Background: The lipid sensitivity of the prokaryotic pentameric ligand-gated ion channel (pLGIC), GLIC, is poorly characterized.

Results: GLIC is more thermally stable and does not exhibit the same propensity to adopt an uncoupled conformation as the Torpedo nAChR.

Conclusion: GLIC is less sensitive to its surrounding membrane environment.

Significance: The GLIC and nAChR structures suggest molecular features governing the lipid sensitivity of pLGICs.

Although the activity of the nicotinic acetylcholine receptor (nAChR) is exquisitely sensitive to its membrane environment, the underlying mechanisms remain poorly defined. The homologous prokaryotic pentameric ligand-gated ion channel, Gloeobacter ligand-gated ion channel (GLIC), represents an excellent model for probing the molecular basis of nAChR sensitivity because of its high structural homology, relative ease of expression, and amenability to crystallographic analysis. We show here that membrane-reconstituted GLIC exhibits structural and biophysical properties similar to those of the membrane-reconstituted nAChR, although GLIC is substantially more thermally stable. GLIC, however, does not possess the same exquisite lipid sensitivity. In particular, GLIC does not exhibit the same propensity to adopt an uncoupled conformation where agonist binding is uncoupled from channel gating. Structural comparisons provide insight into the chemical features that may predispose the nAChR to the formation of an uncoupled state.

Cys-loop receptors mediate rapid chemical communication between cells in the nervous system by opening a transmembrane ion channel across the synaptic membrane in response to neurotransmitter binding. Channel opening leads to the flow of either cations or anions down their electrochemical gradient into the cell, resulting in either an excitatory or an inhibitory response, respectively. Cys-loop receptors play a central role in brain function, are implicated in a variety of neurological disorders, and are the targets of both endogenous and exogenous modulators (1–5).

Early attempts at purifying and reconstituting the prototypic Cys-loop receptor, the Torpedo nicotinic acetylcholine receptor (nAChR), 2 in lipid bilayers revealed the importance of lipids in Cys-loop receptor function (6). In the presence of both cholesterol and anionic lipids, the nAChR is stabilized predominantly in an activatable resting conformation (7–10). In their absence, the nAChR adopts an “uncoupled” conformation, where agonist binding fails to elicit channel gating (11). Understanding the mechanisms by which lipids influence the coupling of binding and gating remains central to understanding lipid-nAChR interactions. Uncoupled nAChRs may also have broader significance in that neuronal nAChRs that are functionally uncoupled have been observed in heterologous expression systems and may play a role in the physiological response to nicotine (12).

Unfortunately, detailed insight into the mechanisms of lipid-dependent uncoupling remains elusive (11, 13). A major bottleneck is the inability to reliably express large quantities of Cys-loop receptors with site-directed mutations designed to test potential models of lipid-nAChR interactions.

Several prokaryotic pentameric ligand-gated ion channels (pLGICs) homologous to the eukaryotic Cys-loop receptors have recently been identified, and crystal structures of two of these solved at high resolution (14–17). Prokaryotic pLGICs provide an opportunity for probing the mechanisms of Cys-loop receptor-lipid interactions at a molecular level because of their high structural homology (Fig. 1), their relative ease

1 The abbreviations used are: nAChR, nicotinic acetylcholine receptor; GLIC, Gloeobacter ligand-gated ion channel; aso-GLIC, GLIC in asolectin membranes; aso-nAChR, nAChR in asolectin membranes; Carb, carbachol; DDM, dodecylmaltoside; EcoLip-GLIC, GLIC in E. coli lipid membranes, pLGIC, pentameric ligand-gated ion channel; PC, 1-palmitoyl-2-oleoyl-sn-glycero-3-phosphocholine; PC-GLIC, GLIC in PC membranes; PC-nAChR, nAChR in PC membranes; PA, phosphatidic acid; Chol, cholesterol.

of expression in bacterial systems, and their amenability to crystallographic analysis. Although a recent study suggested that cholesterol depletion may influence the gating kinetics of one pLGIC, GLIC (18), the broader effects of lipids on prokaryotic pLGIC structure and function remain to be studied. In fact, a reliable protocol for reconstituting pLGICs in membranes at lipid to protein ratios that are amenable to spectroscopic studies, particularly in the context of probing the electrophysiologically silent uncoupled state, has yet to be developed.

Here, we compare the structural and biophysical properties of membrane-reconstituted GLIC with those of its highly lipid-sensitive eukaryotic homolog, the Torpedo nAChR. These comparisons were performed both in membranes that support GLIC alone and in those that promote formation of the uncoupled nAChR. Our results suggest that although the gating properties of GLIC are sensitive to its lipid environment, GLIC does not possess the exquisite lipid sensitivity of its eukaryotic homolog. In particular, GLIC does not exhibit the same propensity to adopt an uncoupled conformation where agonist binding is uncoupled from channel gating. Structural comparisons provide insight into the chemical features that may predispose Cys-loop receptors to the formation of an uncoupled state.

EXPERIMENTAL PROCEDURES

Materials—Soybean asolectin (l-α-phosphatidylycholine, type II-S), sodium cholate, carbamylcholine (Carb), and amantadine were from Sigma. Escherichia coli polar lipid extracts and 1-palmitoyl-2-oleoyl-sn-glycero-3-phosphocholine were from Avanti (Alabaster, AL). Torpedo californica electroploque organ was from Aquatic Research Consultants (San Pedro, CA). Dodecylmaltoside (DDM) was from Affymetrix (Santa Clara, CA). [125I]α-Bungarotoxin (107 Ci/mmol) was obtained from PerkinElmer Life Sciences. Nonradioactive α-bungarotoxin was from Biotium, Inc. (Hayward, CA).

GLIC Expression and Purification—GLIC was expressed in the C43 strain of E. coli transformed with a pET-20b (+) vector containing the DNA sequence for the maltose-binding protein fused to the N terminus of GLIC through a thrombin-sensitive peptide linker (14). Briefly, 2-liter cultures of the transformed C43 cells were grown in 2YT medium containing 50 μg/ml ampicillin at 37 °C to an A600 of ~1.2, and the cultures were induced overnight at 30 °C with 100 μM isopropyl β-D-thiogalactopyranoside. The cells were harvested, resuspended in Buffer A (250 mM NaCl, 25 mM Tris, pH 7.2) in the presence of Roche Complete™ antiprotease tablets, and lysed with an Avestin Emulsiflex-C5 homogenizer (Ottawa, Canada). Membrane fractions were solubilized in 1% DDM in Buffer A, and the GLIC fusion protein was bound to an amylose affinity resin. After treatment with plasminogen-free thrombin from Calbiochem (Gibbstown, NJ), GLIC was eluted in 0.02% DDM and further purified on a Superpose 6 10/300 gel filtration column (GE Healthcare). The highly purified GLIC was passed quickly through 1 ml of amylase resin to remove small amounts of an endogenous amylose binding protein that co-elutes with GLIC from the size exclusion column.

Membrane Reconstitution of GLIC—The purified GLIC in 0.02% DDM in buffer A was slowly diluted at least 1:4 with lipids solubilized in 0.625% cholate in Buffer A to give the desired final lipid to protein ratio, in this case 2:1 (w/w) (19, 20). After gently mixing for ~30 min, the protein/detergent/lipid mixture was dialyzed five times at 4 °C against 2 liters of Buffer A leading to a turbid solution of proteoliposomes, which were harvested by ultracentrifugation at 100,000 × g for 2 h. The pelleted membranes were resuspended and layered onto a discontinuous sucrose density gradient. After ultracentrifugation at 100,000 × g for 20 h in a Beckman SW41 swinging bucket rotor, sequential 400-μl aliquots were removed and assayed for both protein (BCA™ assay from Thermo-Pierce) and lipid (phospholipid C/choline assay from Wako Chemicals (Richmond, VA)). Appropriate fractions were pooled and either dialyzed a further five times or subjected to several centrifugation resuspension cycles to remove sucrose.

Reconstituted nAChR Membranes—nAChR purification and reconstitution was performed as described (11, 21). The nAChR was solubilized from Torpedo electroploques with 1% sodium cholate and purified on a bromoacetylcholine affinity column in the presence of lipid. Protein was eluted with 10 mM Carb, and then the membrane was reconstituted by dialysis.

Fourier Transform Infrared Spectroscopy—Hydrogen/deuterium infrared spectra (Fig. 2A) were recorded on a Digilab (now Agilent Technologies (Santa Clara, CA)) FTS40 spectrometer using a Golden-Gate™ attenuated total internal reflection accessory (SpecAc; Oprington (Kent, UK)). 10 μl of the membrane-reconstituted GLIC (~1 mg/ml) in 2 mM phosphate buffer (pH 7.0) were dried down onto the accessory under a gentle stream of N2 gas. After collecting a 64-scan spectrum at 4 cm⁻¹ resolution, 10 μl of buffer A in 2H2O was added, and another 64-scan spectrum was collected.

For the more detailed amide I band analyses (Fig. 2B) and for thermal stability measurements, the membrane-reconstituted GLIC was exchanged into 2 mM phosphate 2H2O
**RESULTS**

Membrane Reconstitution of GLIC—GLIC was reconstituted into membranes at a lipid to protein ratio of 2:1 (w/w), because this ratio is ideal for spectroscopic studies, such as those used previously to characterize the uncoupled nAChR (see “Discussion”) (11). To reconstitute into model membranes, DDM-solubilized GLIC (supplemental Fig. S1) was diluted below the critical micellar concentration for DDM with a cholate-solubilized lipid solution, and the protein/detergent/lipid mixture was dialyzed extensively to remove residual DDM and cholate. Sucrose density gradients showed that GLIC efficiently incorporates into model membranes. Neither residual DDM nor cholate could be detected in the reconstituted membranes using an infrared based assay for detergent (24). GLIC was initially reconstituted into membranes composed of either asolec-tin lipids (aso-GLIC) or *E. coli* polar lipid extracts (EcoLip-GLIC). These membranes were chosen because asolectin lipids (as well as defined membranes composed of phosphatidylyceroline, phosphatidic acid, and cholesterol (PC/PA/Chol) 3:1:1 (molar ratios)) stabilize the nAChR in a functional resting conformation and minimize GLIC aggregation (18), whereas *E. coli* polar lipid extracts likely resemble the natural lipid environment of GLIC. We expected both membranes to stabilize an activatable “resting” conformation.

Structure of Membrane-reconstituted GLIC—Infrared spectra of both aso-GLIC and EcoLip-GLIC gently dried from $^2$H$_2$O buffer (to eliminate the intense overlapping vibrations of bulk water) exhibit two relatively intense protein bands: the amide I band between 1700 and 1600 cm$^{-1}$ and the amide II band centered near 1547 cm$^{-1}$ (Fig. 2A). The amide I band is due pri...
arily to peptide backbone C=O stretching vibrations and is sensitive to protein secondary structure. The amide II band, primarily due to peptide backbone C-N stretching vibrations coupled to N-H bending vibrations, is also sensitive to secondary structure but is used primarily to monitor the exchange of peptide N-H to N-D. The amide II band shifts down in frequency from 1547 cm⁻¹ to near 1450 cm⁻¹ in D₂O, the downshifted vibration often referred to as the amide II’ band.

The GLIC amide I contour observed in spectra dried from D₂O exhibits a peak maximum near 1655 cm⁻¹, due to the overlapping vibrations of α-helix and loop/random secondary structures, and a prominent broad shoulder between 1640 and 1625 cm⁻¹, primarily due to the vibrations of β-sheet. The amide I band shape is similar to that observed for functional membrane-reconstituted Torpedo nAChRs (supplemental Fig. S2), suggesting a similar mixed α-helix/β-sheet secondary structure. The slightly increased intensity between 1640 and 1620 cm⁻¹ indicates a slightly higher β-sheet content in GLIC.

The mixed α-helix/β-sheet secondary structure of the reconstituted GLIC was confirmed by recording spectra in D₂O buffer, where there is no overlap of the solvent vibrations with the amide I band (Fig. 2B). The resulting amide I contour still exhibits features at frequencies characteristic of both α-helix (1655 cm⁻¹) and β-sheet (1640–1625 cm⁻¹), as shown clearly by resolution enhancement. Curve fitting (supplemental Fig. S3) suggests roughly 35% α-helix and 40% β-sheet (supplemental Fig. S3), estimates that compare well with the crystal structure (roughly 35% α-helices with >5 residues and 30% β-sheet). The slight overestimate of β-sheet content could reflect difficulties precisely defining the start and end point of each β-strand in the crystal structure. In addition, spectra of the α-helical protein myoglobin (no β-sheet) exhibit weak intensity between 1640 and 1620 cm⁻¹, demonstrating that structures other than β-sheet can contribute weak intensity to this region (25).

Note that we recorded spectra both immediately after exposure to (Fig. 2A) and after prolonged equilibration with D₂O buffer (72 h, 4 °C) (Fig. 2B). The spectra recorded immediately after exposure exhibit changes in band shape that result from the downshifts in frequency of solvent-exposed regions of the peptide backbone. Subtle downshifts in the frequencies of amide I component bands caused by turn (1700–1670 cm⁻¹) region; see supplemental materials), loop/random and/or α-helical structures (1655 cm⁻¹ down to ~1645 cm⁻¹), and β-sheet (primarily 1640–1620 cm⁻¹ region) are detected (26). These rapid amide I band shifts are accompanied by a drop in amide II band intensity, further demonstrating the rapid exchange of peptide N-H to N-D. The spectral changes are all similar to those observed immediately upon exposure of other Cys-loop receptors to D₂O (supplemental Fig. S2) (27) but differ from those typically observed for proteins with different tertiary folds (26). The results emphasize the existence of a substantial population of solvent-exposed secondary structures, consistent with the large solvent-exposed extramembranous agonist-binding domain in GLIC (16, 17).

One notable feature of the GLIC spectra is that the relatively intense 1655 cm⁻¹ amide I component band, which is due to the vibrations of protiated and thus solvent-shielded α-helical and/or loop/random structures, is still observed in spectra recorded after prolonged exposure of GLIC to D₂O. This suggests the existence of a large population of exchange-resistant and likely transmembrane α-helices, as has been characterized for the nAChR (25, 28). A large population of solvent-shielded peptide hydrogens is also suggested by the residual amide II band intensity (Fig. 2B). The proportion of exchange-resistant peptide hydrogens in both aso-GLIC and EcoLip-GLIC is slightly higher than in aso-nAChR, although aso-GLIC exchanges to a greater extent than EcoLip-GLIC (see “Discussion”). The proportion of exchange-resistant peptide hydrogens in aso-nAChR was estimated to be ~40%, sufficient to account for the peptide hydrogens located in the transmembrane domain (11, 29). The greater proportion of exchange-resistant peptide hydrogens in GLIC is likely due to the lack of an intracellular domain: the exchange-resistant transmembrane domain of GLIC makes up a greater proportion of the total protein structure (Fig. 1).

The one notable difference between the deconvolved amide I contours of GLIC and the nAChR is the existence in the latter of a more intense band centered near 1645 cm⁻¹ caused by downshifted and thus peptide N-H to N-D exchanged α-helical and loop/random structures. This band appears immediately after exposure of the nAChR to D₂O, suggesting that the affected structures are solvent-exposed (28). Solvent-exposed α-helical and loop/random structures exist in the intracellular domain of the nAChR. The lack of a similarly intense band centered near 1645 cm⁻¹ in the GLIC spectra is consistent with the absence of an intracellular domain in GLIC.

Finally, the thermal stabilities of both aso-GLIC and EcoLip-GLIC were examined by recording infrared spectra as a function of temperature. In both cases, increasing temperature led to changes in amide I band shape characteristic of protein denaturation (supplemental Fig. S4), confirming that the reconstituted GLIC adopts a folded structure. It is noteworthy that the previously "exchange-resistant peptide hydrogens” in the transmembrane domain of GLIC undergoes complete N-H to N-D exchange concomitant with unfolding. This behavior is similar to that observed for the nAChR but differs from that of other membrane proteins, such as LacY, which undergoes complete N-H to N-D exchange at elevated temperatures, but prior to unfolding (20). The latter property of LacY has been attributed to a temperature-induced increase in the conformational dynamics of the transmembrane domain, whereas the transmembrane domain of GLIC may be conformationally “static” in the absence of bound agonist. The transmembrane domain of GLIC is also not expected to undergo such large conformational transitions (16, 17, 30). Both aso-GLIC and EcoLip-GLIC have higher thermal stabilities of 68.8 ± 1.5 and 73.7 ± 1.4 °C, respectively, than that of the nAChR ~55 °C (Fig. 3 and Table 1). The higher thermal stability of GLIC is consistent with its enhanced suitability for crystallization (31).

Gating Properties of the Membrane-reconstituted GLIC—Although reconstituted membranes at a lipid to protein ratio of 2:1 (w/w) are ideal for spectroscopic studies, they are not useful for direct measurements of channel activity using
Lipid Sensitivity of a Prokaryotic pLGIC

Electrophysiological approaches. Instead, we indirectly probed activity by injecting the reconstituted GLIC membranes into Xenopus laevis oocytes and then monitoring the appearance of proton-activated currents across the oocyte plasma membranes using a two-electrode voltage clamp apparatus (23, 32).

We first tested the feasibility of this approach using reconstituted nAChR membranes of defined function. Carb-induced currents that decay slowly because of desensitization are observed in oocytes injected with either aso-nAChR or PC/PA/Chol-nAChR, showing that the functional reconstituted nAChR membranes fuse with the oocyte plasma membrane, leading to the appearance of functional nAChRs on the oocyte surface (16 fmol of binding sites/oocyte, with 0.12 ± 0.061 μA/fmol [125I]-bungarotoxin-binding sites/oocyte; Fig. 4). In contrast, weak or negligible Carb-induced currents were observed in oocytes injected with the uncoupled and nonactivatable PC-nAChR, even though the reconstituted PC membranes fuse with the plasma membrane leading to the appearance of nAChR agonist sites on the surface of the oocyte (5.5 fmol of [125I]-α-bungarotoxin-binding sites/oocyte, with 0.0034 ± 0.0006 μA current/fmol binding sites/oocyte; Fig. 4). The lack of activity of the plasma membrane-incorporated PC-nAChR (~40-fold reduction in normalized current levels compared with the injected PC/PA/Chol-nAChRs) has several possible explanations. First, the lack of activity could reflect clustering of the reconstituted membranes within the oocyte plasma membrane and thus the nAChR retaining its “reconstituted membrane” lipid environment. Such clustering of the nAChR on the oocyte surface has been suggested from previous studies, (32). PC-nAChR may also be locked in an uncoupled conformation because the oocyte plasma membrane lipids do not promote transitions from uncoupled to coupled conformations. Recent studies suggest that the uncoupled nAChR in long chain PC membranes can undergo ligand-induced transitions to coupled conformations (data not shown). Finally, it is possible that detergent solubilization leads to irreversible effects on nAChR structure and function. The latter seems unlikely, however, given that detergent solubilization has no deleterious effects on the nAChR reconstituted into other membranes. In addition, no detectable effects of detergent solubilization and PC reconstitution are observed on nAChR secondary structure. Regardless, these control experiments confirm that the injection of reconstituted nAChR membranes into oocytes can, in principle, be used to indirectly assess the gating activity of reconstituted nAChRs.

We next characterized the response of uninjected, mock injected (membranes alone), and GLIC mRNA-injected oocytes to jumps in proton concentration. Both uninjected and mock injected oocytes exhibit weak proton-activated currents because of endogenous acid-sensitive channels (Fig. 5). These currents, however, show a roughly linear response to proton concentration at pH values down to 3.5, are insensitive to the GLIC pore blocker amantadine, and had maximal currents of 0.069 ± 0.016 μA (n = 4) and 0.063 ± 0.021 μA (n = 6), respectively, at the maximal utilized proton concentration (pH 3.5). In contrast, oocytes injected with GLIC RNA exhibit robust proton-activated cationic currents (supplemental Fig. S5) with relatively large maximal currents typically close to 4 μamps. A plot of whole cell currents versus proton concentration for the latter yielded a pH50 for activation of 4.82 ± 0.04 (Fig. 4B), consistent with that observed previously for oocyte-expressed GLIC (14).}

---

TABLE 1
Thermal stability of GLIC

| Reconstitution   | Tm   | Boltzmann slope | n  |
|------------------|------|-----------------|----|
| aso-GLIC         | 68.8 ± 1.5 | 2.44 ± 0.16   | 5  |
| EcoLip-GLIC      | 73.7 ± 1.4 | 1.98 ± 0.22   | 5  |
| PC-GLIC          | 70.4 ± 0.9 | 2.35 ± 0.20   | 4  |
| aso-nAChR        | 55.4 ± 1.0 | 2.25 ± 0.01   | 2  |
| PC/PA/Chol-nAChR | 56.4 ± 0.8 | 2.08 ± 0.20   | 6  |
| PC-nAChR         | 52.4 ± 0.1 | 3.08 ± 0.12   | 6  |

* From daCosta and Baenziger (11).
amantadine. 150 μM amantadine blocked close to ~50% of the pH-activated currents.

Oocytes injected with either aso-GLIC or EcoLip-GLIC both exhibit currents that respond to proton concentration in a dose-dependent manner. The maximal responses at pH 3.5 of 0.181 ± 0.008 μA (n = 5) and 0.157 ± 0.014 μA (n = 5), respectively, are roughly 3-fold larger than the responses observed in mock or uninjected oocytes yet are consistent in magnitude to the Carb-induced currents observed in aso-nAChR-injected oocytes. Of particular significance, these proton-induced currents were sensitive to the GLIC channel blocker, amantadine, whereas the endogenous acid-sensitive channels in oocytes are not. These data suggest that the reconstituted GLIC in both membranes retains the ability to gate open in response to proton binding. Interestingly, the proton concentration dependence of GLIC activation is right-shifted relative to the dose response observed with mRNA-injected oocytes, whereas the endogenous acid-sensitive channels in oocytes are not. These data suggest that the reconstituted GLIC in both membranes retains the ability to gate open in response to proton binding. Interestingly, the proton concentration dependence of GLIC activation is right-shifted relative to the dose response observed with mRNA-injected oocytes, suggesting weaker proton sensitivity. A weaker proton sensitivity has also been observed for GLIC reconstituted into giant unilamellar asolectin liposomes at the high lipid to protein ratios required for electrophysiological studies (18). The right shifted dose response suggests that GLIC may also cluster within the oocyte plasma membrane, thus maintaining its reconstituted lipid environment. The shifted dose response suggests that the gating activity of GLIC is sensitive to its membrane environment.

**Effects of an Uncoupling Lipid Environment on GLIC Structure and Function**—We next compared the structural and functional properties of aso-GLIC and EcoLip-GLIC with that of GLIC reconstituted into PC membranes (PC-GLIC). The minimal PC environment is of interest because it stabilizes the nAChR in an uncoupled conformation that binds agonist but does not undergo agonist-induced conformational transitions. A key goal of this work was to ascertain whether GLIC exhibits the same propensity to uncouple as the nAChR in a PC bilayer. The uncoupled PC-nAChR exhibits biophysical properties that distinguish it from the predominantly resting state aso-nAChR (Figs. 2 and 3). The secondary structure-sensitive amid I contours in spectra recorded from PC-nAChR are similar to that of amide I contours in spectra recorded from PC-nAChR versus aso-nAChR. This change in amid I band shape occurs as a result of enhanced levels of peptide N-H/N-2H exchange in the uncoupled state, as opposed to a change in the global secondary structure (33). The enhanced peptide N-H/N-2H exchange is shown by the reduced residual amid II band intensity in spectra recorded from PC-nAChR versus aso-nAChR.

A more detailed analysis of the peptide N-H/N-2H exchange kinetics of uncoupled versus resting or desensitized nAChRs shows that regions of the polypeptide backbone that are buried from solvent in the resting conformation become exposed to solvent in the uncoupled state (11). The uncoupled PC-nAChR...
Lipid Sensitivity of a Prokaryotic pLGIC

also undergoes thermal denaturation at temperatures slightly lower than aso-nAChR, and the cooperativity of denaturation is reduced (11). These altered biophysical properties of PC-nAChR have been attributed to weakened interactions leading to an increased physical separation between the agonist-binding and transmembrane domains (11). Weakened interactions could account for the increased solvent exposure, the reduced cooperativity of unfolding, and the lack of coupling of binding and gating (supplemental Fig. S6).

Significantly, we detect little if any structural or biophysical difference between PC-GLIC and either aso-GLIC or EcoLip-GLIC (Figs. 2 and 3). The amide I band shapes of GLIC in all three membranes are similar, suggesting a similar global secondary structure (however, see below). There is no further shift in amide I component band intensity from 1655 cm$^{-1}$ down to near 1645 cm$^{-1}$ after prolonged exposure of PC-GLIC to $^2$H$_2$O. There are no changes in the levels of peptide N-$^1$H/N-$^2$H exchange, as shown by the similar residual amide II band intensities, although both aso-GLIC and PC-GLIC are more exchanged than EcoLip-GLIC. The thermal denaturation temperature of PC-GLIC is also similar to that of both aso-GLIC and EcoLip-GLIC, and there are no changes in the cooperativity of unfolding (Table 1).

In fact, the only substantial difference observed between spectra recorded from PC-GLIC and either aso-GLIC or EcoLip-GLIC is a slight broadening of the amide I contour, noticeable near 1630 cm$^{-1}$. The degree of this subtle broadening, however, varied between PC-GLIC reconstitutions. Although the structural basis of this spectral effect remains to be determined, it could reflect variations in GLIC aggregation within the membrane. Previous studies have suggested that the monodispersity of the pentameric GLIC within the membrane is lipid-sensitive (18). Monodispersity was found to be ideal in asolectin bilayers. GLIC may tend to aggregate more in PC than in other lipid environments, leading to broadening of the amide I band. Regardless, our structural data suggest that GLIC does not adopt an uncoupled conformation in PC membranes similar to that adopted by PC-nAChR.

Finally, we indirectly assessed whether PC-GLIC exhibits the ability to gate open in response to proton binding (Fig. 4). As noted, very weak or negligible Carb-induced currents are observed in oocytes injected with PC-nAChR, even though PC-nAChR fuses with the oocyte plasma membrane. In contrast, oocytes injected with PC-GLIC exhibit currents that both respond to protons in a dose-dependent manner and are sensitive to amantadine block. The maximal currents obtained upon injection of PC-GLIC are substantially higher than those in mock or uninjected oocytes and are indistinguishable from those observed in oocytes injected with either aso-GLIC or EcoLip-GLIC. The pH-activated currents are also sensitive to amantadine. The electrophysiological recordings suggest that GLIC does not adopt a conformation in PC membranes similar to the uncoupled conformation adopted by the nAChR. Even the minimal PC membrane environment appears sufficient to stabilize GLIC in a conformation that gates open in response to agonist binding.

DISCUSSION

The underlying mechanisms by which lipids modulate nAChR function have been the subject of continuous debate for over 30 years (6). There has long been a consensus that both cholesterol and anionic lipids are required in a reconstituted membrane to obtain optimal nAChR function (7–10, 34–36). It has also been suggested that both lipids influence nAChR function by an allosteric mechanism, whereby lipids alter the functional response to acetylcholine by stabilizing differing proportions of pre-existing resting (activatable) versus desensitized or uncoupled (inactivatable) conformations (7, 29). The mechanisms by which these lipids influence function, however, are not clear. It has been suggested that some act by binding to interstitial sites between different $\alpha$-helices in the transmembrane domain (13, 37). Lipids may also interact directly with the lipid-protein interface (11, 37–39). Although the consensus is that lipid chemistry and thus specific lipid sites are likely important, molecular insight into any such binding sites has yet to be obtained. The lack of mechanistic insight reflects both the complexity of lipid-nAChR interactions and the inability to express site-directed mutants of the nAChR, which can be used to test proposed mechanisms of lipid-protein interactions.

Prokaryotic pLGICs provide a new opportunity for probing the molecular details of pLGIC-lipid interactions (14, 40). The prokaryotic pLGIC, GLIC, adopts a similar tertiary fold to that of the nAChR. Both GLIC and the nAChR are cation-selective ion channels, although GLIC and the nAChR are gated by protons and acetylcholine, respectively. The structural similarities of GLIC and the nAChR, as well as the added advantage that GLIC can be expressed in sufficient studies for biophysical and crystallographic studies, have led the increasing use of GLIC as a model for probing pLGIC structure (15–17), basic mechanisms of pLGIC activation (15–17), pLGIC-drug interactions (41, 42), etc. The ability to express large quantities of site-directed mutants finally opens the door for detailed mechanistic studies of lipid-GLIC interactions. Such studies, however, first require a detailed characterization of the effects of lipids on GLIC structure and function.

We report here a simple protocol for reconstituting the prokaryotic pLGIC, GLIC, into defined lipid membranes. Our protocol differs from the standard vesicle detergent destabilization approach typically used to form high lipid to protein ratio membranes for electrophysiological studies (18). One advantage of our approach is the high efficiency incorporation of GLIC into the model membranes (supplemental Fig. S1). It is easy to accurately adjust the lipid to protein ratio of the reconstituted membranes. In addition, this protocol can be used to form relatively low lipid to protein ratio proteoliposomes.

Our goal was to reconstitute GLIC into membranes at lipid to protein ratios of roughly 2:1 (w/w) because the resulting vesicles are ideal for structural studies, such as those used previously to characterize the uncoupled nAChR. These low lipid to protein ratio vesicles can be easily separated from both protein-free vesicles and low lipid-protein ratio protein aggregates (supplemental Fig. S1). They are ideal for spectroscopic studies because the scattering of light from the membrane vesicles (per
Lipid Sensitivity of a Prokaryotic pLGIC

mol of reconstituted protein) is minimized, and the spectral overlap between signals from lipid and protein is less of an issue. The higher density low lipid to protein ratio proteoliposomes are easier to pellet (particularly in higher density $^3$H$_2$O buffers) and thus exchange into $^3$H$_2$O. Low lipid to protein ratio vesicles are also ideal for structural studies using infrared difference spectroscopy, a technique that detects residue-specific changes in structure of the nAChR upon agonist-binding (27, 43, 44). Application of this approach to prokaryotic pLGICs would be particularly informative given the ability to express mutants and thus assign detected vibrational changes to specific amino acid side chains.

Membrane-reconstituted GLIC and the nAChR exhibit similar structural and biophysical properties. Both proteins exhibit a mixed $\alpha$-helix/$\beta$-sheet secondary structure with both a substantial proportion of the polypeptide backbone exposed to solvent-exposed secondary structures. This vibration could reflect primarily the $\alpha$-helix and loop/random secondary structures found in the transmembrane channel pore domain. GLIC exhibits a higher $\beta$-sheet content than the nAChR, as expected given that the predominantly $\beta$-sheet agonist-binding domain in GLIC makes up a larger proportion of the total protein structure (see below). The membrane-reconstituted GLIC also undergoes thermal denaturation, albeit at higher temperatures than the nAChR. These observations show that the reconstituted GLIC maintains the expected structural fold.

On the other hand, infrared spectroscopy detects a relatively intense vibration near 1645 cm$^{-1}$ in spectra of the nAChR because of solvent-exposed $\alpha$-helix and/or loop/random secondary structures. This vibration could reflect primarily the solvent-exposed $\alpha$-helix and loop/random secondary structures found in the intracellular domain of the nAChR (Fig. 1). The lack of similar intensity in this region in spectra of GLIC is consistent with the lack of an intracellular domain in the GLIC crystal structure.

We used an indirect electrophysiological approach to probe the ability of the reconstituted GLIC to gate open in response to agonist binding. Injection of membrane-reconstituted GLIC into oocytes led to the appearance of proton activated currents across the oocyte plasma membrane. The oocyte membrane-incorporated GLIC responds in a dose-dependent manner to protons, and the resulting currents were blocked by the GLIC channel blocker amantadine. Both our structural and electrophysiological studies thus suggest that the reconstituted GLIC adopts a native structure that gates open in response to agonist binding.

A major goal of this work was to compare the lipid sensitivities of both GLIC and the nAChR. In particular, the nAChR in complex natural lipid membranes, such as those composed of either soybean asolectin lipids, or mixtures of defined lipids (PC plus cholesterol and anionic lipids) adopts an activatable resting conformation. In contrast, the nAChR in PC membranes lacking the two “activating lipids” adopts an uncoupled conformation that binds agonist with a resting state-like affinity but does not typically undergo agonist-induced conformational transitions. We are interested in the uncoupled nAChR because of increasing anecdotal evidence hinting that functionally uncoupled nAChRs may play a role in nicotinic receptor physiology (12). A main goal of this work was to assess whether GLIC exhibits a propensity similar to that of the nAChR to adopt an uncoupled conformation in PC bilayers.

Although our data show that GLIC activity is sensitive to lipids (see below), PC-GLIC does not exhibit the structural or functional characteristic of the uncoupled conformation adopted by PC-nAChR. Specifically, PC-GLIC does not exhibit the substantial increase in solvent accessibility of polypeptide backbone hydrogens, which has been attributed to weakened interactions between the agonist-binding and transmembrane domains. PC-GLIC does not exhibit the reduced cooperativity of thermal denaturation that is observed for PC-nAChR. Finally, unlike PC-nAChR, which remains inactive even after fusion with oocyte plasma membranes, fusion of PC-GLIC leads to an active conformation. Although further studies are required to fully characterize the functional properties of GLIC in different membranes, it appears that PC-GLIC is not locked in an uncoupled conformation that is unresponsive to agonist binding.

The finding that GLIC does not exhibit the same propensity as the nAChR to adopt an uncoupled conformation can be interpreted in light of our working model of uncoupling. This model proposes that lipids influence the coupling of binding and gating via the M4 transmembrane $\alpha$-helices (one per subunit) (11), which are exposed to the surrounding lipid bilayer and thus ideally situated to sense membrane physical and/or chemical properties (Fig. 1) (45). Each M4 $\alpha$-helix extends beyond the bilayer to interact directly with the Cys-loop, a key structure at the interface between the agonist-binding and transmembrane domains. By influencing the conformation of the M4 “lipid sensor,” lipids may modulate interactions between M4 and the Cys-loop (supplemental Fig. S6 and Ref. 11). Weakened M4/Cys-loop interactions could lead to a Cys-loop conformational change that ultimately reduces contact between the agonist binding and the transmembrane domains and leads to the uncoupled state.

A dynamic equilibrium may exist between coupled and uncoupled conformations where M4 is bound tightly or tilted away from the Cys-loop, respectively (46, 47). In fact, an equilibrium between M4 solvated by lipid and M4 bound tightly to the other transmembrane $\alpha$-helices, M1 + M3, has been demonstrated for the homologous glycine receptor (48). Significantly, aromatic-aromatic interactions play a key role driving associations between M4 and M1 + M3, thus stabilizing a folded structure. In the context of the M4 lipid sensor model, aromatic-aromatic interactions could play a key role dictating the propensity of M4 to bind tightly to M1 + M3 and to thus form a coupled conformation. Aromatic-aromatic interactions could play a role dictating the propensity of a pLGIC to adopt an uncoupled conformation in PC membranes.

In light of this hypothesis, we compared the aromatic-aromatic interactions that exist between M4 and M1 + M3 in GLIC versus the nAChR (Fig. 6). Consistent with the above hypothesis, GLIC exhibits a plethora of aromatic-aromatic interactions between M4 and M1 + M3, with clusters located in both the cytoplasmic and extracellular leaflets of the lipid bilayer. These aromatics could lead to a highly stable transmembrane domain that is resistant to the formation of an uncoupled conformation.
Lipid Sensitivity of a Prokaryotic pLGIC

In contrast, whereas the nAChR exhibits aromatic residues at the interface between M4 and M1 + M3, there appear to be few if any direct interactions that could stabilize the nAChR in a coupled conformation where M4 binds tightly to M1 + M3, although the lower resolution of the nAChR structure makes this interpretation less definitive. Although other features likely play important roles, the paucity of aromatic-aromatic interactions between M4 and M1 + M3 in the nAChR may contribute to weaker M4/M1 + M3 interactions and thus to the high propensity of this receptor to adopt an uncoupled conformation. The lack of aromatic-aromatic interactions may also contribute to the lower thermal stability of the nAChR relative to GLIC. Future studies should lead to definitive insight into the molecular basis of lipid sensitivity in pLGICs.

Finally, it is notable that although GLIC does not exhibit the same propensity to uncouple as the nAChR, it still appears to be sensitive to its membrane environment. The dose response of membrane-reconstituted GLIC incorporated into oocyte membranes is shifted to higher proton concentrations, suggesting a weaker ability of protons to gate open the channel. A lower pH\textsubscript{50} has also been observed in electrophysiology studies of GLIC reconstituted into asolectin membranes at high lipid-protein ratios. In fact, lipid effects may account for the altered pH\textsubscript{50} values observed for GLIC in different heterologous expression systems (49, 50). Note that altered sensitivity to protons could reflect altered proton binding and/or altered coupling of binding to gating. Lipids may still influence the coupling of binding and gating in GLIC, albeit to a lesser extent than with the nAChR.

In addition, we detect both an increased thermal stability and a reduced level of peptide backbone N-\textsuperscript{1}H/N-\textsuperscript{2}H exchange after prolonged exposure to \textsuperscript{2}H\textsubscript{2}O of EcoLip-GLIC relative to both aso-GLIC and PC-GLIC. Both suggest a slightly more rigid structure in the membranes formed from \textit{E. coli} polar lipid extracts. A more detailed characterization of the effects of membranes on GLIC structure should lead to further insight into the molecular coupling of pLGICs with their membrane environment.

Acknowledgments—We thank Julian Surujbali and Peter Juranka for assistance with the electrophysiological measurements.
