Ultrafast switching of photonic entanglement

To deploy and operate a quantum network which utilizes existing telecommunications infrastructure, it is necessary to be able to route entangled photons at high speeds, with minimal loss and signal-band noise, and—most importantly—without disturbing the photons’ quantum state. Here we present a switch which fulfills these requirements and characterize its performance at the single photon level; it exhibits a 200-ps switching window, a 120:1 contrast ratio, 1.5 dB loss, and induces no measurable degradation in the switched photons’ entangled-state fidelity (< 0.002). Furthermore, because this type of switch couples the temporal and spatial degrees of freedom, it provides an important new tool with which to encode multiple-qubit states in a single photon. As a proof-of-principle demonstration of this capability, we demultiplex a single quantum channel from a dual-channel, time-division-multiplexed entangled photon stream, effectively performing a controlled-bit-flip on a two-qubit subspace of a five-qubit, two-photon state.

PACS numbers:

Switching technologies enable networked rather than point-to-point communications. Next-generation photonic quantum networks will require switches that operate with low loss, low signal-band noise, and without disturbing the transmitted photons’ spatial, temporal, or polarization degrees of freedom [1]. Additionally, the switch’s operational wavelength must be compatible with a low-loss, non-dispersive transmission medium, such as standard optical fiber’s 1.3-µm zero-dispersion band [2, 3]. Unfortunately, no previously demonstrated technology [4–15] is capable of simultaneously satisfying each of the above requirements: waveguide electro-optic modulators (EOMs) [10] and resonators [17, 18] can operate at very high speeds (10 GHz) but completely destroy any quantum information stored in the polarization degree of freedom; micro-electromechanical switches [6, 19] do not degrade the photon’s quantum state, but operate at very low speeds (< 250 kHz); polarization-independent EOMs [16] can operate at moderate speeds (~100 MHz) but with relatively high loss; and finally, traditional 1550-nm devices based on nonlinear-optical fiber loops [2, 20] generate unacceptably high levels of Raman-induced noise photons (> 1 in-band noise photon per 100-ns switching window [21]).

Although the requirements for ultrafast entangled-photon switching are collectively daunting, they describe a device that is capable of selectively coupling the spatial and temporal degrees of photonic quantum information. In other words, a device that can encode multiple-qubit quantum states onto a single photon, enabling quantum communication protocols that exploit high-dimensional spatio-temporal encodings. In this Letter we describe the construction and characterization of an all-optical switch which meets each of the aforementioned requirements, and whose aggregate performance (in terms of loss, speed, and in-band noise) exceeds that of all available alternatives [4–20] by orders of magnitude [22]. Moreover, this switch design is scalable: by its extension one can create devices that are capable of coupling many temporal qubits and many spatial qubits. As a proof-of-principle demonstration of this capability, we utilize the switch to perform a controlled-bit-flip operation on a two-qubit subspace of a two-photon, five-qubit system, where a temporally encoded qubit is used as the control and a spatially encoded qubit is used as the target. This operation is used to demultiplex a single quantum channel from a dual-channel, time-division-multiplexed entangled photon stream encoded into the larger five-qubit space.

In order to simultaneously achieve low loss and ultrafast switching, we utilize an all-optical, fiber-based design in which bright 1550-nm pump (C-band) pulses control the trajectory of 1310-nm (O-band) single-photon signals (see Fig. 1(b)). Physically, this switch exploits polarization-insensitive cross-phase modulation (XPM) [23] in a nonlinear-optical loop mirror (NOLM) [24], the reflectivity of which is determined by the phase difference between the clockwise and counter-clockwise propagating paths in a fiber Sagnac interferometer (the “loop”) [25]. To actively control the state of this switch, we initially configure an intra-loop fiber polarization controller such that the loop reflects all incoming photons. Multiplexing a strong 1550-nm pump pulse into the clockwise or counter-clockwise loop path then creates an XPM-induced phase shift on the respective clockwise or counter-clockwise signal amplitude, with a π phase shift causing the switch to transmit all incoming photons. As XPM is inherently polarization dependent, and polarization is often used to encode quantum information, it is important that the pump pulse itself be effectively unpolarized. We accomplish this by temporally overlapping two orthogonally polarized pump pulses, each with a slightly different wavelength [23].

Note that the traditional NOLM-based C-band devices are unsuitable for single-photon switching for two
reasons: Firstly, and most importantly, such switches generate very high levels of Raman-induced back- ground photons at signal wavelengths [21]. These noise photons would swamp any single-photon signals, effectively “washing out” any two-photon quantum correlations. Secondly, traditional NOLM-based devices utilize pump pulses which are group-velocity matched to the signals being switched. While this increases the interaction time, the nonlinear character of the XPM process limits the switching contrast in this type of operation. Because the pump pulse can not be made perfectly square-shaped, the center of the signal pulse receives a stronger nonlinear phase shift than the pulse wings, making it effectively impossible to choose a single pump power which maximizes switching contrast over the entire signal pulse.

Our switch design is immune to each of these two fundamental problems and allows for noiseless, high contrast switching operation. Firstly, the large anti-Stokes detuning (≈35 THz) between the 1550-nm pump pulses and the 1310-nm single-photon pulses reduces contamination of the quantum channels by spontaneous Raman scattering of the pump (≈2 × 10⁻⁷ background photons per ps of signal pulse). Secondly, in standard single-mode fiber (the loop medium) this detuning leads to a large group-velocity difference (≈2 ps/m) between the pump and signal pulses. This allows the switch to operate in a regime where the pump pulse walks completely through the signal’s temporal mode, providing the type of uniform phase-shift which is essential for high-contrast switching operation. The effective phase shift is therefore determined by the total energy in a single pump pulse, regardless of that pulse’s temporal profile. The switching window, \( \tau \), is in turn determined by the length of the fiber between the WDMs, \( L \), multiplied by the speed at which the signal sweeps through the pump (i.e., the group velocity difference between signal and pump). For our case, \( \tau = 1 \times 2 \text{ ps/m} \). The turn-on time of this switching window is set by the temporal extent of the pump pulses (i.e., the time it takes for the pump to physically enter and leave the fiber loop). For 5-nm bandwidth, transform-limited C-band pump pulses, for example, the turn-on time can be as short as 1 ps.

Two key experimental technologies are required to operate and characterize this type of switch: a short-pulse dual-wavelength 1550-nm pump and a source of 1310-nm entangled photons. To create the dual-wavelength pump, two 5-ps duration pulses (1545-nm and 1555-nm wavelengths) are spectrally carved with diffraction gratings from the output of a 50-MHz repetition rate mode-locked fiber laser (IMRA Femtolite Ultra, Model BX-60), which are then multiplexed using a polarization beam combiner (PBC). The power necessary to produce a \( \pi \) phase shift is obtained by amplifying the multiplexed pulses with a cascade of erbium-doped fiber amplifiers (EDFAs). A long-pass filter with a 1543-nm edge is used after each EDFA to ensure that the optical gain is confined to the pump pulses and that no contaminating O-band photons are introduced by the pump preparation process.

The IMRA laser also provides an electrical clock signal for a 1310-nm entangled photon source and an array of four single-photon detectors. The entangled photon source, described in detail in reference [3] and shown in Fig. 11(a), utilizes spontaneous four-wave-mixing in standard single-mode fiber to produce pairs of polarization-entangled photons from 100-ps wide, 50-MHz repetition-rate pump pulses at 1305 nm. After switching, the photon pairs are measured with a correlated photon detection system (Nucrypt LLC, Model CPDS-4) consisting of an array of four InGaAs/InP avalanche photodiodes.

In order to test the switch’s effectiveness for quantum communications, we measured both active and passive switching of polarization-entangled photon pairs. Fig.
shows the switch as integrated into the fiber-based source of entangled photons referenced above. To test multiple switching windows, loop lengths of 500 m (≈900-ps window) and 100 m (≈180-ps window) were used. The insertion loss introduced by these switches in the O-band quantum channel was measured to be 1.3 dB (L = 100 m, port T), 1.7 dB (L = 100 m, port R), 1.7 dB (L = 500 m, port T), and 2.1 dB (L = 500 m, port R). Because all of these directly measured losses include the 0.4 dB or 0.8 dB loss from one or two passes through an optical circulator, the raw switching loss for either transmission or reflection from the switching loop is 0.9 dB (1.3 dB) for the L = 100-m (500-m) loop.

To set a performance benchmark for the switch, unswitched (no pump) entangled photons from port R were characterized using coincidence-basis quantum-state tomography [26, 27]. Both signal and idler photons were analyzed using separate quarter waveplate (QWP), half waveplate (HWP), polarizing beam splitter (PBS) combinations, which together perform arbitrary single qubit measurements. The measured coincidence rates—after subtracting accidental coincidences, a procedure which lowers statistical errors [28]—for 36 combinations of analyzer settings [28] were subjected to a numerical maximum likelihood optimization, which reconstructs the density matrix most likely to have produced the measured results. Figs. 1(c) and 1(d), respectively, show reconstructed density matrices for passively switched (port R) and actively switched (port T) entangled photons, after reflection or transmission through the L = 100-m loop. Similar reconstructions were performed for the L = 500-m loop; in all four cases, the fidelity of the measured state to a maximally-entangled state exceeded 99.0%. In addition, no measurable state degradation resulted from active versus passive switching.

Another important metric for both quantum and classical routers is the switching contrast—or the ratio of power directed to the desired output port divided by the power directed to the complementary output port. Fig. 2(a) shows the single-photon switching contrast as a function of the pump-pulse energy. A contrast of 120:1 is achieved at a pump energy of 2.5 nJ for L = 500 m. Although the switching contrast is expected to be independent of L, the 100-m data does not appear to achieve full contrast—only 43:1. This artifact is due to a long, low-power tail (≈370-ps total pulse width) in the 1305-nm pump pulses used to create the test photons. As a result, the switching window is too short to completely envelop the photon to be switched, resulting in an artifically lower switching contrast for the L = 100-m loop. We expect the true switching contrast to be the same in both cases (≥ 120:1).

Closely related to contrast is the generated single-photon background, from—for example—Raman scattering of the 1550-nm pump pulses. We measured the probability of generating a 1310-nm background photon count and found it to be proportional to L (≈ 4 × 10^{-5}m^{-1}).

In addition to its use as a single-photon router, the switch is a spatio-temporal coupler, enabling the encoding and decoding of quantum information into a temporally multimode Hilbert space, which is, in principle, boundless. The extent to which this Hilbert space can be effectively accessed, however, is determined by the temporal switching profiles of the devices described above. To characterize the shape and width of the switching window, we introduce a relative delay between the signal and the pump pulses. Sweeping this delay while measuring the switched single photons we map the switching window (shown in Fig. 2(b)). Note that the temporal extent of the photons being switched blurs the true switching window. To quantitatively estimate the extent of this blurring, we directly measure the temporal shape of the 1305-nm pump pulses used to create the test photons. We perform this measurement by constructing a third 100-m switch with a switching window of ≈10-ps (full width at half maximum) and the pump pulses. Using the now-characterized 1305-nm classical pump pulses, we re-measure the switching windows while applying a numerical-fit deconvolution to the results. In this way we obtain the instantaneous temporal widths of the 100-m and 500-m switching windows to be 180 ps and 900 ps, respectively.

The switch’s ability to manipulate spatial and temporal quantum information has the potential to enable new quantum communication protocols. As an example of this functionality, we use the switch to demultiplex a single quantum channel from a dual-channel entangled photon stream, on which we encode a five-qubit state (see Fig. 3(a)) defined by signal and idler polarization qubits (|H^s⟩, |V^s⟩), signal and idler temporal qubits (|t^s⟩, |t^i⟩), and an idler spatial qubit (|R⟩)—see Fig. (3(b)). Using this encoding, we create the five-qubit hyper-entangled state |Ψ⟩ = c1|ψ⟩|t^s⟩|t^i⟩|T⟩ + c2|ψ⟩|t^s⟩|t^i⟩|T⟩, where |ψ⟩ = 1/2 (|H⟩|H⟩ + |V⟩|V⟩), |ψ⟩ = 1/2 (|H⟩|H⟩ + |V⟩|V⟩).
\( \frac{1}{\sqrt{2}} (|H\rangle|H\rangle - |V\rangle|V\rangle) \), and \( c_1 \) and \( c_2 \) are arbitrary coefficients. Measuring \( |\Phi\rangle \) using polarization-basis tomography while tracing out temporal degrees of freedom and projecting into the idler spatial mode \( |T\rangle \) will yield a highly mixed state, exactly the result one expects from a simultaneous measurement of multiple entangled quantum channels. A switch capable of implementing a controlled-NOT operation which couples the spatial and temporal qubits (see Fig. 3(a)), however, would exhibit maximal entanglement when projected into the spatial mode \( |T\rangle \), because even after tracing over the temporal degrees of freedom only the maximally entangled polarization state \( |\psi_i\rangle \) would be present.

To implement this proof-of-principle test of the switch’s ability to couple spatial and temporal degrees of freedom, we modify our O-band entangled-photon source [2] by pumping it with a pair of pulses separated by \( \Delta t \equiv t_1 - t_0 \approx 300 \) ps. The polarizations of the leading and trailing pump pulses are chosen such that the unnormalized pump state is \( \sqrt{c_1} (|H\rangle + |V\rangle) t_0 + \sqrt{c_2} (|H\rangle - i|V\rangle) t_1 \) which upon SFWM gives the output signal-idler state \( |\Phi\rangle \). For the demultiplexing test, we choose \( c_1/c_2 \approx 1.25 \) and \( \Delta t \approx 300 \) ps.

Figure 3(b) shows the experimentally measured density matrix for the multiplexed quantum channels. As expected, the state is highly mixed; its fidelity to the nearest maximally entangled state is only 58.9%. Utilizing the 100-m switch we then demultiplex (i.e., actively switch) only the first quantum channel (\( t = t_0 \)), creating the state \( |\Phi\rangle \). As shown in Fig. 3(c), after demultiplexing we are able to recover the high fidelity (98.6%) of the target state to a maximally entangled state. Because the cross-Kerr phase shift has previously been shown to maintain spatial and temporal coherence in NOLM switches [2,20], we anticipate that this switch’s cross-Kerr-based demultiplexing operation is in fact coherent and equivalent to the controlled-NOT operation depicted in Fig. 3(a). Moreover, unlike LOQC-based controlled-NOT gates, this switch is completely deterministic and easily extensible, capable of independently tunable couplings (e.g., controlled-π/4) to many temporal qubits encoded onto the same photon (by changing the control-pulse’s intensity as a function of time). By cascading several switches, it is also possible to couple to multiple spatial qubits.

In conclusion, we have demonstrated the first all-optical switch suitable for single-photon quantum communications. It achieves low-loss (< 1 dB when used to switch between transmitted and reflected modes, < 1.7 dB when combined with a circulator), high-isolation (> 20 dB), and high-speed (< 200 ps) performance without a measurable disturbance to the quantum state of the routed single photons. We demonstrate its ultrafast capability by demultiplexing a single quantum channel from a time-division-multiplexed stream of entangled photons. Very few fundamental limitations apply to this type of switch design. With carefully designed fiber components, one has the potential to dramatically reduce the switch’s loss. In principle the only unavoidable switching losses are fiber transmission losses (0.15–0.2 dB/km) and circulator insertion losses (waveguide-based circulators with a 0.05 dB insertion loss have been designed and simulated [34]). Additionally, decreasing \( L \) to a few meters will reduce the switch’s speed to \( \approx 10 \) ps while simultaneously decreasing the background by an order of magnitude. Even without these improvements, however, this switch represents an important new tool for manipulating spatially- and temporally-encoded quantum information.
