Detailed study of the quark-antiquark flux tubes and flux tube recombination

Marco Cardoso, Pedro Bicudo, Nuno Cardoso

CFTP, Instituto Superior Técnico

In this work we compute the color fields in the mediator plane between a static quark and a static antiquark using quenched lattice QCD. In special, we see the effect of the quark-antiquark distance on the flux tube. To obtain this results an improved multihit technique is developed and an extend smearing technique is used. Then, we also discuss the flux-tubes in a system composed of two quarks and two antiquarks. The ground and first excited states fields are studied for different dispositions of the system.

1. Introduction

This work is divided in two parts. In the first one we will study an isolated fundamental flux-tube in a quark-antiquark system. In the second one we will study the fields a system made of two quarks and two antiquarks, where we can observe the interaction between two fundamental flux tubes.

2. Chromo-fields computation

To calculate the gauge invariant squared chromoelectric and chromomagnetic fields in the lattice, we only have to calculate the correlation of the Wilson loop operator $W$ which in large euclidean time limit $t \to \infty$ should describe the static system, with the plaquettes corresponding to each one of the fields. Concretely, we have:

$$\langle E_i^2 \rangle = \langle P_{bi} \rangle - \frac{\langle WP_{bi} \rangle}{\langle W \rangle}$$  \hspace{1cm} (1)$$

$$\langle B_i^2 \rangle = \frac{\langle WP_{jk} \rangle}{\langle W \rangle} - \langle P_{jk} \rangle$$  \hspace{1cm} (2)$$

* Presentated at Excited QCD 2012, 6-12 May 2012, Peniche(Portugal)
where $P_{\mu\nu} = 1 - \frac{1}{3} \text{Tr}[U_{\mu}(s)U_{\nu}(s + \mu)U_{\nu}(s + \nu)U_{\mu}^\dagger(s)]$. The spatial indices $j$ and $k$ complement index $i$. The Lagrangian density is given by $L = \frac{1}{2} (E^2 - B^2)$.

3. Fundamental flux-tube

For a simple, quark-antiquark singlet, the Wilson Loop operator $W$ describes the system. We compute the chromo-fields in the mediator plane between the quark and the antiquark, using 1100 pure gauge $32^4$ configurations with $\beta = 6.0$. In order to improve the signal to noise ratio, we use two techniques: an improved version of the multihit [6] and an extended spatial smearing technique.

3.1. Signal to noise ratio improvement

In the multihit method we replace each temporal link by its thermal average, with it’s first neighbors fixed, that is $U_4 \rightarrow \overline{U}_4 = \frac{\int [DU_4] \Omega U_4 e^{\beta \text{Tr}[U_4 F_4^\dagger]}}{\int [DU_4] \Omega e^{\beta \text{Tr}[U_4 F_4^\dagger]}}$.

We generalize this method by replacing each temporal link by it’s thermal average with the $N^{th}$ neighbors fixed, that is:

$$U_4 \rightarrow \overline{U}_4 = \frac{\int [DU] \Omega U_4 e^{\beta \sum_{\mu} \text{Tr}[U_{\mu}(s)F_{\mu}(s)]}}{\int [DU] \Omega e^{\beta \sum_{\mu} \text{Tr}[U_{\mu}(s)F_{\mu}^\dagger]}} \quad (3)$$

In this way we have an error reduction greater than the one of multihit.

To increase the ground state overlap, we use a spatial extended smearing

$$U_i \rightarrow \mathcal{P}_{SU(3)} \left[ U_i + w_1 \sum_j S_{ij}^1 + w_2 \sum_j S_{ij}^2 + w_3 \sum_j S_{ij}^3 \right] \quad (4)$$

with staples $S_{ij}^1$, $S_{ij}^2$ and $S_{ij}^3$ being given on figure 1.

Even using this technique we weren’t able to find a value of $t$ for which the plaquette to Wilson Loop correlators are stable within error bars, while still have a sufficiently high signal to noise ratio. To solve this, we note that the correlator which gives the average of field $\langle F \rangle_t = \langle F \rangle_\infty + b e^{-\Delta t}$ for large values of $t$, with $\Delta = V_1 - V_0$, being the difference between the first excited and the ground state potentials. To compute $\Delta$, we use a variational basis of four levels of APE smearing, with the potentials $V_1$ and $V_0$ being given by the solution of the variational generalized eigensystem

$$\langle W_{ij}(t) \rangle^\text{c}_{ij}(t) = w_n(t) \langle W_{ij}(0) \rangle^\text{c}_{ij}(t) \quad (5)$$
Figure 1. Staples used in the extended spatial smearing.

Figure 2. Left: Lagrangian density in the mediator plane between the quark and the antiquark. Right: Width of the flux tube $w_{1/e}$ as a function of $R$.

where $\langle W_{ij} \rangle = \langle O_i(t)O_j^\dagger(0) \rangle$ is the correlation between the meson annihilation and creation operators at time $t$ and 0 in the smeared states $i$ and $j$ respectively.

3.2. Results and conclusions

The results for the Lagrangian density in the quark-antiquark mediator plane are shown on the left side of Fig. 2. As can be seen the tube flux becomes wider as the quark-antiquark distance is increased. To estimate the width of the flux tube we define the value $w_{1/e}$ by $\langle \mathcal{L} \rangle (w_{1/e}) = \frac{1}{e} \langle \mathcal{L} \rangle (0)$. The results for this are shown on the right side of Fig. 2.

It was predicted [4, 7] that the squared width $w^2$ of this flux tube diverges logaritmically as $R \to \infty$, that is $w^2 \sim w_0^2 \log \frac{R}{R_0}$, where $w^2$. This behavior is called “roughening”. So, we can say that the flux tube roughening has been observed from $R \sim 0.4 \, fm$ to $R \sim 1.2 \, fm$. However, we weren’t yet able to confirm the that the behavior is logarithmic.
Now, we consider a system of two quarks $Q_1, Q_2$ and two antiquarks $\bar{Q}_3, \bar{Q}_4$. The study of this kind of systems is important for the understanding of meson meson scattering processes and the possible formation of tetraquarks, particles made of two valence quarks and two valence antiquarks.

In this system we have two linearly independent color singlets. Those can be, for instance, the two meson states: $|I\rangle = \frac{1}{\sqrt{3}}|Q_i \bar{Q}_j \bar{Q}_j Q_i\rangle$ and $|II\rangle = \frac{1}{\sqrt{3}}|Q_i \bar{Q}_j Q_j \bar{Q}_i\rangle$, or the anti-symmetric and symmetric color states: $|A\rangle = \sqrt{3} \left( |I\rangle - |II\rangle \right)$ and $|S\rangle = \sqrt{\frac{3}{2}} \left( |I\rangle + |II\rangle \right)$. In accordance with lattice results [1, 5], the ground state could be either $|I\rangle$, $|II\rangle$ or $|A\rangle$, with the static potential being given by the flip-flop potential $V_{FF} = \min(V_I, V_{II}, V_T)$, where $V_I$ and $V_{II}$ are the two possible two-meson potentials, given by the sum of the intra-meson potentials, and $V_T$ is the tetraquark potential, which confines all the particles, with the confining part being proportional to the minimal length of a fundamental string linking the four particles.

4.1. Geometries

We use the two geometries, shown in Fig. 3. In both, the four particles form a rectangle, however in one of them — the parallel — similar particles are on the same side of the rectangle while on the other they are on opposite corners — the anti-parallel. With the first one, we can study the tetraquark to mesons transition while with the second we can see the transition between the two meson states.

In this work, we use 1121 Quenched $24^3 \times 48$ lattice configurations with $\beta = 6.2$. APE Smearing was applied to the spatial links, while Hyper-cubic blocking [3] was applied to the temporal links.

Figure 5. Lagrangian density for the ground state of the antiparallel geometry.

4.2. Variational method

To obtain not only the ground state, but also the first excited state, we use a variational basis similar to Eq. (5) but using two different kind of operators. This way, the Wilson loop which appears on Eqs. (1) and (2) is $W_n = c_i^n W_{ij} c_j^n$. The two operator basis will be formed by the $|I\rangle$ and $|II\rangle$ annihilation operators in the anti-parallel geometry and in the parallel geometry, by the $|I\rangle$ and $|A\rangle$ annihilation operators. This gives the matrix elements on Fig. 4.

4.3. Results

The results for the Lagrangian density $L$ in the ground state and the first excited state are given on Figs. 5 and 6. For the ground state the system collapses in a two meson state, when $r_2 \gg r_1$, as expected. Looking at the Wilson loop composition we also conclude that when $r_1 = r_2$ the ground state is color symmetric. The excited state is not so readily explainable. The results for $L$ in the parallel geometry can be seen on Figs. 7 and 8. The results are the expected ones for the ground state, with the system passing from a two meson state to a tetraquark state as we increase $r_2$. We discuss the first excited state in the conclusion.

4.4. Discussion/Conclusion

The results for the ground state are consistent with the flip-flop ground state potential with the color fields dispositions being consistent with $|I\rangle$,
We can explain the excited states if we consider that the vibrational and rotational flux tube excitations effects are negligible. In this case the first excited state is orthogonal to the ground state. In that case, if we compute the Casimir factors for this orthogonal states, as in [2], that they predict the correct behavior of the fields, with a repulsion between particles, where we expect it.
