expected log relative risk \( \theta \) for these models thus represented as follows:

- Model I: \( \theta = \alpha + \beta_{\text{Temp}} + \beta_{\text{Rain}} + \beta_{\text{Int}} + \beta_{\text{Poverty}} + \beta_{\text{Education}} + \beta_{\text{Internet}} + \beta_{\text{Population}} \)
- Model II: \( \theta = \alpha + \beta_{\text{Temp}} + \beta_{\text{Rain}} + \beta_{\text{Education}} + \beta_{\text{Internet}} + \beta_{\text{Population}} \)
- Model III: \( \theta = \alpha + \beta_{\text{Temp}} + \beta_{\text{Rain}} + \beta_{\text{Education}} + \beta_{\text{Internet}} + \beta_{\text{Population}} + \beta_{\text{Population Adjacency Matrix}} \)
- Model IV: \( \theta = \alpha + \beta_{\text{Temp}} + \beta_{\text{Rain}} + \beta_{\text{Education}} + \beta_{\text{Internet}} + \beta_{\text{Population}} + \beta_{\text{Population Adjacency Matrix}} + \beta_{\text{Population Structure}} \)
- Model V: \( \theta = \alpha + \beta_{\text{Temp}} + \beta_{\text{Rain}} + \beta_{\text{Education}} + \beta_{\text{Internet}} + \beta_{\text{Population}} + \beta_{\text{Population Structure}} \)
- Model VI: \( \theta = \alpha + \beta_{\text{Temp}} + \beta_{\text{Rain}} + \beta_{\text{Education}} + \beta_{\text{Internet}} + \beta_{\text{Population}} + \beta_{\text{Population Structure}} + \beta_{\text{Population Unstructured Random Effect}} \)

where \( \alpha \) is a constant, \( \beta \) is the coefficient for temperature, \( \beta_1 \) is the coefficient for temperature variation, \( \beta_2 \) is the coefficient for rainfall, \( \beta_3 \) is the coefficient for percentage of education at district level, \( \beta_4 \) is the coefficient for percentage of poverty at district level, and \( \beta_5 \) is the population density per square kilometer. \( v \) is a spatially unstructured random effect that is assumed to be normally distributed with mean zero and variance \( \sigma_v^2 \); and \( u_k \) is a spatially structured random effect that was modeled using a conditional autoregressive (CAR) prior \( u_k \sim N\left(\bar{u}_k, \sigma_u^2 / n_k\right) \), where \( n_k \) denotes the neighbors of the \( k \)th district based on a simple adjacency matrix and \( n_k \) is the corresponding number of neighbors.
