Abstract

In most versions of beyond the standard model (BSM) physics, the Yukawa couplings of the quarks and charged leptons are not all to the same complex scalar doublet but to different ones. Comparison to the standard model (SM) with only one scalar doublet, using the known mass of the W boson, provides a sum rule constraint on the Yukawa couplings $Y_i$, $i = t, b, \tau, ...$ of the form $\Sigma_i r_i^2 = 1$ where $r_i = Y_i^{(SM)}/Y_i^{(BSM)}$ and the sum is over distinct scalar doublets. The LHC data on the branching ratios $H \rightarrow \gamma\gamma$, $\bar{b}b$, $\tau^+\tau^-$, etc., allows detailed comparison to this sum rule constraint and, as accuracy improves, will constrain or exclude many BSM theories.

Starting with the discovery, in 2012, of the scalar boson $H$ with mass $M_H \simeq 126$ GeV \cite{1} and appropriate CP and spin properties \cite{2,3} underlying the Brout-Englert-Higgs mechanism \cite{4,5} for spontaneously breaking \cite{6} the electroweak $SU(2) \times U(1)$ gauge symmetry, we are now entering a golden age of particle phenomenology, a field which had previously been data-starved for a very long time. In particular, the detailed examination of the properties of $H$ \cite{7-10} can drastically whittle down viable possibilities for constructing theories which go beyond the standard model.

A general characteristic of most models beyond the standard model (BSM) which distinguishes them from the standard model (SM) is that they contain more than one complex scalar doublet. The different flavors of quarks and leptons couple generically not all to the same scalar doublet but to different ones. The detailed pattern of these couplings varies from model to model but we shall take a general approach which includes all possibilities. Namely, we shall first assume that each flavor couples to a different doublet, and then special cases will be degenerate examples of this general case. In the SM, all flavors couple to the same scalar doublet.

The Large Hadron Collider (LHC) has not only made the dramatic discovery of the $H$ boson and finally nailed down its previously-unknown mass but equally importantly opens up the experimental measurement of the detailed couplings of $H$ through its production cross section and especially through its decay modes and partial decay widths. Of special interest here are the couplings of $H$ to fermions. We recall the scandal of the fermion masses that none of the twelve quark and lepton masses have a satisfactory theoretical understanding. These masses are simply parametrized in the SM by Yukawa couplings $Y_i$ where $i = t, b, \tau, \ldots$.

Let us begin by reviewing the situation in the SM. We shall focus on the third generation fermions $t, b,$ and $\tau$ but the generalization to the lighter fermions will be straightforward. The third generation is the most relevant to the LHC experiments.

The corresponding Yukawa couplings of the SM are written

$$\mathcal{L}_{Y}^{(SM)} = \left[ Y_t^{(SM)} \bar{t}t + Y_b^{(SM)} \bar{b}b + Y_{\tau}^{(SM)} \bar{\tau}\tau \right] H + \text{c.c.}$$

in terms of the mass eigenstates. The spontaneous breaking occurs through the BEH mechanism where $H$ develops a vacuum expectation value $< H >$ uniformly throughout the
universe and given by

\[ <H> = V = (\sqrt{2}G_F)^{-1/2} \simeq 246 \text{ GeV}. \] (2)

From Eq. (1), the SM Yukawa couplings

\[ Y_i^{(SM)} = \left( \frac{M_i}{V} \right) \] (3)

for \( i = t, b, \tau \) have the values \( Y_t^{(SM)} \simeq 0.704, Y_b^{(SM)} \simeq 0.0170, \) and \( Y_{\tau}^{(SM)} \simeq 0.00722, \) where we have used \( M_t = 173.07 \) GeV, \( M_b = 4.18 \) GeV, and \( M_{\tau} = 1.77682 \) GeV.

Note that the W mass \( M_W \) is given by

\[ M_W^2 = \left( \frac{g_2^2V^2}{4} \right) = (80.385 \text{ GeV})^2 \] (4)

where \( g_2 \) is the gauge coupling for the \( SU(2) \) factor of the electroweak gauge group.

In a BSM model, the generalization of Eq. (1) involves different H doublet scalar fields and can be written

\[ \mathcal{L}_Y^{(BSM)} = Y_t^{(BSM)} \bar{t}tH_t + Y_b^{(BSM)} \bar{b}bH_b + Y_{\tau}^{(BSM)} \bar{\tau}\tau H_{\tau} + \text{c.c.} \] (5)

and, writing the VEVs as \( <H_i> = V_i \), the generalization of Eq. (3) are now written in the form

\[ Y_i^{(BSM)} = \left( \frac{M_i}{V_i} \right) \] (6)

for \( i = t, b, \tau \).

In such a theory, the W mass is given by a generalization of Eq. (4) to

\[ M_W^2 = \left( \frac{g_2^2}{4} \right) \Sigma_i V_i^2 = (80.385 \text{ GeV})^2 \] (7)

where the sum is over the distinct scalar doublets, \( i.e., \) any of the \( H_i \) fields in Eq. (5) that are identified separately, are included in the sum only once.

Defining

\[ r_i = \left( \frac{Y_i^{(SM)}}{Y_i^{(BSM)}} \right) \] (8)
then using Eqs. (3, 4, 6, 7) one finds the useful sum rule

$$\Sigma_i r_i^2 = 1$$

(9)

where, in any given BSM model, the summation is restricted as discussed following Eq. (7).

One interesting consequence of the sum rule, Eq. (9), is that consistency with experiment requires that

$$|Y_i^{(BSM)}| \geq |Y_i^{(SM)}|$$

(10)

for all $i = t, b, \tau, ...$

There exist a large number of BSM theories in the literature and a majority of the popular ones fall into one of two classes, (I) and (II), as follows proceeding in a direction away from the standard model:

**Class I:** In Eq. (5), the $b$ and $\tau$ scalar doublet are identified, $H_b = H_\tau$.

In this class, the sum rule simplifies to

$$r_t^2 + r_b^2 = r_t^2 + r_\tau^2 = 1 \quad r_b = r_\tau$$

(11)

and it is conventional to parametrize

$$V_t = V \sin \beta \quad V_b = V_\tau = V \cos \beta$$

(12)

Examples of Class I are the minimal supersymmetric standard model (MSSM), the most usual type of two Higgs double model (2HDM), and the Peccei-Quinn model (PQ).

**Class II:** In Eq. (5), the scalar doublets $H_t, H_b, H_\tau$ are all distinct.

In this case, the sum rule is

$$r_t^2 + r_b^2 + r_\tau^2 = 1$$

(13)

and it is convenient to parametrize the VEVs as

$$V_t = V \sin \beta \quad V_b = V \cos \beta \sin \alpha \quad V_\tau = V \sin \beta \cos \alpha$$

(14)
Most renormalizable flavor models using as symmetry $SU(3) \times SU(2) \times U(1) \times G_F$ where $G_F$ is a global flavor symmetry are of this class. Many models of this type have appeared in the literature [11, 12], including in our own work [13].

There are some BSMs that are not constrained by the sum rule Eq. (9). These have extra Higgs doublets, but they do not get VEVs. For example, inert Higgs models [14] can be of this type. See [15] for a recent discussion.

Our purpose here is mainly to present the sum rule constraint Eq. (9) on building BSMs, but we now indicate how one can confront the already existing LHC data with this constraint. Here we give just a few examples and use the present LHC experimental results to demonstrate the procedure. A more complete analysis will be presented elsewhere.

To lowest order the amplitude for $H \rightarrow \tau \bar{\tau}$ is proportional to $Y_\tau$ and so the cross section goes like $(Y_\tau)^2$. Likewise to lowest order the cross section $H \rightarrow b \bar{b}$ goes like $(Y_b)^2$. The CMS and ATLAS experiments quote values for the cross section and compares it with that predicted by the SM. (See [16, 17] for $H \rightarrow \tau \bar{\tau}$ decays and [18, 19] for $H \rightarrow b \bar{b}$.)

| LHC Collaboration | 1σ | 2σ | 3σ |
|-------------------|----|----|----|
| CMS               | 0.952 | 0.719 | 0.581 |
| ATLAS             | 0.562 | 0.400 | - - - |

As an example we now use the 1σ CMS results to extract values for $r_\tau$ and $r_b$. For $m_H = 125$ GeV, the CMS best fit of the observed $H \rightarrow \tau \tau$ signal strength is $(0.78 \pm 0.27)$, which is the ratio of cross section times branching fraction for BSM to the SM $Y_\tau^{SM} = m_\tau/V$ and we use $m_\tau = (1776.82 \pm 0.16)$ MeV. If we ignore branching ratio effects (which is a reasonable first approximation) then we have

$$\sigma(H \rightarrow \tau \bar{\tau})_{\text{expt}} = (0.78 \pm 0.27)\sigma_{SM}$$

1σ (CMS) (15)

where all errors quoted are one standard deviation. We also assume all the difference from the SM is in the Yukawas. Hence we conclude $(Y_\tau)_{\text{expt}} = \sqrt{(0.78 \pm 0.27)} (Y_\tau)^{SM}$ where we identify $(Y_\tau)_{\text{expt}}$ with the BSM Yukawa $(Y_\tau)^{BSM}$. We can also write Eq.(15) as

$$r_\tau^{-2} = 0.78 \pm 0.27$$

1σ (CMS) (16)
and requiring that $r_\tau$ remain within the error bars gives

$$r_\tau^2 \geq 0.95, \quad 1\sigma \text{ (CMS)}$$

thus $r_\tau \geq 0.976$ and $\tan \beta \leq 0.22$.

For $H \rightarrow b\bar{b}$ the CMS signal cross section times branching fraction for $m_H = 125$ GeV is $(1.0 \pm 0.5)$ times the standard model expectation, hence (Using $Y_b^{SM} = m_b/V$ where $m_b = (4.18 \pm .03)$ GeV in the \MS scheme.) $(Y_b)_{\text{expt}} = \sqrt{(1.0 \pm 0.5)(Y_b)_{SM}}$ where as above we identify $(Y_\tau)_{\text{expt}}$ with the BSM Yukawa $(Y_\tau)_{BSM}$. Again we assume the only unknown in the cross section is the Yukawa coupling so that we can also write

$$r_b^{-2} = (1.0 \pm 0.5) \quad 1\sigma \text{ (CMS)}$$

and requiring that $r_b$ remain within the error bars gives

$$r_b^2 \geq 0.66, \quad \text{(CMS)}$$

thus $r_b \geq 0.819$, which corresponds to $\tan \beta \leq 0.70$. Hence the bound on $\beta$ from $H \rightarrow b\bar{b}$ is somewhat weaker than from $H \rightarrow \tau\tau$, but they both will impact Class I BSMs including a variety of 2HDMs \cite{20,21} and various SUSY models \cite{22,23} including MSSM. We stress that we have made approximations that can and will be improved, but it is clear that the sum rule constraint will have teeth. As in the above examples, the $1\sigma$, $2\sigma$ and $3\sigma$ lower limit values of $r_\tau^2$ and $r_b^2$ are calculated from CMS and ATLAS data and are quoted in tables I and II respectively.

Regarding Class II BSMs, even without including $r_t^2$, it is clear that the combined $3\sigma$ CMS result $r_\tau^2 + r_b^2 \geq 0.87$ will begin to be able to constrain models of this Class. Note that CMS results are more restrictive than those of ATLAS in this case, as for most of the discussion in this paper.

**TABLE II. $r_b^2$ lower limits**

| LHC Collaboration | 1σ   | 2σ   | 3σ   |
|-------------------|------|------|------|
| CMS               | 0.658| 0.476| 0.286|
| ATLAS             | 0.909| -    | -    |
Now we proceed to the top Yukawa coupling and $H \to \gamma\gamma$. Since the top is heavier than $M_H/2$ we estimate $Y_t$ using the decay mode $H \to \gamma\gamma$. There are two one-loop contributions to $H \to \gamma\gamma$, a top loop and a $W$ loop. We assume the $W$ loop is known and as in the SM, and the deviation from SM results of the decay width of the Higgs in this channel is all in the top Yukawa $Y_t$. We need to compare the data with the SM calculation [24–26] which has been recently summarized in [27].

This calculation has a venerable history and was first presented in 1976 [24] in a certain limit, then more generally in 1979 [26]. These early results were confirmed much more recently in 2011 [27, 28] in response to a false criticism by [29, 30]. We therefore use the following established formulas from [27], generalized for BSM, where the rate is given by

$$\Gamma(H \to \gamma\gamma) = |F|^2 \left(\frac{\alpha}{4\pi}\right)^2 \frac{G_F m_H^3}{8\sqrt{2}\pi}$$

where the function $F$ for BSMs is given by

$$F = F(\beta_W) + \Sigma_f N_c Q_f^2 r_f^{-1} F(\beta_f)$$

with $\beta_W = \frac{4m_W}{m_H^2}$, $\beta_t = \frac{4m_t}{m_H^2}$. The standard model form of $F$ is recovered by setting $r_f = 1, \forall f$. If we include only the top quark in the sum, with color factor $N_c = 3$ and $Q_t = 2/3$, then

$$F = F(\beta_W) + \frac{4}{3} r_t^{-1} F(\beta_t)$$

where

$$F_W = 2 + 3\beta + 3\beta(2 - \beta)f(\beta),$$

$$F_t = -2\beta[1 + (1 - \beta)f(\beta)]$$

and

$$f(\beta) = \left[\arcsin\left(\frac{1}{\sqrt{\beta}}\right)\right]^2.$$ 

This last expression is valid for $\beta > 1$ as is true for both $\beta_W$ and $\beta_t$. Eq.(20) with $r_t = 1$, as in the SM, is consistent with the observed $H \to \gamma\gamma$ rate. In a Class I model, such as the MSSM, on the other hand, the sums rule constraint together with the $\bar{\tau}\tau$ final state constrain $r_t \geq 0.111$

Substituting the observed masses for $W$, $t$ and $H$ we find that,

$$\frac{F_{BSM}}{F_{SM}} = \frac{8.354 - 1.836 r_t^{-1}}{6.519}$$

7
The ratio of $\Gamma(H \to \gamma\gamma)$ for the BSM vs the SM as a function of $r_t$. The SM is on the curve at the point (1,1).

and thence

$$\frac{\Gamma_{BSM}(H \to \gamma\gamma)}{\Gamma_{SM}(H \to \gamma\gamma)} \leq 1.58 \quad 3\sigma(CMS)$$

which is displayed in Fig. 1.

TABLE III. Upper limits of measured $H \to \gamma\gamma$ rate divided by SM rate.

| LHC Collaboration | 1$\sigma$ | 2$\sigma$ | 3$\sigma$ |
|-------------------|-----------|-----------|-----------|
| CMS               | 1.04      | 1.31      | 1.58      |
| ATLAS             | 1.88      | 2.21      | 2.54      |
The combination of the above results suggests that some MSSM, PQ and Class II models are disfavored.

The next to leading order (NLO) percentage corrections to the decay width $\Gamma(H \rightarrow \gamma\gamma)$ has been calculated \[31\] where it is found that the electroweak and QCD correction are both about 2% but of opposite signs, so they nearly cancel leading to a total correction of less than one percent compared with the leading order calculation.

Although the preliminary LHC data on H decay is presently of limited accuracy, it is nevertheless exciting that it is already enough to dispose of some examples of BSM models.

With the upcoming second run of the LHC, anticipated to begin in 2015 at higher energy and luminosity, one can confidently expect a great improvement in the accuracy of the measurements for the H partial decay modes and hence a better and more detailed check of the constraint sum rule. This heralds a new chapter of particle phenomenology. Constructing viable theories beyond the standard model will become very tightly constrained which is obviously a good thing. There are models with extra Higgs doublets that do not acquire VEVs, like inert Higgs models, that can avoid the sum rule constraint.

To conclude, we have found a sum rule that applies to BSMs that have more than one Higgs doublet with VEVs and Yukawa coupling to light fermions. The sum rule constrains all models of this type including but not limited to a large class of flavor symmetry models, 2HDMs, SUSY models including MSSM.
