Abstract.
We report the parameter-free, density functional theory calculations of interatomic exchange interactions and Curie temperatures of half-metallic ferrimagnetic full Heusler alloys \( \text{Mn}_2\text{VZ} \) (Z=Al, Ge). To calculate the interatomic exchange interactions we employ the frozen-magnon approach. The Curie temperatures are calculated within the mean-field approximation to the classical Heisenberg Hamiltonian by solving a matrix equation for a multi-sublattice system. Our calculations show that, although a large magnetic moment is carried by Mn atoms, competing ferromagnetic (inter sublattice) and antiferromagnetic (intra sublattice) Mn-Mn interactions in \( \text{Mn}_2\text{VAl} \) almost cancel each other in the mean-field experienced by the Mn atoms. In \( \text{Mn}_2\text{VGe} \) the leading Mn-Mn exchange interaction is antiferromagnetic. In both compounds the ferromagnetism of the Mn subsystem is favored by strong antiferromagnetic Mn-V interactions. The obtained value of the Curie temperature of \( \text{Mn}_2\text{VAl} \) is in good agreement with experiment. For \( \text{Mn}_2\text{VGe} \) there is no experimental information available and our calculation is a prediction.

1. Introduction

The increased interest in the field of spin electronics attracts strong attention to the magnetic systems suitable for the realization of spin injection into a semiconductor [1]. The Heusler alloys are considered as a promising class of materials that can possess the necessary combination of properties. Among the features useful for applications are high Curie temperature, high electron spin polarization at the Fermi level and very small lattice mismatch with widely employed semiconductors [2]. Some of the Heusler compounds were found to have half-metallic ground state [3] characterized by a 100% spin-polarization of the charge carriers. An interesting combination of physical properties makes Heusler alloys the subject of intensive experimental and theoretical investigations [4, 5, 6, 7, 8, 9].

In full Heusler compounds characterized by the formula \( \text{X}_2\text{YZ} \) the Mn atoms usually enter as the Y element. The compounds where Mn assumes the X positions are very rare. Up to our knowledge there are only two systems of this type studied experimentally: \( \text{Mn}_2\text{VAl} \) [10] and \( \text{Mn}_2\text{VGa} \) [11].

Mn$_2$VAl received much experimental and theoretical attention. The neutron diffraction experiment by Itoh et al. [10] gave the ferrimagnetic state of compound with Mn magnetic moment of 1.5±0.3µ$_B$ and V moment −0.9µ$_B$. Jiang et al. examined the magnetic structure of Mn$_2$VAl by X-ray diffraction and magnetization measurements [12]. They found that Mn$_2$VAl was nearly half-metallic with the total magnetic moment of 1.94µ$_B$ at 5 K. The Curie temperature of the sample was found to be about 760 K and the loss of half-metallic character was attributed to the small amount of disorder. The electron structure calculation by Ishida et al. performed within the local-density approximation (LDA) to the density functional theory resulted in a ground state of Mn$_2$VAl close to half-metallicity [13]. Recently a detailed theoretical study of the magnetism of Mn$_2$VAl was reported by Weht and Pickett [14] who used the generalized gradient approximation (GGA) for the exchange correlation potential and have shown that Mn$_2$VAl is a half-metallic ferrimagnet with the atomic moments of 1.5µ$_B$ and -0.9µ$_B$ on Mn and V in very good agreement with experiment. The Fermi level was found to lie in the minority spin band.

The main purpose of the present work is a detailed study of the exchange interactions in two half-metallic Mn$_2$VZ compounds: Mn$_2$VAl and Mn$_2$VGe. (Mn$_2$VGe is not yet synthesized. Its half-metallicity is predicted theoretically [4].) Both intra-sublattice and inter-sublattice exchange interactions are calculated. We show that the pattern of exchange interactions in these systems deviates from the physical picture that can be expected on the basis of the experimental information available. Indeed, the Mn-Mn distance of 2.96Å (3.04Å) in Mn$_2$VAl (Mn$_2$VGe) is substantially smaller than the Mn-Mn distance of about 4Å in the $X_2$Mn$Z$-type Heusler alloys [15]. (For Mn$_2$VGe we use the interatomic distance of Mn$_2$VGa [11].) On the other hand, it is comparable with the Mn-Mn distance in the antiferromagnetic fcc Mn (2.73Å) [16]. According to the Bethe-Slater curve [17] there are physical reasons to expect that smaller distances between the 3d atoms stimulate the formation of the antiferromagnetic structure whereas larger distances make the ferromagnetic structure energetically preferable. Among the Heusler alloys, a smaller distance between pairs of the Mn atoms is obtained in the case of random occupation by Mn and Z atoms of the Y and Z sublattices (see, e.g., the system with the B2-type crystal structure in Ref. [15]). Indeed, the experiment gives for such systems the antiferromagnetic ordering [15]. Therefore in the case of Mn$_2$VAl an antiferromagnetism of the two Mn sublattices can be expected.

Our study shows, however, that the situation is more complex. The nearest-neighbor (nn) Mn–Mn exchange interaction is found to be ferromagnetic whereas the next nn Mn–Mn interaction is antiferromagnetic. As a result the contributions of different Mn atoms into the exchange field experienced by a given Mn atom compensate strongly not giving substantial contribution into the Curie temperature. The main role in the formation of the magnetic structure and the magnetic transition temperature is played by the strong Mn–V exchange interaction. We show that also in Mn$_2$VGe the ferromagnetic ordering of the Mn subsystem is governed by the Mn–V exchange interaction.

The paper is organized as follows. In section II we present the calculational approach. Section III contains the results of the calculations and discussion. Section IV gives the conclusions.
2. Calculational Method

The calculations are carried out with the augmented spherical waves (ASW) method [18] within the generalized gradient approximation (GGA) [19] for the exchange–correlation potential. We use the experimental lattice parameter of Mn$_2$VAl [15, 20]. The radii of all atomic spheres are chosen equal.

We describe the interatomic exchange interactions in terms of the classical Heisenberg Hamiltonian

$$H_{\text{eff}} = -\sum_{\mu,\nu} \sum_{R, R'} J_{RR'}^{\mu\nu} s_{R}^\mu s_{R'}^\nu$$

In Eq. (1), the indices $\mu$ and $\nu$ label different sublattices and $R$ and $R'$ are the lattice vectors specifying the atoms within sublattices, $s_R^\mu$ is the unit vector pointing in the direction of the magnetic moment at site ($\mu, R$). The systems considered contain three 3d atoms in the unit cell (see Fig. 1).

We employ the frozen–magnon approach [21, 22] to calculate interatomic Heisenberg exchange parameters. The calculations involve few steps. In the first step, the exchange parameters between the atoms of a given sublattice $\mu$ are computed. The calculation is based on the evaluation of the energy of the frozen–magnon configurations defined by the following atomic polar and azimuthal angles

$$\theta_R^\mu = \theta, \ \phi_R^\mu = q \cdot R + \phi^\mu.$$  

The constant phase $\phi^\mu$ is always chosen equal to zero. The magnetic moments of all other sublattices are kept parallel to the z axis. Within the Heisenberg model [1] the energy of such configuration takes the form

$$E^{\mu\mu}(\theta, q) = E_0^{\mu\mu}(\theta) + \sin^2 \theta J^{\mu\mu}(q)$$

where $E_0^{\mu\mu}$ does not depend on $q$ and the Fourier transform $J^{\mu\nu}(q)$ is defined by

$$J^{\mu\nu}(q) = \sum_R J_{0R}^{\mu\nu} \exp(iq \cdot R).$$

In the case of $\nu = \mu$ the sum in Eq. (4) does not include $R = 0$. Calculating $E^{\mu\nu}(\theta, q)$ for a regular $q$–mesh in the Brillouin zone of the crystal and performing back Fourier transformation one gets exchange parameters $J_{0R}^{\mu\nu}$ for sublattice $\mu$.

The determination of the exchange interactions between the atoms of two different sublattices $\mu$ and $\nu$ is discussed in Ref. [23].

The Curie temperature is estimated within the mean–field approximation for a multi–sublattice material by solving the system of coupled equations [23, 24]

$$\langle s^\mu \rangle = \frac{2}{3k_B T} \sum_\nu J_0^{\mu\nu} \langle s^\nu \rangle.$$

where $\langle s^\nu \rangle$ is the average z component of $s^\nu_R$ and $J_0^{\mu\nu} \equiv \sum_R J_{0R}^{\mu\nu}$. Eq. (5) can be represented in form of an eigenvalue matrix problem

$$(\Theta - T I) S = 0$$

where $\Theta_{\mu\nu} = \frac{2}{3k_B T} J_0^{\mu\nu}$. $I$ is a unit matrix and $S$ is the vector of $\langle s^\nu \rangle$. The largest eigenvalue of matrix $\Theta$ gives the value of the Curie temperature. [24]
3. Results and Discussion

The crystal structure is presented in Fig. 1. The two Mn sublattices are equivalent. The nearest Mn atoms belong to two different sublattices.

In Table 1 we present calculated magnetic moments. For comparison, the available experimental values of the moments and the results of previous calculations are given. The net magnetic moment per unit cell is $2\mu_B$ for Mn$_2$VAl and $1\mu_B$ for Mn$_2$VGe. The magnetic alignment is ferrimagnetic in both systems. The Mn moments are parallel and assume the values close to $1.5\mu_B$ in Mn$_2$VAl and to $1\mu_B$ in Mn$_2$VGe. The moment of V is close to $-1\mu_B$ in both systems. The values of the moments are in agreement with the results of previous calculations.

The calculated Heisenberg exchange parameters are presented in figures 2 and 3. We obtained a strong dependence of the pattern of the Mn–Mn and V–V exchange
interactions on the type of the Z atom. Similar result was obtained earlier for Ni–based full Heusler alloys [23]. The nearest Mn-Mn distance is half of the lattice constant $a$. The exchange interaction between the nearest Mn atoms is ferromagnetic (Fig. 3). Simultaneous examination of both intra- and inter-sublattice Mn-Mn exchange interactions (Figs. 2, 3) indicates the RKKY-type oscillations.

If only Mn-Mn exchange interactions are considered, in Mn$_2$VAl prevail ferromagnetic interactions while in Mn$_2$VGe the Mn-Mn dominate antiferromagnetic interactions. The corresponding Curie and Neél temperature are given in the second column of table 2.

The interactions between V atoms are very small and can be neglected. The formation of the ferrimagnetic structure with all Mn moments being parallel to each other and the V moments directed oppositely is determined by the strong antiferromagnetic exchange interactions between the nearest Mn and V moments. In Mn$_2$VAl this interaction is 5 times larger than the nearest neighbor Mn–Mn interaction. In Mn$_2$VGe this factor increases to 20. The strong Mn–V antiferromagnetic coupling makes a parallel direction of the Mn moments surrounding a V atom energetically preferable leading to the ferromagnetism of the Mn sublattices. In Mn$_2$VGe this trend overcomes the direct antiferromagnetic Mn–Mn interaction.

In the third column of Table 2 we present the Curie temperature calculated with

![Figure 2. Intra–sublattice Mn–Mn (left-hand part) and V–V (right-hand part) exchange interactions in Mn$_2$VZ (Z=Al and Ge) as a function of the distance given in units of the lattice constant.](image-url)
First-principles study of Heusler alloys $\text{Mn}_2\text{VZ}$ ($Z=\text{Al, Ge}$)

**Figure 3.** Inter-sublattice $\text{Mn}^1-\text{Mn}^2$ (left side) and $\text{Mn}-\text{V}$ (right side) exchange interactions in $\text{Mn}_2\text{VZ}$ ($Z=\text{Al and Ge}$) as a function of the distance given in units of the lattice constant.

**Table 2.** Mean-field estimation of the Curie temperatures for $\text{Mn}_2\text{VZ}$ ($Z=\text{Al, Ge}$). The second (third) column gives the Curie temperature calculated with account for $\text{Mn-Mn}$ ($\text{Mn-V}$) interactions only. In the fourth column both types of interactions are taken into account. The experimental value of Curie temperature for $\text{Mn}_2\text{VAl}$ is taken from Ref.[15].

|         | $T_{c,[\text{Mn-Mn}]}^{\text{MF A}}(K)$ | $T_{c,[\text{Mn-V}]}^{\text{MF A}}(K)$ | $T_{c}^{\text{MF A}}(K)$ | $T_{c}^{\text{Exp}}(K)$ |
|---------|---------------------------------|---------------------------------|-----------------|-----------------|
| $\text{Mn}_2\text{VAl}$ | 30                              | 623                             | 638             | 760             |
| $\text{Mn}_2\text{VGe}$  | 170                             | 488                             | 413             | -               |

The Mn-Mn exchange interaction being neglected. The Curie temperature given in the forth column takes into account both Mn-V and Mn-Mn interactions. It is clearly seen that the main contribution for both systems comes from the Mn-V interaction. In $\text{Mn}_2\text{VAl}$, the correction of $T_c$ due to the Mn-Mn exchange interaction is positive and very small. In $\text{Mn}_2\text{VGe}$, it is negative and amounts to 15%.

In $\text{Mn}_2\text{VAl}$, where the experimental estimation of the Curie temperature is available, both the theoretical and experimental values are in good agreement. The theoretical Curie temperature of $\text{Mn}_2\text{VGe}$ should be considered as prediction.
4. Conclusion

In conclusion, we have systematically studied exchange interactions and Curie temperatures in two half-metallic ferrimagnetic full Heusler alloys Mn$_2$VZ (Z= Al, Ge). The calculations are performed within the parameter–free density functional theory. We show that various Mn–Mn exchange interactions compensate each other and the ferromagnetism of the Mn subsystem is favored by very strong antiferromagnetic Mn–V interactions. Good agreement with experiment is obtained for the Curie temperature of Mn$_2$VAl. We give prediction for the Curie temperature of Mn$_2$VGe.
