INTRODUCTION

DNA methylation is one of the basic epigenetic markers involved in regulation of various biological functions in both prokaryotes and eukaryotes (Bird, 2007; Vasu and Nagaraja, 2013). Among the methylation modifications, DNA adenine N⁶-methylation (6mA) and 5-methylcytosine (5mC) are two of the most important. The 5mC modification has been well studied as an epigenomic marker in eukaryotes (Zemach et al., 2010), while adenine N⁶-methylation has been found to be predominantly distributed in prokaryotic genomes (Blow et al., 2016) and eukaryotic RNA (Fu et al., 2014). In recent years, 6mA has also been found to be widespread in the genomic
DNA of many eukaryotes, including fungi (Mondo et al., 2017), Chlamydomonas (Fu et al., 2015), Caenorhabditis elegans (Greer et al., 2015), Arabidopsis thaliana (Liang et al., 2018), rice (Zhou et al., 2018) and humans (Xiao et al., 2018). However, compared with those in prokaryotes, the characteristics of 6mA methylation in eukaryotes are still largely unknown.

Previous studies have shown that 6mA is dynamically controlled by methyltransferase and demethylase (Greer et al., 2015; Zhang et al., 2015). In prokaryotes, M. MunI is a classic 6mA methyltransferase (Iyer et al., 2016). It has been well documented that the orthologs of MT-A70 that evolved from M.MunI (Iyer et al., 2011) in eukaryotes are important 6mA methyltransferases (Bujnicki et al., 2002). Three MT-A70 methyltransferases, namely, Mettl1 in Bombyx mori (Wang et al., 2018) and Mettl3 and Mettl14 in humans (Wang et al., 2016), have been shown to play important roles in regulating the levels of 6mA. Mta1, an MT-A70 ortholog in Oxytricha, can form a dimer with Mta9 and has the function of a DNA methyltransferase (Woodcock et al., 2020). We found an MT-A70 homologous protein, BcMettl4, in Botrytis cinerea, but the function of this protein in DNA methylation was unclear.

Botrytis cinerea is an important necrotrophic fungal pathogen that infects over 1,000 plants and causes gray mold disease. Many economically important vegetables and fruits, including strawberry, tomato, cucumber and grape, are susceptible to B. cinerea. B. cinerea is ranked as the second most common plant pathogenic fungus in the world (Dean et al., 2012) and causes severe preharvest and postharvest economic losses worldwide (Mousavi-Derazmahalleh et al., 2019). However, the biological role of the 6mA DNA modification in B. cinerea is still unclear.

In this study, the 6mA DNA modification in B. cinerea was investigated and 6mA was found to be widely distributed in B. cinerea. The gene BcMETTL4 was disrupted in the wild-type strain B05.10. Methylated DNA immunoprecipitation sequencing (MeDIP-Seq) was further employed to analyze the methylome characteristics of the wild-type strain B05.10 and the gene disruption mutant BcMettl4. Deletion of BcMETTL4 caused a global reduction in DNA 6mA. RNA-Seq analysis was subsequently used to investigate global gene expression patterns in the disruption mutant BcMettl4 and its wild-type strain B05.10. Finally, the relationships between 6mA, gene expression and virulence were investigated. Expression of key genes involved in virulence and conidiation was strongly affected by 6mA modification in B. cinerea.

**MATERIALS AND METHODS**

**Strains and Growth Assays**

Strain B05.10 of B. cinerea used in this study was isolated from Vitis vinifera (Yang et al., 2018). The wild-type strain, gene deletion derivatives and complemented strains were grown on PDA plates (20% potato, 2% dextrose, and 1.5% agar). The growth ratios, conidial development, and sclerotium formation of different strains of B. cinerea were measured according to previously described methods (Yang et al., 2019). For mycelial growth assays, the different strains were cultured at 25°C for 3 day on PDA plates supplemented with 0.5 mM CR, 0.73 mM SDS, 20 mM H2O2, 1 M sorbitol, 1 M KCl, 1 M NaCl, and 1 M glycine.

**Construction of Gene Deletions, Complementation, Subcellular Localization and Point Mutations**

To construct the gene mutant cassette for targeted deletions, two flanking sequences of each gene were obtained from genomic DNA of strain B05.10 by PCR. The hygromycin B phosphotransferase (HPH) gene was derived from the plasmid pBS-HPH1 (Yang et al., 2018). The two flanking fragments and the HPH gene were fused by splice overlap PCR. The resulting deletion cassettes (Promoter:HPH:Terminator) were connected to the pMD19-T vector for sequencing. The gene deletion cassette was transformed into strain B05.10.

For complementation, full-length genes, including promoters and terminators, were amplified from the B05.10 genome. The resulting PCR products were cloned into plasmid pBS-neo (Yang et al., 2018). The resulting vectors were subsequently transformed into the deletion mutants.

To construct BcMettl4-GFP, BcDamt-GFP, and BcMettl4Δ-NLS-GFP fusion cassettes, the open reading frames (ORFs) of BcMETTL4 and BcDAMT without the stop codons were amplified by PCR from strain B05.10. The NLS of BcMettl4 was deleted using overlap PCR (Heckman and Pease, 2007). The PCR products were ligated into plasmid pNAH-OGG-G418 that was derived by replacing the hygromycin B resistance gene of pNAH-OGG (Schumacher, 2012) with a geneticin G418 resistance gene from plasmid pBS-neo (Yang et al., 2018).

For generation of the BcMettl4 point mutant, we first designed primers that contained the mutated site. The sites upstream and downstream of the mutated site were obtained by PCR and the products were joined by overlap PCR. The resulting PCR products were cloned into the plasmid pBS-neo and transformed into the AbcMettl4 strain using standard protoplast formation procedures as previously described (Gronover et al., 2001; Yang et al., 2018).

All primers and their descriptions are shown in Supplementary Table 1. Positive transformants were selected on PDA plates with 0.01% hygromycin B or 0.01% geneticin G418 sulfate. PCR was used to confirm the positive transformants.

**Dot Blot Assay**

Genomic DNA from various strains was extracted using a Fungi Genomic DNA Purification Kit (Sangon Biotech, China). After denaturation at 98°C for 5 min, the extracted DNA was chilled on ice for 10 min and then transferred to a HybondTM-N + membrane. After drying at room temperature, the DNA was fixed to the membrane by UV cross-linking. The HybondTM-N + membrane was blocked in 5% skim milk powder for 1.5 h at room temperature, followed by incubation with 6mA antibody (1:2,000 dilution, Abcam, ab151230) for 10 h at 4°C. The membrane was then washed four times for 8 min using Tween-20. After incubation with secondary antibody (1:5,000 dilution, Abcam, ab151230) for 1 h at room temperature, the membrane was washed four times for 8 min using 20% Tween-20, then incubated with secondary antibody (1:2,000 dilution, Abcam, ab151230) for 1 h at room temperature. The membrane was washed four times for 8 min using 20% Tween-20, then incubated with secondary antibody (1:2,000 dilution, Abcam, ab151230) for 1 h at room temperature. The membrane was washed four times for 8 min using 20% Tween-20, then incubated with secondary antibody (1:2,000 dilution, Abcam, ab151230) for 1 h at room temperature. The membrane was washed four times for 8 min using 20% Tween-20, then incubated with secondary antibody (1:2,000 dilution, Abcam, ab151230) for 1 h at room temperature.
dilution, Sigma A0545) at room temperature for 2 h, the membrane was washed 4 times for 8 min using TBST. Finally, an ECL Immunoblotting Detection Kit (Thermo Fisher) was used for signal visualization. The input DNA was normalized by using methylene blue.

**MeDIP-Seq**

MeDIP-Seq was performed according to previously described protocols (Fu et al., 2015; Chen et al., 2018; Zhou et al., 2018). In brief, the genomic DNAs of different strains were extracted from conidia grown in YEPD medium for 24 h at 25°C, followed by incubation with RNase A overnight. After sonication, the DNA fragments (200–400 bp) were repaired, followed by adaptor ligation. The resulting DNA was purified using a TIANquick Midi Purification Kit (DP204, TIANGEN BIOTECH, China). The purified DNA fragments were denatured at 94°C for 15 min and chilled on ice for 10 min. An aliquot of denatured DNA was used as input. The remaining DNA was incubated with anti-6mA antibody at 4°C for 12 h. After elution by 6mA salt competition, a 6mA-IP-Seq library was constructed by PCR amplification. The resulting DNA fragments were sequenced with a HiSeq 2500 (Illumina) (Zhou et al., 2018). Raw reads were trimmed to remove adaptors and low-quality bases, and the reads with 6mA-rich regions were called with MASC2 (Liu, 2014).

**RNA-Seq Analysis**

After conidial germination in YEPD medium at 25°C for 24 h, the mycelia of different strains were collected by centrifugation for RNA extraction. Total RNA was extracted using TRIzol Reagent (Invitrogen). A NanoDrop spectrophotometer (Thermo Scientific) was employed to determine the RNA concentration, quality and integrity. Poly-T oligo-attached magnetic beads were purified to enrich mRNA. First-strand cDNA was obtained using random oligonucleotides and SuperScript II. Second-strand cDNA synthesis was subsequently performed using DNA polymerase I and RNase H. The resulting cDNA fragments were further adenylated at the 3’ ends and ligated with Illumina PE adaptor oligonucleotides. PCR was performed to enrich the DNA fragments with ligated adaptors on both ends. After purification using an AMPure XP system and quantification using an Agilent high-sensitivity DNA assay, the obtained sequencing library was sequenced on a NovaSeq 6000 platform (Illumina).

**Bioinformatics Analysis**

TopHat (v2.0.12) was employed to map the obtained sequences against the database of *B. cinerea* (Trapnell et al., 2009). The mapped genes were calculated using HTSeq (v0.6.1) (Anders et al., 2015). Gene expression was quantitatively estimated by using the reads per kilobase per million mapped reads (RPKM)

value (Trapnell et al., 2010). DESeq was used to analyze the differentially expressed genes between the wild-type and the gene deletion mutants (Wang et al., 2010).

Pathogenicity Experiments on Tomato Leaves and Onion Epidermis

After growth on PDA plates at 25°C for 7 days, the conidia produced by different strains of B. cinerea were harvested and resuspended in buffer (6.7 mm K<sub>2</sub>HPO<sub>4</sub> and 10 mm glucose). A total of 5 µl of conidia suspension (5.0 × 10<sup>5</sup> conidia/ml) was transferred to 8-week-old tomato (Solanum lycopersicum) leaves, incubated at 25°C for 72 h, and developing disease lesions caused by different strains were measured. Additionally, infection-related morphogenesis was observed on onion epidermis. The conidial suspensions (3.0 × 10<sup>3</sup> conidia/ml) were inoculated onto the epidermis. After culturing for 12 h at 25°C in the dark, the onion skin was stained with aniline blue and observed.

Induced Expression of BcMETTL4 and BcDAMT in Interactions Between Botrytis cinerea and Tomato Leaves

The expression levels of BcMETTL4 and BcDAMT in wild-type B05.10 in interaction between B. cinerea and tomato leaves were investigated by real-time PCR. In brief, 45 ml of conidia suspension (5.0 × 10<sup>6</sup> conidia/ml) and 5 ml of YEPD

(B) Lesions on tomato leaves caused by different strains 72 h after inoculation. (C) Lesion diameter of the strains inoculated on tomato leaves. Three experiments were carried out and nine leaves were measured in one biological experiment. Statistical tests were carried out using Tukey’s test. The same letters marked on the bars indicate no significant difference in values at $p < 0.05$. (D) Infection of conidia from different strains after 12 h of incubation on onion epidermis. Mycelia growing outside onion cells were colored blue, while mycelia growing inside onion cells are not stained. Penetrated positions are marked by purple arrows. (E) Mycelia length of different strains at 12 h after conidia infection on onion epidermis. Data are given as the mean ± SD, $n = 10$. The different letters showed on the columns were significantly different at $p < 0.05$.

medium were mixed and 3 g of sterile fresh intact tomato leaves (3 weeks old) was added, and then gently agitated in a shaker at 25°C. Samples were collected at 6 h intervals for 24 h. RNA was extracted according to a previously described protocol (Yang et al., 2018). cDNA was biosynthesized by reverse transcription using a PrimeScript RT Kit (Takara, Japan). The
Western Blot

The mycelia grown in YEPD medium at 25°C for 24 h were collected. A nuclear protein extraction kit (R0050, Solarbio) was used to separate nuclear and cytoplasmic proteins. The proteins were separated by SDS-PAGE and immunoblotted using anti-GFP antibody (ab290, Abcam), anti-H3 antibody (ab1791, Abcam), and anti-TUBA4A antibody (D110022, BBI Life Sciences).

RESULTS

Analysis of the Methyltransferases in Botrytis cinerea

To investigate the presence of 6mA in \textit{B. cinerea}, we searched the genome of \textit{B. cinerea} B05.10 using BLAST and found two potential candidates for 6mA methyltransferase. One candidate was BCIN\_12g06440 (also known as BC1G\_13837), encoding a hypothetical protein (NCBI id: XP\_024552389.1) which is a 462-amino-acid ortholog of MT-A70 in \textit{B. cinerea} (Figure 1A). The other was BCIN\_02g05970 (also known as BC1G\_16157), encoding a hypothetical protein (255 amino acids) containing a N6-adenineMlase (probable N6-adenine methyltransferase) catalytic domain (NCBI id: XP\_024547190.1) (Figure 1B). As shown in Figure 1A, the protein encoded by BCIN\_12g06440 contained a conserved catalytic motif (“DPPW”) and a nuclear localization signal (NLS). However, the protein encoded by BCIN\_02g05970 contained only one catalytic motif, “DPPF” (Figure 1B).

A variety of methyltransferases, including Mta1, Mta9, Mettl3, Mettl4, Mettl14, and Damt, have previously been reported (Wang et al., 2016, 2018; Chen et al., 2018; Beh et al., 2019; Woodcock et al., 2020). A phylogenetic tree of methyltransferase orthologs was constructed using MEGA 7.0 software, revealed that the protein encoded by BCIN\_12g06440 in \textit{B. cinerea} was closely related to a branch representing the MT-A70 ortholog Mettl4, while the protein encoded by BCIN\_02g05970 belonged to a clade of Damt (Figure 1C). The hypothetical proteins encoded by BCIN\_12g06440 and BCIN\_02g05970 were thus named BcMettl4 and BcDamt, respectively. The roles of BcMettl4 and BcDamt in the virulence of \textit{B. cinerea} were subsequently studied in some detail.

Effects of BcMETTL4 and BcDAMT Disruption on Genome Methylation in Botrytis cinerea

Since BcMettl4 contains a predicted NLS signal (Figure 1A), this protein might localize in the nucleus. To test this hypothesis, two fusion proteins, BcMettl4-GFP and BcMettl4\textsubscript{NLS}-GFP (without a NLS), were expressed in strain B05.10 of \textit{B. cinerea}. After growth on PDA plates for 3 days, the transformants containing the fusion protein BcMettl4-GFP or BcMettl4\textsubscript{NLS}-GFP were observed by fluorescence microscopy. The results showed that the GFP signal of BcMettl4-GFP overlapped with nuclei stained with DAPI fluorescent dye, while BcMettl4\textsubscript{NLS}-GFP was present in both the cytoplasm and the nucleus (Figures 2A,B). A western blot analysis was performed using extracted total proteins, nuclear proteins and cytoplasmic proteins and revealed that BcMettl4-GFP was significantly enriched in the nucleus compared with BcMettl4\textsubscript{NLS}-GFP (Figure 2C). These findings confirmed that BcMettl4 was located in the nucleus and that the NLS of BcMettl4 played an important role in controlling the subcellular localization of BcMettl4. By contrast, the fusion protein BcDamt-GFP was mainly located in the cytoplasm (Figures 2A–C).

The genes \textit{BcMETTL4} and \textit{BcDAMT} were disrupted in the wild-type strain B05.10. PCR amplification revealed that one transformant, ΔBcMettl4, exhibited \textit{BcMETTL4} gene disruption (Supplementary Figure 1), and another transformant, ΔBcDamt, exhibited \textit{BcDAMT} gene deletion (Supplementary Figure 2). To investigate the presence of 6mA DNA modification in \textit{B. cinerea}, the genomic DNAs (gDNAs) of B05.10, ΔBcMettl4, and ΔBcDamt were extracted and a dot blot assay performed using a specific 6mA antibody. As shown in Figure 2D, a strong immune blot signal was detected in the gDNA of B05.10. Compared with those of B05.10 and ΔBcDamt, the signal in the gene deletion mutant ΔBcMettl4 was significantly weaker, based on ImageJ analysis (p < 0.05) (Figure 2D).

Taken together, these observations suggested that 6mA was a widespread DNA modification in the genome of \textit{B. cinerea} and that BcMettl4 might play a role in modifying nuclear DNA.

Impacts of BcMETTL4 and BcDAMT Disruption on Virulence of Botrytis cinerea

The transcript levels of \textit{BcMETTL4} and \textit{BcDAMT} at the point of germination in culture in the presence of tomato leaf tissue to 24 h later were assessed as a proxy for the early interaction stage between \textit{B. cinerea} and tomato leaves. As shown in Figure 3A, the expression levels of \textit{BcMETTL4} and \textit{BcDAMT} remained stable until 12 h and then increased approximately four-fold compared to those at 0 h. However, after 24 h of growth, the expression of \textit{BcMETTL4} increased approximately 110-fold, compared with a twofold increase in \textit{BcDAMT} gene expression (Figure 3A). Highly induced expression of \textit{BcMETTL4} by presence of tomato leaf tissue indicated that BcMettl4 might be involved in the virulence of \textit{B. cinerea}.

The impacts of \textit{BcMETTL4} and \textit{BcDAMT} disruption on the virulence of \textit{B. cinerea} were therefore investigated. First, the mutants ΔBcMettl4 and ΔBcDamt were complemented with the genes \textit{BcMETTL4} and \textit{BcDAMT}, respectively. These two genes including their native promoters and terminators were amplified from wild-type strain B05.10 genomic DNA using the primers listed in Supplementary Table 1. The obtained fragments were inserted into the plasmid pBS-neo and subsequently transformed into the mutants according to the method described above. Finally, two complemented strains, ΔBcMettl4-C and ΔBcDamt-C, were obtained. Deletion of any of the genes, that is, \textit{BcMETTL4} or \textit{BcDAMT}, reduced the pathogenicity of \textit{B. cinerea} on tomato,
especially deletion of BcMETTL4 (Figure 3B). As shown in Figure 3C, the spreading of the lesion induced by the disruption mutant ΔBcMettl4 was significantly reduced compared with that induced by the wild-type strain B05.10 or the disruption mutant ΔBcDamt.

We further examined the ability of these strains to penetrate onion epidermal cells. As shown in Figure 3D, deletion of BcMETTL4 weakened the infection of mycelia in onion epidermal cells. Mycelia length of different strains of B. cinerea at 12 h after conidia infection on onion epidermis were further investigated. It was found that the mycelia length of ΔBcMettt4 invaded onion cells were 144 µm, while those of other strains, B05.10, ΔBcMettt4-C, ΔBcDamt, and ΔBcDamt-C, were 359, 338, 320, and 349 µm (Figure 3E), respectively, revealing that BcMETTL4 interruption decreased virulence of B. cinerea on onion by reducing the conidia infectivity.

Effects of BcMETTL4 and BcDAMT Disruption on Mycelial Growth, Conidial, Sclerotial Formation and Stress Tolerance

The reduction in genome-wide 6mA (Figure 2D) in the disruption mutant ΔBcMettl4 led to investigations of the biological phenotypes of the different mutations affecting 6mA. After 3 days of cultivation on PDA plates, there were no obvious differences in mycelial growth of B05.10, ΔBcMettt4, ΔBcDamt, ΔBcMettt4-C, and ΔBcDamt-C (Figure 4A). Disruption of BcMETTL4 or BcDAMT also did not affect conidial formation (Figure 4A). However, after growth on PDA plates for 30 days in darkness, ΔBcMettt4 exhibited significantly decreased sclerotial formation compared with B05.10, ΔBcMettt4-C, ΔBcDamt, and ΔBcDamt-C (Figure 4B). Our previous studies have shown that the reduction of sclerotia in B. cinerea is often accompanied by a decrease in pathogenicity (Yang et al., 2015; Wang et al., 2020). These observations suggested that the reduction in sclerotia in the BcMETTL4 mutant might also be correlated with a decrease in the pathogenicity of B. cinerea.

The sensitivity of different strains to stress tolerance was also measured. Disruption of BcMETTL4 or BcDAMT did not cause significant sensitivity to cell wall stress, osmotic stabilization, or oxidative stress (Figures 4C,D), indicating that BcMETTL4 and BcDAMT were not involved in the regulation of cell stress tolerance.

The Point Mutant BcMettl4-APPA Exhibited Phenotypes Similar to Those of ΔBcMettl4

Methyltransferases contain a conserved catalytic motif, “DPPW.” A 3-dimensional structure of BcMettl4 was constructed, and the signature motif “DPPW” was found to be located in the catalytic domain (Figure 5A). Multiple sequence alignments of the catalytic motifs in 6mA methyltransferases were performed. The results showed that the conserved catalytic motif “DPPW” in BcMettl4 exhibited high similarity with Mettl4 orthologs (Figure 5B). To study the catalytic function of BcMettl4, the catalytic domain “DPPW” was mutated to “APPA” in BcMettl4. After the mutation to “APPA,” the methylation level of DNA in B. cinerea decreased (Figure 5C) and both virulence and sclerotium formation decreased (Figures 5D,E), which was consistent with the phenotype of the ΔBcMettl4 mutant. These data suggested that the catalytic motif “DPPW” plays a key role in the enzymatic function of BcMettl4 and that BcMettl4 is involved in the regulation of DNA methylation levels and virulence.

Genomic Profiling of 6mA in Botrytis cinerea

To detect naturally occurring methylated genes globally regulated by BcMETTL4 in B. cinerea, we performed a MeDIP-Seq analysis of the 6mA methyllomes of the disruption mutant ABCMettl4 and its wild-type strain B05.10. The expression of BcMETTL4 increased significantly after 24 h infection (Figure 3A). We therefore collected the samples of conidial germination at 24 h for MeDIP-seq. Three biological replicates for each strain of ΔBcMettl4 and B05.10 were investigated in MeDIP-Seq experiments. A total of 30,320 6mA-enriched regions (peaks) were captured from the three B05.10 biological replicates, while a total of 28,385 methylation peaks were obtained from the three ΔBcMettl4 biological replicates (Supplementary Table 2). These observations further confirmed that disruption of BcMETTL4 reduced the methylation level of B. cinerea. After assembling the attained sequences, it was found that most of the 6mA peaks (57%) were distributed in the upstream regions of genes, followed by 24% in the exon, and 15% in the downstream regions in wild-type B05.10 and the mutant ΔBcMettl4 (Figures 6A,B). The 6mA peaks were further investigated and wild-type B05.10 exhibited 1,297 unique 6mA peaks while 689 unique 6mA peaks were identified in the mutant ΔBcMettl4 (Figure 6C). There were 8,357 6mA peaks that were found in both the wild-type B05.10 and the mutant ΔBcMettl4 (Figure 6C). Among the unique 6mA peaks of wild-type B05.10, 2,396 genes were detected (Figure 6D and Supplementary Table 3). However, only 1,330 genes were detected in the unique 6mA peaks of the mutant ΔBcMettl4 (Figure 6D and Supplementary Table 4).

BcMETTL4 Inactivation Downregulated the Expression of 13 Methylated Genes in Which Methylation Occurred in the Promoter Region

Since the majority of the 6mA peaks were identified in the regions upstream of the affected genes (Figures 6A,B), involvement of the promoter regions and regulation of gene expression was indicated. To identify all genes that might exhibit differential expression due to the disruption of BcMETTL4 in B. cinerea, we performed an RNA-Seq analysis of the full transcriptomic profiles of the wild-type strain B05.10 and the disruption mutantΔBcMettl4. The differentially expressed genes were further analyzed using DESeq software (Wang et al., 2010). A total of 792 genes, including 601 upregulated genes (Supplementary Table 5) and 191 downregulated genes (Supplementary Table 6), were found to be differentially
FIGURE 4 | Mycelial growth, conidial and sclerotial formation and stress tolerance of the indicated strains. (A) Mycelial growth, conidial and sclerotial development of various strains grown on PDA plates. (B) Number of sclerotia produced by various strains grown on PDA plates for 30 days in darkness. Bars denote standard errors from three plates. Tukey’s test was employed to calculate significance. The same letters indicated on the bars mean no significant difference in values at $p < 0.05$. (C) The sensitivity of various strains on stress tolerance. (D) Colony diameter of the indicated strains grown on various stress conditions. Bars represent standard errors from three plates.
expressed in the BcMETTL4 mutant compared with the wild-type strain B05.10, which accounted for 4.82% (792/16,448) of the annotated genes in B. cinerea.

To test the hypothesis that the unique genes modified at promoter sites might be directly regulated by BcMettl4, the transcription levels of the unique genes were further analyzed in the mutant ΔBcMettl4. After disruption of BcMETTL4, among the unique methylated genes modified at promoter sites in the wild-type strain B05.10, 32 genes were upregulated (Supplementary Table 7) and 13 genes were downregulated (Figures 7A,B). Since the virulence of the BcMETTL4 mutant was significantly reduced, we hypothesized that the 13 methylated genes modified in the promoter region with downregulated expression might be associated with...
FIGURE 6 | The 6mA methylated genes in *B. cinerea*. (A) Peak distribution in genomic elements of the wild-type strain B05.10. (C) Venn diagram comparing unique 6mA peaks between the wild-type B05.10 and the mutant \( \Delta \text{BcMettl4} \). (D) The number of unique methylated genes in wild-type strain B05.10 and the disruption mutant \( \Delta \text{BcMettl4} \).

pathogenicity. The genes shown in Figure 7A were therefore subsequently further analyzed.

The reduced transcript levels of the 13 genes shown in Figure 7B were further validated by fluorescent real-time qRT-PCR (Figure 7C). As shown in Figure 7A, these methylated genes were divided into five categories, including oxidoreduction, secretory pathways, autophagy and carbohydrate metabolism, according to their biological functions. It has been well documented that proteins related to oxidative stress sensitivity (Yang et al., 2015), autophagy (Ren et al., 2018), and secretion (Zhang et al., 2016) are important factors affecting the virulence of *B. cinerea*. These observations indicated that the downregulated methylated genes related to oxidoreduction, secretory pathways and autophagy may cause a decrease in the pathogenicity of *B. cinerea*.

The Roles of BcMfs2 and BcFdh in the Virulence of *Botrytis cinerea*

Deletion of *BcMETTL4* both reduced the methylation and expression levels of 13 genes (Figure 7). We speculated that these genes might be involved in virulence of *B. cinerea*. Two of them were randomly selected for targeted disruption. *BcMFS2* encoding a major facilitator superfamily (MFS) transporter and *BcFDH* encoding a FAD/FMN-containing dehydrogenase were independently deleted in the wild-type strain B05.10. Two mutants, \( \Delta \text{BcMfs2} \) and \( \Delta \text{BcFdh} \), were subsequently obtained. The genes *BcMFS2* and *BcFDH* were also cloned and complemented both mutants, resulting in transformants, \( \Delta \text{BcMfs2-C} \) and \( \Delta \text{BcFdh-C} \), respectively. Deletion of *BcMFS2* reduced sclerotium formation (Figures 8A,B). Further infection assays of tomato leaves were performed, and the results showed that deletion of *BcMFS2* did not reduce the virulence of *B. cinerea* (Figures 8A,B). These findings indicated that *BcMFS2* was involved in sclerotium formation but not in the virulence of *B. cinerea*. Another interesting finding was that deletion of *BcFDH* severely hindered conidium formation in *B. cinerea* (Figure 8B). Infection of tomato leaves by \( \Delta \text{BcFdh} \) was further performed, and the results showed that deletion of the *BcFDH* gene reduced the pathogenicity of *B. cinerea* by 20% (Figure 8B). These observations demonstrated that *BcFDH* was involved in both conidium formation and the pathogenicity of *B. cinerea*.

DISCUSSION

As a basic epigenetic marker, DNA methylation has been widely documented in both eukaryotes and prokaryotes (Bird, 2007; Vasu and Nagaraja, 2013). However, its characteristics in *B. cinerea* are still elusive. In this study, we found that 6mA
is a widespread DNA modification in the *B. cinerea* genome. Previous studies have shown that DNA methylation levels are dynamic and controlled by two enzymes, methyltransferase and demethylase (Greer et al., 2015; Zhang et al., 2015). MT-A70 is an important 6mA methyltransferase (Bujnicki et al., 2002). Gray mold contains two homologous methyltransferases, BcMettl4 (Figure 1A) and BcDamt (Figure 1B). As shown in Figure 2D, disruption of *BcMETTL4* but not *BcDAMT* resulted in a decrease in the DNA methylation level of *B. cinerea*, suggesting that BcMettl4 is related to 6mA modification. Previous reports have shown that the signature motif “DNSH/PP/YFW” of 6mA methyltransferase is responsible for substrate binding and catalytic activity (Iyer et al., 2016; Wang et al., 2019). After the mutation of “DPPW” to “APPA,” the methylation level in *B. cinerea* decreased (Figure 5C), demonstrating a catalytic role of “DPPW” in BcMettl4. Consistent with these results, the AMT1 APPA mutant of *Tetrahymena thermophila* had a reduced 6mA level (Wang et al., 2019). Unlike the genome of *B. cinerea*, the genome of *Phytophthora sojae* contains three 6mA methyltransferase genes (*DAMT1, DAMT2, and DAMT3*), and single knockouts of any of these genes in the *P. sojae* strain P6497 resulted in a significant decrease in DNA methylation (Chen et al., 2018).

Using MeDIP-Seq analysis, we identified a large number of 6mA peaks that were distributed in the genome of *B. cinerea*. As shown in Figures 6A,B, 6mA was significantly enriched in upstream and downstream gene regions in both the wild-type strain B05.10 and the disruption mutant ΔBcMettl4. Consistent with our observations, almost all of the 6mA were found in the promoter regions, either at or slightly downstream of the transcription start sites in early-diverging fungi, *Hesseltinella vesiculosa, Absidia repens, Lobosporangium transversale,* and *Syncephalastrum racemosum* (Mondo et al., 2017). Several other studies also revealed that the transcription initiation sites of *Chlamydomonas* (Fu et al., 2015) and *Phytophthora* (Chen et al., 2018) were readily modified by 6mA. In *Arabidopsis*, the 6mA modification level in gene bodies was higher than that of intergenic regions (Liang et al., 2018).
Similar to the result for Arabidopsis, DNA 6mA modification was preferentially distributed in the gene bodies rather than the intergenomic regions in Tetrahymena (Wang et al., 2017). However, 6mA was evenly distributed on chromosomes and correlated with 5mC distribution in rice (Zhou et al., 2018). Inconsistent with the above findings, DNA 6mA modification was significantly enriched in exon regions in the human genome (Xiao et al., 2018). Taken together, the results suggested that the genomic localization pattern of DNA 6mA modification in different species varies greatly, indicating that these modifications are hitherto unknown epigenetic markers.
**Botrytis cinerea** is an important necrotizing pathogen. It has been well documented that cellular accumulation of reactive oxygen species (ROS) is one of the immune responses of plants after infection by pathogens (Kaku et al., 2006; Cheval et al., 2013; Wada et al., 2019). Previous studies have documented that the virulence of pathogens is often related to resistance to oxidative stress (Yan et al., 2011; Yang et al., 2015, 2018). In a previous study, we found that knocking out the catalase BcCAT (BC1G_12146) reduced the toxicity of gray mold (Wang et al., 2020). In this study, BcCAT was downregulated in the disruption mutant ΔBcMettl4 (Supplementary Table 6). We also found that three oxidative stress-related genes, BcCATA (BC1G_01095), BcCAT3 (BC1G_02407), and BcCAT4 (BC1G_09386), were upregulated in ΔBcMettl4 (Supplementary Table 5), which might compensate for the effect of downregulation of BcCAT. After BcMETTL4 was inactivated, two methylated genes, BcFDH and BcTHI, which are related to oxidoreduction, were also downregulated (Figure 7A). Further experiments confirmed that knockout of BcFDH reduced the pathogenicity of B. cinerea (Figure 8B). The disruption of BcFDH severely hindered conidial formation (Figure 8B). The genome of B. cinerea contains 16 genes involved in conidiation (Amselem et al., 2011). We found that only one of them, BcPPOA80 (BC1G_14780), were downregulated when BcMETTL4 was deleted (Supplementary Table 6), indicating that the downregulation of only BcPPOA80 might have little effect on conidial formation. However, it is still completely unknown why the conidial formation was severely hindered when the BcFDH gene was deleted.

Two methylated genes, BcMFS1 and BcMFS2, which are associated with MFS transporters, were downregulated in the mutant ΔBcMettl4 (Figure 7A). After BcMFS2 was deleted, the mutant’s ability to form sclerotia was reduced (Figure 8A). BcSec14 and BcSec31 are involved in vesicle transport, and deletion of BcSec14 and BcSec31 resulted in a reduction in pathogenicity and protein secretion in gray mold (Zhang et al., 2016). It has been well documented that MFS is the largest group of membrane transporters (Law et al., 2008). MFS transporters are also involved in cell secretion and can transport some secondary metabolites and compounds (Vela-Corcía et al., 2019). The polysaccharide components of the cell wall are mainly hydrolyzed into monosaccharides and oligosaccharides by degrading enzymes, thereby reducing the protection of the cell wall against pathogens and increasing the ability of pathogens to infect plants (Cantarel et al., 2009; Kubicke et al., 2014). A cell polysaccharide-degrading enzyme-encoding gene, BcGLU, was found among the downregulated methylated genes (Figure 7A); this gene may be involved in the pathogenicity of B. cinerea. Taken together, these findings suggest that BcMettl4 may regulate pathogenicity via its effect on multiple pathways.

**CONCLUSION**

DNA adenine N6-methylation sites are widely distributed in the genome of B. cinerea. BcMettl4 is nuclear-localized and contains the conserved motif “DPPW,” which is likely related to its interaction with DNA for methylation modification. MeDIP-Seq showed that the regions 2,000 bp upstream and downstream of the genes were preferentially modified by methylation in B. cinerea. BcMETTL4 disruption and mutation of “DPPW” to “APPA” both resulted in a significant reduction in the genomic methylation and pathogenicity of B. cinerea. These observations indicate that 6mA provides potential epigenetic markers in B. cinerea and that BcMettl4 regulates the level of DNA methylation in this important plant pathogen. Our results extend the current understanding of the global regulatory role of 6mA in filamentous plant pathogens.

**DATA AVAILABILITY STATEMENT**

The data has been made available at NCBI with accession numbers PRJNA817858 and PRJNA817835.

**AUTHOR CONTRIBUTIONS**

ZM, GW, and WL contributed to the conception and design of the study. ZM, GW, and XW performed the experiments. ZM, GW, and WL wrote the first draft of the manuscript. GW, WL, and DG reviewed and edited the manuscripts. All authors provided comments on the manuscript and approved the submitted version.
