High dimensional integration of kinks and jumps
– smoothing by preintegration

Andreas Griewank, Frances Y. Kuo, Hernan Leövey and Ian H. Sloan

August 2017

Abstract

We show how simple kinks and jumps of otherwise smooth integrands over $\mathbb{R}^d$ can be dealt with by a preliminary integration with respect to a single well chosen variable. It is assumed that this preintegration, or conditional sampling, can be carried out with negligible error, which is the case in particular for option pricing problems. It is proven that under appropriate conditions the preintegrated function of $d-1$ variables belongs to appropriate mixed Sobolev spaces, so potentially allowing high efficiency of Quasi Monte Carlo and Sparse Grid Methods applied to the preintegrated problem. The efficiency of applying Quasi Monte Carlo to the preintegrated function are demonstrated on a digital Asian option using the Principal Component Analysis factorisation of the covariance matrix.

1 Introduction

In the present paper we analyse a natural method for numerical integration over $\mathbb{R}^d$, where $d$ may be large, in the presence of “kinks” (i.e. discontinuities in the gradients) or “jumps” (i.e. discontinuities in the function). In this method one of the variables is integrated out in a “preintegration” step, with the aim of creating a smooth integrand over $\mathbb{R}^{d-1}$.

Integrands with kinks and jumps arise in option pricing, because an option is normally considered worthless if the value falls below a predetermined strike price. In the case of a continuous payoff function this introduces a kink, while in the case of a binary or other digital option it introduces a jump.

A simple strategy is to ignore the kinks and jumps, and apply directly a method for integration over $\mathbb{R}^d$. While there has been very significant recent progress in Quasi Monte Carlo (QMC) methods [5] and Sparse Grid (SG) methods [4] for high dimensional integration when the integrand is somewhat smooth, there has been little progress in understanding their performance when the integrand has kinks or jumps.

The performance of QMC and SG methods is degraded in the presence of kinks and jumps, but perhaps not as much as might have been expected, given that in both cases the standard error analysis fails in general for kinks and jumps: the standard assumption in both cases is that the integrand has mixed first partial derivatives for all variables, or at least that it has bounded Hardy and Krause variation over the unit cube $[0,1]^d$, whereas even a straight non-aligned kink (one that is not orthogonal to one of the axes) lacks mixed first partial derivatives even for $d = 2$, and generally exhibits unbounded Hardy and Krause variation on $[0,1]^d$ for $d \geq 3$ [16].

A possible path towards understanding the performance of QMC and SG methods in the presence of kinks and jumps was developed in [9]. That paper studied the terms of the “ANOVA decomposition” of functions with kinks defined on $d$-dimensional Euclidean space $\mathbb{R}^d$, and showed
that under suitable circumstances all but one of the $2^d$ ANOVA terms can be smooth, with the single exception of the highest order ANOVA term, the one depending on all $d$ of the variables. If the “effective dimension” of the function is small, as is commonly thought to be the case in applications, then that single non-smooth term can be expected to make a very small contribution to both supremum and $L_2$ norms. In a subsequent paper [10] the same authors showed, by strengthening the theorems and correcting a mis-statement in [9], that the smoothing of all but the highest order ANOVA term is a reality for the case of an arithmetic Asian option with the Brownian bridge construction.

More precisely, the papers [9] and [10] showed, for a function of the form $f(x) = \max(\phi(x), 0)$ with $\phi$ smooth (so that $f$ generically has a kink along the manifold $\phi(x) = 0$), that if the $d$-dimensional function $\phi$ has a positive partial derivative with respect to $x_j$ for some $j \in \{1, \ldots, d\}$, and if certain growth conditions at infinity are satisfied, then all the ANOVA terms of $f$ that do not depend on the variable $x_j$ are smooth. The underlying reason, as explained in [9], is that integration of $f$ with respect to $x_j$, under the stated conditions, results in a ($d - 1$)-dimensional function that no longer has a kink, and indeed is as often differentiable as the function $\phi$.

Going beyond kinks, we prove in this paper that Theorem 1 in [10] can be extended from kinks to jumps – thus jumps are smoothed under almost the same conditions as kinks. The smoothing occurs even in situations (such as occur in option pricing) where the location of the kink or jump treated as a function of the other $d - 1$ variables moves off to infinity for some values of the other variables.

In this paper we pay particular attention to proving that the presmoothed integrand belongs to an appropriate mixed-derivative function space.

The preintegration method studied in the present paper has appeared as a practical tool under other names in many other papers, including those related to “conditional sampling” (see [7]; the paragraph leading up to and including Lemma 7.2 in [1]; the remark at the end of Section 3 in [2]), and other root-finding strategies for identifying where the payoff is positive (see [11,15]), as well as those under the name “smoothing” (see [3, 19]). In contrast to the cited papers, the emphasis in this paper is on rigorous analysis. Also, we here prefer the description “preintegration” because to us “conditional sampling” suggests a probabilistic setting, which is not necessarily relevant here.

Even for the classical Monte Carlo (MC) method the preintegration step can be useful: to the extent that the preintegration can be considered exact, there is a reduction in the variance of the integrand, by the sum of the variances of all ANOVA terms that involve the preintegration variable $x_j$ (since the ANOVA terms are eliminated because their exact integrals with respect to $x_j$ are all zero). In our numerical experiments that reduction proves to be quite significant.

The problem class and the method are stated in Section 2. Immediately Section 3 gives numerical examples in the context of an option pricing problem with 256 time steps, treated as a problem of integration in 256 dimensions. Section 4 briefly discusses the variance reduction by preintegration for $L_2$ functions. Section 5 focuses on the smoothing effect of preintegration. It gives mathematical background on needed function spaces and states two new smoothing theorems, extended here in a non-trivial way from [10, Theorem 1]. Section 6 applies our theoretical results to the option pricing example. Technical proofs are given in Section 7.

2 The problem and the method

The problem is the approximate evaluation of

$$I_d f := \int_{\mathbb{R}^d} f(x) \rho_d(x) \, dx = \int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} f(x_1, \ldots, x_d) \rho_d(x) \, dx_1 \cdots dx_d,$$  \hspace{1cm} (1)
with
\[ \rho_d(x) := \prod_{k=1}^{d} \rho(x_k), \]
where \( \rho \) is a continuous and strictly positive probability density function on \( \mathbb{R} \) with some smoothness, and \( f \) is a real-valued function integrable with respect to \( \rho_d \).

To allow for both kinks and jumps we assume that the integrand is of the form
\[ f(x) = \theta(x) \text{ind}(\phi(x)), \]
where \( \theta \) and \( \phi \) are somewhat smooth functions, and \text{ind}(\cdot) is the indicator function which gives the value 1 if the input is positive and 0 otherwise. When \( \theta = \phi \) we have \( f(x) = \max(\phi(x), 0) \) and thus we have the familiar kink seen in option pricing through the occurrence of a strike price. When \( \theta \) and \( \phi \) are different (for example, when \( \theta(x) = 1 \)) we have a structure that includes binary digital options.

Our key assumption on \( \phi(x) \) is that it has a positive partial derivative (and so is an increasing function) with respect to some variable \( x_j \), that is, we assume that for some \( j \in \{1, \ldots, d\} \) we have
\[ \frac{\partial \phi}{\partial x_j}(x) > 0 \quad \text{for all} \quad x \in \mathbb{R}^d. \]
In other words \( \phi \) is monotone with respect to \( x_j \).

We also make an assumption about the behavior as \( x_j \to +\infty \). To state this it is convenient, given \( j \in \{1, \ldots, d\} \), to write the general point \( \mathbf{x} \in \mathbb{R}^d \) as \( \mathbf{x} = (x_j, \mathbf{x}_{-j}) \), where \( \mathbf{x}_{-j} \) denotes the vector of length \( d-1 \) denoting all the variables other than \( x_j \). With this notation, a second assumption is that
\[ \lim_{x_j \to +\infty} \phi(x) = \lim_{x_j \to +\infty} \phi(x_j, \mathbf{x}_{-j}) = +\infty \quad \text{for fixed} \quad \mathbf{x}_{-j} \in \mathbb{R}^{d-1}. \]
The latter growth property follows automatically if we assume in addition to (3) that \( (\partial^2 \phi/\partial x_j^2)(\mathbf{x}) \geq 0 \) for all \( \mathbf{x} \in \mathbb{R}^d \). Additional properties at infinity will be assumed in Theorems 2 and 3.

Assuming that the properties (3) and (4) both hold for some \( j \in \{1, \ldots, d\} \), the method is easily described: we write (1) as the repeated integral using Fubini’s theorem
\[ I_d f = \int_{\mathbb{R}^{d-1}} \left( \int_{-\infty}^{\infty} f(x_j, \mathbf{x}_{-j}) \rho(x_j) \, dx_j \right) \rho_{d-1}(\mathbf{x}_{-j}) \, d\mathbf{x}_{-j}, \]
and first evaluate the inner integral for each needed value of \( \mathbf{x}_{-j} \). This is the “preintegration” step. The essential point of the method is that the outer integral can then be evaluated by a standard QMC or SG method, in the knowledge that the integrand for this \((d-1)\)-dimensional integral is smooth.

Looking more closely at the preintegration step, we write the operation of integration with respect to \( x_j \) as
\[ (P_j f)(\mathbf{x}_{-j}) := \int_{-\infty}^{\infty} f(x_j, \mathbf{x}_{-j}) \rho(x_j) \, dx_j. \]
It follows from (2) and (3) that the integrand in this integral has generically a jump at the (unique) point at which \( \phi(x_j, \mathbf{x}_{-j}) \) passes through zero. By the implicit function theorem (see Theorem 6 below) for each \( \mathbf{x}_{-j} \) there is a unique value \( \psi(\mathbf{x}_{-j}) \) of \( x_j \) at which \( \phi(x_j, \mathbf{x}_{-j}) \) passes from negative to positive values with increasing \( x_j \). The preintegration step may then be written as
\[ (P_j f)(\mathbf{x}_{-j}) = \int_{\psi(\mathbf{x}_{-j})}^{\infty} f(x_j, \mathbf{x}_{-j}) \rho(x_j) \, dx_j. \]
An essential ingredient in any implementation of the method is the accurate evaluation of $\psi(x_{-j})$, for each point $x_{-j}$ of the outer integration rule. The semi-infinite integral $P_j f$ may then be evaluated, for each needed point $x_{-j}$, by a standard method for 1-dimensional integrals, for example by a formula of Gauss type. On the other hand, in certain important applications such as option pricing, the integration can be performed in more or less closed form.

The monotonicity condition (3) and the infinite growth condition (4) imply that for fixed $x_{-j}$ the function $\phi(x_j, x_{-j})$ either has a simple root $x_j = \psi(x_{-j})$ or is positive for all $x_j \in \mathbb{R}$. The zero set of $\phi$, denoted by

$$\phi^{-1}(0) := \{ x \in \mathbb{R}^d : \phi(x) = 0 \},$$

is then a hypersurface, i.e., a continuous manifold of dimension $d - 1$. However, its projection onto $\mathbb{R}^{d-1}$ obtained by ignoring the component $x_j$ can be very complicated, even if $\phi$ is highly differentiable.

An example with $d = 2$ and $j = 1$ illustrating the complications that can arise is given by

$$\phi(x_1, x_2) := \begin{cases} \exp(x_1) - x_2^m \sin(1/x_2) & \text{for } x_2 > 0, \\ \exp(x_1) & \text{for } x_2 \leq 0, \end{cases}$$

for some large $m$. Since $\phi(x_1, x_2)$ is monotonically increasing in $x_1$, the explicit solution of $\phi(x_1, x_2) = 0$ is

$$x_1 = \psi(x_2) := m \log(x_2) + \log((\sin(1/x_2))_+) \quad \text{for } x_2 \in U_1,$$

where $z_+ := \max(0, z)$, and

$$U_1 := \{ x_2 \in \mathbb{R} : \phi(x_1, x_2) = 0 \text{ for some } x_1 \in \mathbb{R} \} = \left( \frac{1}{2}, \infty \right) \cup \bigcup_{k \in \mathbb{N}} \left( \frac{1}{(2k+1)\pi}, \frac{1}{2k\pi} \right),$$

while $\phi(x_1, x_2) = 0$ has no solution for $x_2$ in the complicated complementary set

$$U_1^+ := (-\infty, 0] \cup \bigcup_{k \in \mathbb{N}} \left[ \frac{1}{2k\pi}, \frac{1}{(2k-1)\pi} \right].$$

The graph of the zero set $\phi^{-1}(0)$ for $m = 2$ is shown in Figure 1. The solid lines represent the zero set, while the broken lines parallel to the horizontal axis define the boundaries on the $x_2$ axis between subsets of $U_1^+$ for which there is no solution of $\phi(x_1, x_2) = 0$ and subsets of $U_1$ for which there is a solution $x_1 = \psi(x_2)$. The preintegrated version of $f$ given by (2) for any smooth $\theta$ will rather clearly be differentiable on both $U_1$ and $U_1^+$, but it is not obvious that this is the case on the complicated boundary between the two sets. To ensure the necessary differentiability properties it turns out in Section 5 to be necessary to assume that the functions $\theta$ and $\phi$ and their derivatives, when multiplied by the appropriate weight functions, decay sufficiently rapidly as $x_1 = \psi(x_2)$ runs to $-\infty$.

3 Numerical experiments: application to option pricing

In this section we apply the preintegration method to an option pricing example, for which the payoff function is discontinuous.

An important aspect of the method presented in this paper is that the user needs to choose a variable $x_j$ such that the condition (3) is satisfied. In the paper [9] it is shown that for the
standard and Brownian bridge constructions for path simulation of Brownian motions every choice of the variable $x_j$ will be suitable. More interesting for the present paper is the popular Principal Component Analysis (or PCA) method of constructing the Brownian motion [6]: for this case the only result known to us, from [8, Section 5], is that the property (3) is guaranteed if $x_j$ is the variable that corresponds to the largest eigenvalue of the Brownian motion covariance matrix. For this reason it is of particular interest to apply the present theory to the PCA case, as we do below.

For our tests, we consider now the example of an arithmetic average digital Asian option. We assume that the underlying asset $S_t$ follows the geometric Brownian motion model based on the stochastic differential equation

$$dS_t = rS_t \, dt + \sigma S_t \, dW_t,$$

(7)

where $r$ is the risk-free interest rate, $\sigma$ is the (constant) volatility and $W_t$ is the standard Brownian Motion. The solution of this stochastic equation can be given as

$$S_t = S_0 \exp \left( \left( r - \frac{\sigma^2}{2} \right) t + \sigma W_t \right).$$

(8)

The problem of simulating asset prices can be reduced to the problem of simulating discretized Brownian motion paths taking values $W_{t_1}, \ldots, W_{t_d}$, where $d$ is the number of time steps taken in the discretization of the continuous time period $[0, T]$. In our tests, the asset prices are assumed to be sampled at equally spaced times $t_\ell := \ell \Delta t$, $\ell = 1, \ldots, d$, where $\Delta t := T/d$. The Brownian motion is a Gaussian process, therefore the vector $(W_{t_1}, \ldots, W_{t_d})$ is normally distributed, and in this particular case is a vector with mean zero and covariance matrix $C$ given by

$$C = \left( \min(t_\ell, t_k) \right)_{\ell, k=1}^d.$$

The value of an arithmetic average digital Asian call option is

$$V = \frac{e^{-rT}}{(2\pi)^{d/2} \sqrt{\det(C)}} \int_{\mathbb{R}^d} \operatorname{ind}\left( \frac{1}{d} \sum_{\ell=1}^d S_{t_\ell}(w_\ell) - K \right) e^{-\frac{1}{2} w^\top C^{-1} w} \, dw,$$

with $w = (W_{t_1}, \ldots, W_{t_d})^\top$. After a factorization $C = AA^\top$ of the covariance matrix is chosen (for the choice of $A$ is not unique), we can rewrite the integration problem using the substitution
\[ w = Ax \text{ as} \]
\[
V = \frac{e^{-rT}}{(2\pi)^{d/2}} \int_{\mathbb{R}^d} \text{ind} \left( \frac{1}{d} \sum_{\ell=1}^{d} S_{t_\ell}(Ax)_\ell - K \right) e^{-\frac{1}{2}x^\top x} \, dx.
\]

The new variable vector \( x = (x_1, \ldots, x_d)^\top \) can be assumed to consist of independent standard normally distributed random variables. Then the identity \( w = Ax \) defines a construction method for Brownian paths. We therefore have an integral of the form (1)–(2) with \( \rho(x) = e^{-x^2/2\pi} \), \( \theta(x) = e^{-rT} \), and

\[
\phi(x) = \frac{S_0}{d} \sum_{\ell=1}^{d} \exp \left( \frac{r - a^2}{2} \ell \Delta t + \sigma \sum_{k=1}^{d} A_{\ell k} x_k \right) - K. \tag{9}
\]

We use in our experiments the PCA factorization of \( C \), which is based on the orthogonal factorization

\[
C = (u_1; \ldots; u_d) \text{diag}(\lambda_1, \ldots, \lambda_d) (u_1; \ldots; u_d)^\top,
\]

where the eigenvalues \( \lambda_1, \ldots, \lambda_d \) (all positive) are given in non-increasing order, with corresponding unit-length column eigenvectors \( u_1, \ldots, u_d \), and as a result

\[
A = (\sqrt{\lambda_1} u_1; \ldots; \sqrt{\lambda_d} u_d).
\]

Note that we have \( A_{i1} > 0 \) for \( 1 \leq \ell \leq d \) because the elements of the eigenvector \( u_1 \) are all positive.

For approximate integration with quadrature, we generate randomized QMC or MC samples \( x^{(1)}, \ldots, x^{(N)} \) over \( \mathbb{R}^d \) by first generating classical randomized QMC or MC samples over unit cube \( (0, 1)^d \), and then transforming them to \( \mathbb{R}^d \) using in each coordinate the univariate inverse normal cumulative distribution function \( \Phi^{-1}(\cdot) \). The randomized QMC points over \( (0, 1)^d \) are obtained by first generating Sobol’ points over \( [0, 1]^d \) with direction numbers taken from [12], and then applying the random linear-affine scrambling method as proposed by Matousek [14] (as implemented in the statistics toolbox of MATLAB). Note that taking randomly scrambled Sobol’ points not only allows us to generate statistically independent QMC samples, but also allows us to avoid in practice having points lying on the boundary of \( (0, 1)^d \) (which is usually the case for non-randomized QMC points), since the boundary is sampled with zero probability. The MC points were taken from the Mersenne Twister PRNG. For the function \( \Phi^{-1}(\cdot) \), we have used Moro’s algorithm [6]. The matrix \( A \) can be given explicitly [8], but more importantly, each matrix-vector multiplication \( Ax^{(i)} \), \( 1 \leq i \leq N \) can be done with \( O(d \log d) \) cost by means of the fast-sine transform [17] (as long as time steps for discretization are taken of equal size).

For the preintegration approach, we generate randomized QMC or MC points over \( [0, 1]^{d-1} \), following the procedure for the \( d \)-dimensional case, and so obtain \( N \) sample points over \( \mathbb{R}^{d-1} \). We then evaluate the paths without using the first variable \( x_1 \), i.e., we sample over the coordinates \( x_2, \ldots, x_d \). Once a sample point on these coordinates is fixed, the resulting problem is a one-dimensional integral on the variable \( x_1 \). We take then the approximation

\[
V \approx Q_{N,d-1}(P_1(f)) = P_1(Q_{N,d-1}(f)) = \frac{1}{N} \sum_{i=1}^{N} \int_{-\infty}^{\infty} f(\xi, x^{(i)}) \rho(\xi) \, d\xi,
\]

where the quadrature with respect to \( \xi \) is to be carried out for each of the \( N \) sample points \( x^{(i)} \) in \( \mathbb{R}^{d-1} \). In the PCA case in this problem, the resulting \( N \) univariate integrals can be calculated in terms of the normal cumulative distribution function by completing squares and identifying the points \( \xi^{(i)}_*, 1 \leq i \leq N \) (if they exist), where we have \( \frac{1}{d} \sum_{\ell=1}^{d} S_{t_\ell}(A(\xi^{(i)}_*, x^{(i)} +)\ell) = K \). Finding the
points $\xi^{(i)}, 1 \leq i \leq N$, is not a difficult numerical task since each of them can be obtained as the root of an equation defined by a univariate convex function, for which Newton’s method converges in few steps to a satisfactorily accurate solution.

The parameters in our tests were fixed to $K = 100, S_0 = 100, r = 0.1, \sigma = 0.1, T = 1$. We summarize our numerical experiments in Figure 2. In the figure we show the box-plots of the log$_{10}$ of relative root mean square error (RMSE), each obtained from 10 independent random replications, with PCA factorization of covariance matrix for the arithmetic average digital Asian option. Results are shown in four groups containing three box-plots each. Each group corresponds to one of the following method: in order, MC, QMC, MC with preintegration and QMC with preintegration. In each group we have three box-plots to characterize the error convergence, each box-plot containing RMSE sampled with a given sample size. For all integration methods we chose the sample sizes $N = 2^{12}, 2^{14}, 2^{16}$. Note that for MC and QMC we generate samples over $\mathbb{R}^d$, while for the preintegration MC and QMC we generate samples only over $\mathbb{R}^{d-1}$.

The results show that randomized QMC exhibits higher convergence than MC, but the convergence rate is still not optimal ($\sim N^{-0.6}$). When we combine the preintegration method with MC, we observe an improvement in the implied error constant, as predicted, but the convergence rate remains the same as MC ($= N^{-0.5}$), of course it should. Combining the preintegration method with randomized QMC reduces the error satisfactorily, and improves the convergence rate to close to the best possible rate $N^{-1.0}$.

4 Variance reduction by preintegration

In this section we consider the space $L_{2,\rho_d}$ of square-integrable functions on $\mathbb{R}^d$, with $\rho_d$-weighted $L_2$ inner product and norm.

The preintegration step (5) can be viewed more generally as a projection, which is the key operation underlying the well-known ANOVA decomposition. For a general function $g \in L_{2,\rho_d}$ the
ANOVA decomposition takes the form [18]

\[ g = \sum_{u \subseteq \mathcal{D}} g_u, \quad (10) \]

where the sum is over all the \(2^d\) subsets of \(\mathcal{D} := \{1, \ldots, d\}\), and each term \(g_u\) depends only on the variables \(x_k\) with \(k \in u\), and with the additional property that the projection operator \(P_k\) defined by (as in (5))

\[ (P_k g)(x_{-k}) := \int_{-\infty}^{\infty} g(x_k, x_{-k}) \rho(x_k) \, dx_k \]

annihilates all ANOVA terms \(g_u\) with \(k \in u\):

\[ P_k g_u = 0 \quad \text{for} \quad k \in u, \quad \text{whereas} \quad P_k g_u = g_u \quad \text{for} \quad k \notin u. \quad (11) \]

The ANOVA terms can be written explicitly as [13]

\[ g_u = \sum_{v \subseteq u} (-1)^{|u| - |v|} \left( \prod_{k \notin v} P_k \right) g. \]

It follows from (11), since \(I_d\) involves integration with respect to every variable \(x_k\) for \(k \in \mathcal{D}\), that

\[ I_d g = g_{\emptyset}. \]

Another consequence is that the ANOVA terms are orthogonal in \(L^2_{\rho_d}\),

\[ \int_{\mathbb{R}^d} g_u(x) g_v(x) \rho_d(x) \, dx = 0 \quad \text{for} \quad u \neq v. \]

As a result, the variance of \(g\) has the well known property that it is a sum of the variances of the separate ANOVA terms,

\[ \sigma^2(g) = \sum_{\emptyset \neq u \subseteq \mathcal{D}} \sigma^2(g_u), \quad (12) \]

where

\[ \sigma^2(g) := \int_{\mathbb{R}^d} g^2(x) \rho_d(x) \, dx - g_{\emptyset}^2 \quad \text{and} \quad \sigma^2(g_u) = \int_{\mathbb{R}^d} g_u^2(x) \rho_d(x) \, dx \quad \text{for} \quad u \neq \emptyset. \]

With these preparations, we are now ready to make a simple observation that preintegration is a variance reduction strategy for any general \(L^2\) function, not specific to our functions with kinks or jumps. This explains why the preintegration strategy improves the performance of MC methods.

**Lemma 1** The projection \(P_k\) reduces the variance of \(g\) for all \(g \in L^2_{\rho_d}\) and all \(k \in \mathcal{D}\).

**Proof.** For any \(g \in L^2_{\rho_d}\) and any \(k \in \mathcal{D}\), it follows from (10) and (11) that

\[ P_k g = \sum_{k \notin u \subseteq \mathcal{D}} g_u, \]

that is, the operation \(P_k\) applied to \(g\) has the effect of annihilating those ANOVA terms \(g_u\) of \(g\) with \(k \in u\). As a result, the ANOVA terms of the resulting function \(P_k g\) are precisely the ANOVA terms \(g_u\) of \(g\) for which \(k \notin u\). Hence we have

\[ \sigma^2(P_k g) = \sum_{k \notin u \subseteq \mathcal{D}, u \neq \emptyset} \sigma^2(g_u). \quad (13) \]

The result follows by comparing (13) with (12). \(\square\)
5 Smoothing by preintegration

In this section we first slightly generalize the mathematical setting from [9], providing some details on Sobolev spaces and weak derivatives which are needed for the formulation of our main smoothing theorems. Then we establish two new smoothing theorems for these Sobolev spaces, extending [10, Theorem 1] from kink to jumps.

5.1 Sobolev spaces with generalized weight functions

Following [9, Section 2.2], for \( j \in \mathcal{D} \) let \( D_j \) denote the partial derivative operator

\[
(D_j g)(x) = \frac{\partial g}{\partial x_j}(x).
\]

Throughout this paper, the term multi-index refers to a vector \( \alpha = (\alpha_1, \ldots, \alpha_d) \) whose components are nonnegative integers, and we use the notation \( |\alpha| = \alpha_1 + \cdots + \alpha_d \) to denote the sum of its components. For any multi-index \( \alpha = (\alpha_1, \ldots, \alpha_d) \), we define

\[
D^\alpha = \prod_{j=1}^d D_j^{\alpha_j} = \prod_{j=1}^d \left( \frac{\partial}{\partial x_j} \right)^{\alpha_j} = \frac{\partial|\alpha|}{\prod_{j=1}^d \partial x_j^{\alpha_j}}, \quad \text{(14)}
\]

and we say that the derivative \( D^\alpha f \) is of order \( |\alpha| \).

Let \( \mathcal{C}(\mathbb{R}^d) = C^0(\mathbb{R}^d) \) denote the linear space of continuous functions defined on \( \mathbb{R}^d \). For a nonnegative integer \( r \geq 0 \), we define \( \mathcal{C}^r(\mathbb{R}^d) \) to be the space of functions whose classical derivatives of order \( \leq r \) are all continuous at every point in \( \mathbb{R}^d \), with no limitation on their behavior at infinity. For example, the function \( g(x) = \exp(\sum_{j=1}^d x_j^2) \) belongs to \( \mathcal{C}^r(\mathbb{R}^d) \) for all values of \( r \). For convenience we write \( \mathcal{C}^\infty(\mathbb{R}^d) = \cap_{r \geq 0} \mathcal{C}^r(\mathbb{R}^d) \).

In addition to classical derivatives, we shall need also weak derivatives. By definition, the weak derivative \( D^\alpha g \) is a measurable function on \( \mathbb{R}^d \) which satisfies

\[
\int_{\mathbb{R}^d} (D^\alpha g)(x) v(x) \, dx = (-1)^{|\alpha|} \int_{\mathbb{R}^d} g(x) (D^\alpha v)(x) \, dx \quad \text{for all } v \in \mathcal{C}^\infty_0(\mathbb{R}^d), \quad \text{(15)}
\]

where \( \mathcal{C}^\infty_0(\mathbb{R}^d) \) denotes the space of infinitely differentiable functions with compact support in \( \mathbb{R}^d \), and where the derivatives on the right-hand side of (15) are classical partial derivatives. It can be shown, using the definition (15), that \( D_j D_k = D_k D_j \) for all \( j, k \in \mathcal{D} \), thus the ordering of the weak first derivatives that make up \( D^\alpha \) in (14) is irrelevant.

If \( g \) has classical continuous derivatives up to order \( |\alpha| \), then they satisfy (15), which in the classical sense is just the integration by parts formula on \( \mathbb{R}^d \). Unless stated otherwise, the derivatives in this paper are weak derivatives, which in principle allows the possibility that they are defined only “almost everywhere”. However, a recurring theme is that our weak derivatives are shown to be continuous (or strictly, can be represented by continuous functions), in which case the weak derivatives are at the same time classical derivatives.

We now turn to the definition of the function spaces. For \( p \in [1, \infty] \), we first define weighted \( \mathcal{L}_p \) norms:

\[
\|g\|_{\mathcal{L}_p, \tilde{\rho}_d} = \begin{cases} 
\left( \int_{\mathbb{R}^d} |g(x)|^p \tilde{\rho}_d(x) \, dx \right)^{1/p} & \text{if } p \in [1, \infty), \\
\text{ess sup}_{x \in \mathbb{R}^d} |g(x)| & \text{if } p = \infty
\end{cases}
\]

where \( \tilde{\rho}_d \) is a positive integrable function on \( \mathbb{R}^d \).
When dealing with function spaces of derivatives of a function \( g \), it turns out to be convenient to allow flexibility in the choice of weight function \( \rho_d \). We therefore generalize the setting in [9] and introduce a family \( \zeta_{d,\alpha} \) of such weight functions, one for each derivative \( D^\alpha \), given by

\[
\zeta_{d,\alpha}(x) := \prod_{k=1}^{d} \zeta_{\alpha_k}(x_k),
\]

where \( \{\zeta_i\}_{i \geq 0} \) is a sequence of continuous integrable functions on \( \mathbb{R} \), satisfying

\[
\rho(x) = \zeta_0(x) \leq \zeta_1(x) \leq \zeta_2(x) \leq \cdots \quad \text{for all } x \in \mathbb{R}.
\]

The intuitive idea is that higher derivatives with respect to every coordinate need to be limited in their growth towards infinity by making \( \zeta_i \) decay more slowly for larger order of derivatives \( i \).

With these generalized weight functions \( \zeta_{d,\alpha} \), denoted collectively by \( \zeta \), we consider two kinds of Sobolev space: the isotropic Sobolev space with smoothness parameter \( r \geq 0 \), for \( r \) a nonnegative integer,

\[
W_{d,p,\zeta}^r = \{ g : D^\alpha g \in L_{p,\zeta_{d,\alpha}} \quad \text{for all } |\alpha| \leq r \},
\]

and the Sobolev space of dominating mixed smoothness with smoothness multi-index \( r = (r_1, \ldots, r_d) \),

\[
W_{d,p,\zeta_{mix}}^r = \{ g : D^\alpha g \in L_{p,\zeta_{d,\alpha}} \quad \text{for all } \alpha \leq r \},
\]

where \( \alpha \leq r \) is to be understood as \( \alpha = (\alpha_1, \ldots, \alpha_d) \) with \( \sum_{i=1}^{d} \alpha_i \leq r \), and the derivative \( \alpha \) is weak derivatives. For convenience we also write \( W_{d,p,\zeta}^0 = L_{p,\rho_d} \) and \( W_{d,p,\zeta}^\infty = \cap_{r \geq 0} W_{d,p,\zeta}^r \). Analogously, we define \( C_{mix}^r(\mathbb{R}^d) \) to be the space of functions \( g \) whose classical derivatives \( D^\alpha g \) with \( \alpha \leq r \) are all continuous at every point in \( \mathbb{R}^d \), with no limitation on their behavior at infinity.

The norms corresponding to the two kinds of Sobolev space can be defined, for example, as in the classical sense, by

\[
\|g\|_{W_{d,p,\zeta}^r} = \left( \sum_{|\alpha| \leq r} \|D^\alpha g\|_{L_{p,\zeta_{d,\alpha}}}^2 \right)^{1/2} \quad \text{and} \quad \|g\|_{W_{d,p,\zeta_{mix}}^r} = \left( \sum_{\alpha \leq r} \|D^\alpha g\|_{L_{p,\zeta_{d,\alpha}}}^2 \right)^{1/2}.
\]

We have the following relationships between the spaces:

(i) \( W_{d,p',\zeta}^r \subseteq W_{d,p,\zeta}^r \) and \( W_{d,p',\zeta_{mix}}^r \subseteq W_{d,p,\zeta_{mix}}^r \) for \( 1 \leq p \leq p' \leq \infty \).

(ii) \( W_{d,p,\zeta_{mix}}^r \subseteq W_{d,p,\zeta}^r \iff \min_{j \in \mathbb{Z}^d} r_j \geq r \) and \( W_{d,p,\zeta}^r = \cap_{|r|=r} W_{d,p,\zeta_{mix}}^r \).

(iii) \( W_{d,p,\zeta_{mix}}^s \subseteq W_{d,p,\zeta}^r \iff s \geq r \) and \( W_{d,p,\zeta_{mix}}^r \subseteq W_{d,p,\zeta_{mix}}^s \iff r \geq s d \).

(iv) \( W_{d,p,\zeta}^r \subseteq C^k(\mathbb{R}^d) \) if \( r > k + d/p \) (Sobolev embedding theorem).

(v) For \( p \in [1, \infty) \) and \( r \geq 1 \), if \( g \in W_{d,p,\zeta}^r \) then \( D^\alpha g \in W_{d,p,\zeta}^{r-|\alpha|} \) for all \( |\alpha| \leq r \).

(vi) For \( p \in [1, \infty) \) and \( r \geq 1 \), if \( g \in W_{d,p,\zeta}^r \) then \( D^\alpha g \in W_{d,p,\zeta}^{r-|\alpha|} \) for all \( \alpha \leq r \).

Properties (i)–(iv) are straightforward. Properties (v) and (vi) are a bit more involved due to the varying generalized weight functions considered here. Indeed, when \( \alpha \) is a multi-index satisfying \( 0 \leq |\alpha| \leq r - |\alpha| \), we have

\[
\|D^{\overline{\alpha}}(D^\alpha g)\|_{L_{p,\zeta_{d,\overline{\alpha}}}} = \left( \int_{\mathbb{R}^d} |(D^{\overline{\alpha}}(D^\alpha g))(x)|^p \zeta_{d,\overline{\alpha}}(x) \, dx \right)^{1/p} \leq \left( \int_{\mathbb{R}^d} |D^{\tilde{\alpha}} g(x)|^p \zeta_{d,\tilde{\alpha}}(x) \, dx \right)^{1/p} = \|D^{\tilde{\alpha}} g\|_{L_{p,\zeta_{d,\tilde{\alpha}}}} < \infty,
\]
where we introduced $\hat{\alpha} := \alpha + \alpha$ and we used $\zeta_d,\hat{\alpha}(x) \leq \zeta_d,\hat{\alpha}(x)$ since $\alpha \leq \hat{\alpha}$. The finiteness in the final step follows from $g \in \mathcal{W}_{d,\rho,\zeta}^r$ and $|\hat{\alpha}| \leq r$. This justifies (v). The argument can easily be modified to justify (vi).

5.2 New smoothing theorems

In this subsection we establish two smoothing theorems: one for the isotropic Sobolev space, the other for the mixed Sobolev space. The proofs are modeled on the proof of [10, Theorem 1], but are extended here to cover discontinuous integrands.

**Theorem 2 (Result for the isotropic Sobolev space with weight functions $\zeta_{d,\alpha}$)*** Let $d \geq 2$, $r \geq 1$, $p \in [1, \infty)$, and let $\rho \in C^{r-1}(\mathbb{R})$ be a strictly positive probability density function. Let

$$f(x) := \theta(x) \text{ind}(\phi(x)), \quad \text{where} \quad \theta, \phi \in \mathcal{W}_{d,\rho,\zeta}^r(\mathbb{R}^d),$$

with generalized weight functions $\zeta_{d,\alpha}$ satisfying (16) and (17), and with $\text{ind}(\cdot)$ denoting the indicator function. Let $j \in \mathcal{D} := \{1, \ldots, d\}$ be fixed, and suppose that

$$(D_j\phi)(x) > 0 \quad \forall x \in \mathbb{R}^d, \quad \text{and} \quad \phi(x) \to \infty \quad \text{as} \quad x_j \to \infty \quad \forall x_{-j} \in \mathbb{R}^{d-1}. \quad (18)$$

Writing $y := x_{-j}$ so that $x = (x_j, y)$, let

$$U_j := \{y \in \mathbb{R}^{d-1} : \phi(x_j, y) = 0 \text{ for some } x_j \in \mathbb{R}\} \quad \text{and} \quad U_j^+ := \mathbb{R}^{d-1} \setminus U_j, \quad (21)$$

If $U_j$ is empty, then $f = \theta$. If $U_j$ is not empty, then $U_j$ is open, and there exists a unique function $\psi \equiv \psi_j \in C^r(U_j)$ such that $\phi(x_j, y) = 0$ if and only if $x_j = \psi(y)$ for $y \in U_j$. In the latter case we assume that every function of the form

$$h(y) = \frac{(D^n\theta)(\psi(y), y) \prod_{i=1}^a ([D_i\phi](\psi(y), y))^b}{[(D_j\phi)(\psi(y), y)]^b} \rho^c(\psi(y)), \quad y \in U_j, \quad (19)$$

where $a, b, c$ are integers and $\gamma^{(i)}$, $\eta$ are multi-indices with the constraints

$$1 \leq a, b \leq 2r - 1, \quad 1 \leq |\gamma^{(i)}| \leq r, \quad 0 \leq |\eta|, c \leq r - 1, \quad 1 \leq |\gamma^{(i)}| + |\eta| + c \leq r,$$

satisfies both

$$h(y) \to 0 \quad \text{as} \quad y \text{ approaches a boundary point of } U_j \text{ lying in } U_j^+, \quad (20)$$

and

$$\int_{U_j} |h(y)|^p \zeta_{d-1,\alpha_{-j}}(y) \, dy < \infty, \quad \text{for all } |\alpha| \leq r \text{ with } \alpha_j = 0, \quad (21)$$

where $\alpha_{-j}$ denotes the multi-index with $d-1$ components obtained from $\alpha$ by leaving out $\alpha_j$. Then

$$P_j f \in \mathcal{W}_{d-1,\rho,\zeta}^r \cap C^r(\mathbb{R}^{d-1}).$$

**Proof.** We defer the proof of this theorem to Section 7. \qed

In effect, under the conditions in the theorem, the single integration with respect to $x_j$ is sufficient to ensure that $P_j f$ inherits the full smoothness of $\theta$ and $\phi$.

We remark that when $\theta = \phi$ we are back at the same function $f(x) = \max(\phi(x, 0))$ as considered in [10, Theorem 1]. However, for this case we see that the new result is not as sharp as the old one in
the sense that the upper bounds on the values of $a$, $b$, $c$, $|\gamma^{(i)}|$ in the condition (19) are larger than those in [10, Theorem 1]. This is because the explicit prior knowledge of $\theta = \phi$ means that we know a certain term vanishes (precisely, the second term on the right-hand side of [10, Formula (11)]). This observation also indirectly explains how the new result for jumps require stronger conditions on the functions $\theta$, $\phi$ and $\rho$ than the corresponding result for kinks.

The conditions (20) and (21) in the theorem are difficult to verify directly because the function $h$ depends explicitly on the inverse function $\psi(y)$. Fortunately, a sufficient condition for (20) to hold is that

$$\left| \frac{(D^n\theta)(x_j, y) \prod_{i=1}^n [(D^{\gamma^{(i)}})(x_j, y)]}{[(D\phi)(x_j, y)]^b} \rho^{(c)}(x_j) \right| \leq E_1(x_j) E_2(y), \quad (22)$$

where $E_1, E_2$ are positive functions satisfying

- $E_1$ is bounded and $E_1(x_j) \to 0$ as $x_j \to -\infty$,
- $E_2$ is locally bounded (bounded over compact sets) and $\int_{R_{d-1}} |E_2(y)|^p \zeta_{d-1, \alpha-j}(y) dy < \infty$ for all $|\alpha| \leq r$.

Considering a point $y^*$ on the boundary $\Gamma(U_j) \subset U_j^+$, and a sequence $(y_n)_{n \in N} \subset U_j$ such that $y_n \to y^*$, we see that $E_2(y_n)$ is bounded and $E_1(\psi(y_n)) \to 0$ since $\psi(y_n) \to -\infty$. Therefore (22) is sufficient for (20). Moreover, for $|\alpha| \leq r$ we have

$$\int_{U_j} \left| \frac{(D^n\theta)(\psi(y), y) \prod_{i=1}^n [(D^{\gamma^{(i)}})(\psi(y), y)]}{[(D\phi)(\psi(y), y)]^b} \rho^{(c)}(\psi(y)) \right|^p \zeta_{d-1, \alpha-j}(y) dy \leq \int_{U_j} |E_1(\psi(y))|^p |E_2(y)|^p \zeta_{d-1, \alpha-j}(y) dy \leq B \int_{U_j} |E_2(y)|^p \zeta_{d-1, \alpha-j}(y) dy < \infty,$$

for some positive constant $B$. Therefore (22) is also sufficient for (21).

We can also deduce a result for Sobolev spaces of dominating mixed smoothness.

**Theorem 3 (Result for the Sobolev space of dominating mixed smoothness)** Let $d \geq 2$, $p \in [1, \infty)$, $j \in \mathcal{D}$, and let $\rho \in C^{r-1}(\mathbb{R})$ be a strictly positive probability density function. Let $r = (r_1, \ldots, r_d)$ be a multi-index satisfying

$$r_j \geq \sum_{1 \leq k \leq d, k \neq j} r_k \geq 1.$$

If we replace the conditions on $\theta$, $\phi$ in Theorem 2 by

$$\theta, \phi \in \mathcal{W}^{r}_{d,p, \zeta, \text{mix}} \cap C^{r}_{\text{mix}}(\mathbb{R}^d),$$

and further restrict (19)–(21) to functions $h$ with multi-indices $\gamma^{(i)} \leq r$, $\eta < r$, and $\alpha \leq r$, then the conclusion becomes:

$$P_j f \in \mathcal{W}^{r_j}_{d-1,p, \zeta} \cap C^{r_j}_{\text{mix}}(\mathbb{R}^{d-1}).$$

**Proof.** The proof is obtained from minor modifications of the proof of Theorem 2 in Section 7. In particular, the requirement that $r_j$ is greater than or equal to the sum of the remaining $r_k$ for $k \neq j$ is needed because, for any multi-index $\alpha \leq r$ with $\alpha_j = 0$, it is clear from (33) and a generalization of (34) that the expression for $D^{\alpha} P_j f$ includes some terms that depend on $D_j^{[\alpha]} \phi$ and some terms that depend on $D_j^{[\alpha]-1} \theta$. \qed

12
6 Applying the theory to option pricing

We now apply our results to the option pricing example.

Applying the theory to option pricing

Recall from Section 3 that after PCA factorization the function $f$ from the digital option pricing example takes the form (2), with $\theta$ a constant function and $\phi$ given by (9). It follows that

$$(D_j \phi)(x) = \frac{\sigma S_0}{d} \sum_{\ell=1}^{d} \exp \left( \left( \mu - \frac{\sigma^2}{2} \right) \ell \Delta t + \sigma \sum_{k=1}^{d} A_{\ell k} x_k \right) A_{\ell j}.$$ 

In particular, we see that $(D_1 \phi)(x) > 0$ because, as explained in Section 3, $A_{\ell 1} > 0$ for all $\ell$, thus in this case it is appropriate to take $j = 1$ in Theorem 2. It is also clear that $\phi$ is in $C^r(\mathbb{R}^d)$ for all $r \in \mathbb{Z}^+$. Additionally, we may take all the weight functions $\zeta_i$ in (17) equal to the standard normal density $\rho$. It is then clear that the sufficient condition (22) is satisfied, and moreover that all the integrability and decay conditions in Theorem 2 are satisfied, because all derivatives of $\phi$ are “killed” at infinity by the Gaussian weight functions and their derivatives. It then follows from Theorem 2 that

$$P_1 f \in \mathcal{W}_{d-1, p, \rho} \cap C^r(\mathbb{R}^{d-1}) \quad \forall r \in \mathbb{Z}^+, \quad \forall p \in [1, \infty).$$

7 Proof of the main smoothing theorem

Before we proceed to prove Theorem 2, we quote three theorems from [9, Section 2.4], but state them with respect to the Sobolev spaces defined with generalized weight functions $\zeta_{d, \alpha}$. We outline the subtle additional steps needed in the proofs of [9] to allow for this generalization.

The classical Leibniz theorem allows us to swap the order of differentiation and integration. In this paper we need a more general form of the Leibniz theorem as given below.

**Theorem 4 (The Leibniz Theorem [9, Theorem 2.1])** Let $p \in [1, \infty)$. For $g \in \mathcal{W}_{d, p, \zeta}^1$ with generalized weight functions $\zeta_{d, \alpha}$ satisfying (16) and (17), we have

$$D_k P_j g = P_j D_k g \quad \text{for all} \quad j, k \in \mathcal{D} \quad \text{with} \quad j \neq k.$$

**Proof.** We follow the proof of [9, Theorem 2.1] to the last paragraph where Fubini’s theorem was applied a second time. This application of Fubini’s Theorem is valid because

$$\left| \int_{\mathbb{R}^d} \int_{-\infty}^{\infty} (D_k g)(t_j, x_{-j}) \rho(t_j) \ dt_j \ v(x) \ dx \right|$$

$$\leq \int_{\mathbb{R}^{d-1}} \int_{-\infty}^{\infty} |(D_k g)(t_j, x_{-j})| \zeta_1(t_j) \ dt_j \rho_{d-1}(x_{-j}) \int_{-\infty}^{\infty} |v(x, x_{-j})| \ dx_j \rho_{d-1}(x_{-j}) \ dx_{-j}$$

$$\leq \|D_k g\|_{L_{1, d, \alpha, e_k}} \sup_{x_{-j} \in V} \int_{-\infty}^{\infty} |v(x, x_{-j})| \ dx_j \inf_{x_{-j} \in V} \rho_{d-1}(x_{-j}) < \infty,$$

where $e_k$ is the multi-index consisting of 1 in the position $k$, and 0 elsewhere, and where we made use of $\rho(t_j) \leq \zeta_1(t_j)$ and $g \in \mathcal{W}_{d, 1, \zeta}^1$, and that the set $V$ defined in the proof of [9, Theorem 2.1] is a compact set because of the compactness of $\text{supp}(v)$. The remainder of that proof then stands.

The next theorem is an application of the Leibniz theorem; it establishes that $P_j f$ inherits the smoothness of $g$. 

13
Theorem 5 (The Inheritance Theorem [9, Theorem 2.2]) Let \( r \geq 0 \) and \( p \in [1, \infty) \). For \( g \in \mathcal{W}_{d,p}^r \) with generalized weight functions \( \zeta_{d,\alpha} \) satisfying (16) and (17), we have

\[
P_j g \in \mathcal{W}_{d-1,p}^r \quad \text{for all } j \in \mathcal{D}.
\]

Proof. For the case \( r = 0 \) the proof is exactly the same as the proof of [9, Theorem 2.2]. Consider now \( r \geq 1 \). Let \( j \in \mathcal{D} \) and let \( \alpha \) be any multi-index with \( |\alpha| \leq r \) and \( \alpha_j = 0 \). Since now \( g \in \mathcal{W}_{d,p}^r \) with generalized weight functions, we have \( |D^\alpha g|_{\zeta_{d,\alpha}} < \infty \). To show that \( P_j g \in \mathcal{W}_{d-1,p}^r \) we need to show that \( \|D^\alpha P_j g\|_{\zeta_{d-1,\alpha-\beta}} < \infty \). Mimicking the proof of [9, Theorem 2.2], we write successively

\[
D^\alpha P_j g = \left(\prod_{i=1}^{\alpha_1} D_{k_i}\right) P_j g = \left(\prod_{i=2}^{\alpha_1} D_{k_i}\right) P_j D_{k_1} g \\
= \cdots = D_{k_1} \left(\prod_{i=1}^{\alpha_1} D_{k_i}\right) g = P_j \left(\prod_{i=1}^{\alpha_1} D_{k_i}\right) g = P_j D^\alpha g,
\]

where \( k_i \in \mathcal{D} \setminus \{j\} \) and \( k_1, \ldots, k_{|\alpha|} \) need not be distinct. Each step in (23) involves a single differentiation under the integral sign, and is justified by the Leibniz theorem (Theorem 4) because we know from the property (v) in Subsection 5.1 that \( \left(\prod_{i=1}^\ell D_{k_i}\right) g \in \mathcal{W}_{d,p}^{r-\ell} \subseteq \mathcal{W}_{d,p}^r \) for all \( \ell \leq |\alpha| - 1 \leq r - 1 \). We have therefore

\[
\|D^\alpha P_j g\|_{\zeta_{d-1,\alpha-\beta}} = \|P_j D^\alpha g\|_{\zeta_{d-1,\alpha-\beta}} \\
= \left(\int_{\mathbb{R}^d \setminus \{j\}} \left| \int_{-\infty}^{\infty} (D^\alpha g)(x) \rho(x_j) \, dx_j \right|^p \zeta_{d-\alpha-\beta}(x) \, dx \right)^{1/p} \\
\leq \left(\int_{\mathbb{R}^d \setminus \{j\}} \left(\int_{-\infty}^{\infty} (D^\alpha g)(x) \rho(x_j) \, dx_j \right) \zeta_{d-\alpha-\beta}(x) \, dx \right)^{1/p} = \|D^\alpha g\|_{\zeta_{d,\alpha}} < \infty,
\]

where we applied H"older’s inequality to the inner integral as in [9, Equation (2.11)] and used \( \zeta_{\alpha_j}(x_j) = \zeta_0(x_j) = \rho(x_j) \). This completes the proof. \( \square \)

The implicit function theorem stated below is crucial for the main results of this paper. In the rest of the paper, for any \( r \geq 0, k \geq 1, \) and an open set \( U \subset \mathbb{R}^k \), we define \( C^r(U) \) to be the space of functions whose classical derivatives of order \( \leq r \) are all continuous at every point in \( U \).

Theorem 6 (The Implicit Function Theorem [9, Theorem 2.3]) Let \( j \in \mathcal{D} \). Suppose \( \phi \in C^1(\mathbb{R}^d) \) satisfies

\[
(D_j \phi)(x) > 0 \quad \text{for all } x \in \mathbb{R}^d.
\]

Let

\[
U_j := \{x - j \in \mathbb{R}^{d-1} : \phi(x - j) = 0 \text{ for some (unique) } x_j \in \mathbb{R}\}.
\]

If \( U_j \) is not empty then there exists a unique function \( \psi_j \in C^1(U_j) \) such that

\[
\phi(\psi_j(x - j), x - j) = 0 \quad \text{for all } x - j \in U_j,
\]

and for all \( k \neq j \) we have

\[
(D_k \psi_j)(x)_{(j)} = -\frac{(D_k \phi)(x)}{(D_j \phi)(x)} \bigg|_{x_j = \psi_j(x_{(j)})} \quad \text{for all } x_{(j)} \in U_j.
\]

If in addition \( \phi \in C^r(\mathbb{R}^d) \) for some \( r \geq 2 \), then \( \psi_j \in C^r(U_j) \).
Note that the derivatives in the implicit function theorem are classical derivatives, and the condition (24) needs to hold for all \( x \in \mathbb{R}^d \).

We are almost ready to prove Theorem 2. But first we give a remark and a couple of auxiliary results.

**Remark 7** It is easily seen that \( U_j \) and \( U_j^+ \) in Theorem 2 can also be defined by

\[
U_j = \left\{ y \in \mathbb{R}^{d-1} : \lim_{x_j \to -\infty} \phi(x_j, y) < 0 \right\},
\]

\[
U_j^+ = \left\{ y \in \mathbb{R}^{d-1} : \lim_{x_j \to -\infty} \phi(x_j, y) \geq 0 \right\}.
\]

In the proof of the theorem we make essential use of the following lemma. This result is needed to ensure that all the derivatives we encounter are continuous across the boundary between \( U_j \) and \( U_j^+ \).

**Lemma 8** Under the condition (18), the function \( \psi_j : \mathbb{R} \to \mathbb{R} \) has the following property

\[
\psi_j(y) \to -\infty \tag{26}
\]

as \( y \) approaches a point on the boundary of \( U_j \).

**Proof.** Consider a point \( y^* \) a point on the boundary of \( U_j \), and hence (because \( U_j \) is open) lying in \( U_j^+ \). Consider also a sequence \( (y_n)_{n \in \mathbb{N}} \subset U_j \) with \( y_n \to y^* \) as \( n \to \infty \). We assert that the sequence \( (\psi(y_n))_{n \in \mathbb{N}} \) has no accumulation points in \( \mathbb{R} \). This is true because if we assume otherwise then there would exist a convergent subsequence \( (\psi(y_{n_k}))_{k \in \mathbb{N}} \), with \( \psi(y_{n_k}) \to x_j^* \) as \( k \to \infty \) for \( x_j^* \in \mathbb{R} \). But because of the continuity of \( \phi \) we must have

\[
\phi(x_j^*, y^*) = \lim_{k \to \infty} \phi(\psi(y_{n_k}), y_{n_k}) = 0,
\]

since by definition \( \phi(\psi(y_{n_k}), y_{n_k}) = 0, \forall k \in \mathbb{N} \). This implies that \( y^* \in U_j \), which is a contradiction. Therefore the sequence \( (\psi(y_n))_{n \in \mathbb{N}} \) has no accumulation points in \( \mathbb{R} \). This implies (due to the Bolzano-Weierstrass Theorem) that \( (\psi(y_n))_{n \in \mathbb{N}} \cap [a, b] \) is a finite set, for each interval \([a, b], a, b \in \mathbb{R} \). Thus,

\[
\lim_{n \to \infty} |\psi(y_n)| = \infty.
\]

To eliminate the possibility that \( +\infty \) is an accumulation point of \( \psi(y_n) \) we observe that, due to condition (4), and with \( y^* \) as above, there exists an \( x_j^* \) such that \( \phi(x_j^*, y^*) > 0 \). Because of the continuity of \( \phi \), there is a ball around the point \( (x_j^*, y^*) \), denoted by \( B(x_j^*, y^*) \) such that \( \phi \) is positive for each point in \( B(x_j^*, y^*) \). Assume now that we have a subsequence \( (\psi(y_{n_m}))_{m \in \mathbb{N}} \) such that \( \lim_{m \to \infty} \psi(y_{n_m}) = +\infty \). Because \( y_{n_m} \) converges to \( y^* \) as \( m \to \infty \), it follows that \( (x_j^*, y_{n_m}) \in B(x_j^*, y^*) \) for all \( m \) sufficiently large. But assumption \( \psi(y_{n_m}) \to +\infty \), and the monotonicity condition in (18) implies that for all \( m \) sufficiently large we have \( \psi(y_{n_m}) > x_j^* \), and therefore \( 0 < \phi(x_j^*, y_{n_m}) < \phi(\psi(y_{n_m}), y_{n_m}) = 0 \), which is clearly a contradiction. Therefore we conclude that

\[
\lim_{n \to \infty} \psi(y_n) = -\infty.
\]

Another auxiliary result is needed to show that the assumption (20) implies continuous differentiability of \( P_j f \) at boundary points of \( U_j \).
Lemma 9 Let \( r \geq 0 \) and \( k \geq 1 \). Suppose \( g \in C^r(U) \) for some open domain \( U \subset \mathbb{R}^k \) and \( g(y) = 0 \) for all \( y \in U^c \). Suppose that for any multi-index \( \alpha \) with \( |\alpha| \leq r \) and any sequence \( (y_n)_{n \in \mathbb{N}} \subset U \) we have
\[
\lim_{n \to \infty} y_n = y^* \quad \text{with} \quad y^* \in U^c \quad \Rightarrow \quad \lim_{n \to \infty} (D^\alpha g)(y_n) = 0.
\] (27)
Then we have \( g \in C^r(\mathbb{R}^k) \), with \( (D^\alpha g)(y) = 0 \) for all \( y \in U^c \).

Proof. The statement is obviously true for \( r = 0 \) where mere continuity of \( g \) is asserted. Now suppose it holds for a natural number \( r_0 \geq 0 \) and consider any multi-index \( \alpha = \alpha_0 + e_i \), with \( e_i \) denoting a canonical basis vector and \( |\alpha_0| = r_0 \), and hence \( |\alpha| = r_0 + 1 \leq r \). Then we have to show that \( (D^\alpha g)(y) \) exists at all \( y \in \mathbb{R}^k \) and is continuous at every point of \( \mathbb{R}^k \). For points in \( U \) the derivative \( D^\alpha g \) exists and is continuous by assumption, and for points in the interior of \( U^c \) the derivative \( D^\alpha g \) exists and is continuous because \( g \) is zero there. So it remains to consider the existence and continuity of \( D^\alpha g \) at any boundary point \( y^* \), i.e., at any limit point \( y^* \) of a sequence \( (y_n)_{n \in \mathbb{N}} \subset U \).

To show the existence, consider the scalar valued function \( D^{\alpha_0} g \) which is by the induction hypothesis continuous on all of \( \mathbb{R}^k \) and vanishes at any boundary point \( y^* \). Consider first the case \( h > 0 \) and a point \( y^* + he_i \). If \( y^* + he_i \in U \), then because \( U \) is open and \( y^* \in U^c \), we have for
\[
\bar{h} := \sup\{h' : 0 \leq h' < h, \ y^* + h'e_i \in U^c\}
\]
that \( y^* + h'e_i \in U \) for all \( \bar{h} < h' \leq h \). Furthermore, because \( U^c \) is closed it follows that \( (D^{\alpha_0} g)(y^* + \bar{h}e_i) = 0 = (D^{\alpha_0} g)(y^*) \), and thus we conclude from the mean value theorem that
\[
(D^{\alpha_0} g)(y^* + he_i) - (D^{\alpha_0} g)(y^*) = (D^{\alpha_0} g)(y^* + h'e_i) - (D^{\alpha_0} g)(y^* + \bar{h}e_i) = (h - \bar{h}) (D_i D^{\alpha_0} g)(y^* + h'e_i)
\]
for some \( h^* \) satisfying \( \bar{h} < h^* < h \). Hence we have for the quotient
\[
\frac{(D^{\alpha_0} g)(y^* + he_i) - (D^{\alpha_0} g)(y^*)}{h} = \begin{cases} \frac{h - \bar{h}}{h} (D_i D^{\alpha_0} g)(y^* + h'e_i), & \bar{h} < h^* < h, \quad \text{if} \ y^* + he_i \in U, \\ 0, & \text{if} \ y^* + he_i \in U^c. \end{cases}
\]
Then using the assumption (27), letting \( h \) be arbitrarily small, using that \( |\bar{h}| \leq |h| \), and considering the analogous situation for \( h < 0 \), we obtain the existence of \( D_i D^{\alpha_0} g \) at \( y^* \), with \( (D_i D^{\alpha_0} g)(y^*) = 0 \).

To show the derivative continuity at a boundary point \( y^* \), consider any sequence \( (y_n)_{n \in \mathbb{N}} \subset \mathbb{R}^k \) with \( \lim_{n \to \infty} y_n = y^* \). For a given \( n \) either \( y_n \in U \), in which case (27) applies, or \( y_n \in U^c \), in which case \( (D_i D^{\alpha_0} g)(y_n) = 0 \), as above, so that both subsequences converge to \( 0 = (D_i D^{\alpha_0} g)(y^*) \). Finally, since all partial derivatives of order \( r_0 + 1 \) are now proved continuous in \( \mathbb{R}^k \), those mixed partial derivatives are symmetric, and we can write \( D_i D^{\alpha_0} g = D^{\alpha_0} g \).

Hence \( D^{\alpha} g \) exists and is continuous on all of \( \mathbb{R}^k \), i.e., the induction step is proved. It follows then that \( g \in C^r(\mathbb{R}^k) \).

We are now ready to prove Theorem 2.

Proof of Theorem 2. We focus on the non-trivial case when \( U_j \) is not empty. Given that \( \phi \in C^r(\mathbb{R}^d) \), that \( (D_j \phi)(x) \neq 0 \) for all \( x \in \mathbb{R}^d \), and that \( U_j \) is not empty, it follows from the implicit function theorem (see Theorem 6) that the set \( U_j \) is open, and that there exists a unique function \( \psi \equiv \psi_j \in C^r(U_j) \) for which
\[
\phi(x_j, y) = 0 \iff \psi(y) = x_j \quad \text{for all} \quad y \in U_j.
\] (28)
This justifies the existence of the function \( \psi \) as stated in the theorem.
For the function \( f(x) = \theta(x_j, y) \operatorname{ind}(\phi(x_j, y)) \) we can write \( P_j f \) defined by (5) as

\[
(P_jf)(y) = \int_{x_j \in \mathbb{R}} \theta(x_j, y) \rho(x_j) \, dx_j.
\]  
(29)

It follows from the condition \((D_j \phi)(x) > 0\) for all \(x \in \mathbb{R}^d\) and the continuity of \(D_j \phi\) that, for fixed \(y\), \(\phi(x_j, y)\) is a strictly increasing function of \(x_j\).

We now determine the limits of integration in (29). If \(y \in U_j^+\), then \(\phi(x_j, y) \neq 0\) for all \(x_j \in \mathbb{R}\). Since \(\phi\) is continuous, strictly increasing in \(x_j\), and tends to \(+\infty\) as \(x_j \to +\infty\), we conclude that \(\phi(x_j, y) > 0\) for all \(x_j \in \mathbb{R}\), and thus we integrate \(x_j\) from \(-\infty\) to \(\infty\). On the other hand, if \(y \in U_j\), in which case \(\phi(x_j, y)\) changes sign once as \(x_j\) goes from \(-\infty\) to \(\infty\), then there exists a unique \(x_j^* = \psi(y) \in \mathbb{R}\) for which \(\phi(x_j^*, y) = 0\), and in this case we integrate \(x_j\) from \(\psi(y)\) to \(\infty\). Hence we can write (29) as

\[
(P_jf)(y) = \begin{cases} 
\int_{-\infty}^{\psi(y)} \theta(x_j, y) \rho(x_j) \, dx_j & \text{if } y \in U_j^+, \\
\int_{\psi(y)}^{\infty} \theta(x_j, y) \rho(x_j) \, dx_j & \text{if } y \in U_j.
\end{cases}
\]

Note that \(P_j f\) is continuous across the boundary between \(U_j\) and \(U_j^+\), since from Lemma 8 it follows that \(\psi(y) \to -\infty\) as \(y \in U_j\) approaches a boundary point of \(U_j\).

By the Leibniz Theorem and the Inheritance Theorem, we know that the function \((P_j \theta)(y) = \int_{-\infty}^{\psi(y)} \theta(x_j, y) \rho(x_j) \, dx_j\) for \(y \in \mathbb{R}^{d-1}\) is as smooth as \(\theta\), i.e., \(P_j \theta \in W_{d-1,p,\xi} \cap C^r(\mathbb{R}^{d-1})\). Therefore, to obtain the same smoothness property for \(P_j f\) it suffices that we consider in the remainder of this proof the difference

\[
g(y) := (P_j f)(y) - (P_j \theta)(y) = \begin{cases} 
- \int_{-\infty}^{\psi(y)} \theta(x_j, y) \rho(x_j) \, dx_j & \text{if } y \in U_j, \\
0 & \text{if } y \in U_j^+.
\end{cases}
\]  
(30)

First we differentiate \(g\) with respect to the \(k\)th coordinate for any \(k \neq j\). For \(y \in U_j\) we obtain, using the fundamental theorem of calculus,

\[
(D_k g)(y) = -\int_{-\infty}^{\psi(y)} (D_k \theta)(x_j, y) \rho(x_j) \, dx_j - \theta(\psi(y), y) \rho(\psi(y)) \left(D_k \psi\right)(y)
\]

\[
= -\int_{-\infty}^{\psi(y)} (D_k \theta)(x_j, y) \rho(x_j) \, dx_j + \theta(\psi(y), y) \frac{(D_k \phi)(\psi(y), y)}{(D_j \phi)(\psi(y), y)} \rho(\psi(y)),
\]

where we substituted using (25)

\[
(D_k \psi)(y) = -\frac{(D_k \phi)(\psi(y), y)}{(D_j \phi)(\psi(y), y)}.
\]  
(32)

It follows from (20) and Lemma 8 that both terms in (31) go to 0 as \(y \in U_j\) approaches a boundary point \(y^*\) of \(U_j\) lying in \(U_j^+\). Hence the condition (27) in Lemma 9 holds with \(r = 1\), and we conclude that \(g \in C^1(\mathbb{R}^{d-1})\).

Next we differentiate with respect to the \(\ell\)th coordinate for any \(\ell \neq j\) (allowing the possibility that \(\ell = k\)). For \(y \in U_j\) it is useful to note that for any sufficiently smooth \(d\)-variate function \(\xi\) the rule for partial differentiation and the chain rule gives

\[
D_\ell(\xi(\psi(y), y)) = (D_\ell \xi)(\psi(y), y) + (D_j \xi)(\psi(y), y) (D_\ell \psi)(y).
\]  
(33)
Thus we find for $y \in U_j$

\[
(D_\ell D_k g)(y) = -\int_{-\infty}^{\psi(y)} (D_\ell D_k \theta)(x_j, y) \rho(x_j) \, dx_j - (D_k \theta)(\psi(y), y) \rho(\psi(y)) (D_\ell \psi)(y)
\]

\[
+ [(D_\ell \theta)(\psi(y), y) + (D_j \theta)(\psi(y), y) (D_\ell \psi)(y)] \frac{(D_k \phi)(\psi(y), y)}{(D_\ell \phi)(\psi(y), y)} \rho(\psi(y))
\]

\[
+ \theta(\psi(y), y) \frac{(D_k \phi)(\psi(y), y) + (D_j D_k \phi)(\psi(y), y) + (D_j D_\ell \phi)(\psi(y), y) (D_\ell \psi)(y)}{[(D_\ell \phi)(\psi(y), y)]^2} \rho(\psi(y))
\]

\[
+ \theta(\psi(y), y) \frac{(D_k \phi)(\psi(y), y)}{(D_\ell \phi)(\psi(y), y)} \rho'(\psi(y)) (D_\ell \psi)(y),
\]  

(34)

where we used again (32). We have from (20) and Lemma 8 that all terms in (34) go to 0 as $y \in U_j$ approaches a boundary point $y^*$ of $U_j$ lying in $U_j^+$. Hence the condition (27) in Lemma 9 holds for a general $r = 2$, and we conclude that $g \in C^2(\mathbb{R}^{d-1})$.

In general, for every non-zero multi-index $\alpha = (\alpha_1, \ldots, \alpha_d)$ with $|\alpha| \leq r$ and $\alpha_j = 0$, we claim that for $y \in U_j$

\[
(D^\alpha g)(y) = -\int_{-\infty}^{\psi(y)} (D^\alpha \theta)(x_j, y) \rho(x_j) \, dx_j + \sum_{m=1}^{M_{|\alpha|}} h_{\alpha, m}(y),
\]  

(35)

where $M_{|\alpha|}$ is a nonnegative integer, and each function $h_{\alpha, m}$ is of the form (19), with integers $\beta, a, b, c$ and multi-indices $\gamma^{(i)}$ and $\eta$ satisfying

\[
1 \leq a, b \leq 2|\alpha| - 1, \quad 1 \leq |\gamma^{(i)}| \leq |\alpha|, \quad 0 \leq |\eta|, c \leq |\alpha| - 1, \quad 1 \leq |\gamma^{(i)}| + |\eta| + c \leq |\alpha|.
\]  

(36)

We have from (20) and Lemma 8 that all terms in (35) go to 0 as $y \in U_j$ approaches a boundary point $y^*$ of $U_j$ lying in $U_j^+$. Hence the condition (27) in Lemma 9 holds for a general $r$, and we conclude that $g \in C^r(\mathbb{R}^{d-1})$.

We will prove (35)–(36) by induction on $|\alpha|$. The case $|\alpha| = 1$ is shown in (31); there we have $M_1 = 1, a = 1, b = 1, c = 0, \beta = 1, |\gamma^{(1)}| = 1, |\eta| = 0,$ and $|\gamma^{(1)}| + |\eta| + c = 1$. The case $|\alpha| = 2$ is shown in (34); there we have $M_2 = 8, 1 \leq a, b \leq 3, 0 \leq c \leq 1, \beta = \pm 1, 1 \leq |\gamma^{(i)}| \leq 2, 0 \leq |\eta| \leq 1,$ and $1 \leq |\gamma^{(i)}| + |\eta| + c \leq 2$. To establish the inductive step we now differentiate $D^\alpha g$ once more: for $\ell \neq j$ we have from (35)

\[
(D_\ell D^\alpha g)(y) = -\int_{-\infty}^{\psi(y)} (D_\ell D^\alpha \theta)(x_j, y) \rho(x_j) \, dx_j - (D^\alpha \theta)(\psi(y), y) \rho(\psi(y)) (D_\ell \psi)(y)
\]

\[
+ \sum_{m=1}^{M_{|\alpha|}} (D_\ell h_{\alpha, m})(y).
\]  

(37)
For a typical term in (37), we have from (19) of functions of the form (19) satisfying the constraints in (36). This completes the induction proof at most 2, thus we conclude that $D \in \mathcal{L}_{\gamma(i)}$ and $|D| + |\gamma(i)| + c$ increased by at most 1. Hence, $D_i D^\alpha g$ consists of a sum of functions of the form (19) satisfying the constraints in (36). This completes the induction proof for (35)–(36).

We now turn to the task of showing that $D^\alpha g \in \mathcal{L}_{p, U_j - \delta}$ for $p \in (1, \infty)$ and all $\alpha$ satisfying $|\alpha| \leq r$ and $\alpha_j = 0$. We need to consider

$$
\int_{\mathbb{R}^{d-1}} |(D^\alpha g)(y)|^p \, \zeta_{d-1, \alpha, \gamma(i), j}(y) \, dy = \int_{U_j} |(D^\alpha g)(y)|^p \, \zeta_{d-1, \alpha, \gamma(i), j}(y) \, dy,
$$

where we have split the integral noting that $U_j$ is open and its complement $U_j^+$ is closed, as they are both Borel measurable, and that $D^\alpha g$ is zero on $U_j^+$.

For $y \in U_j$, it follows from Hölder’s inequality and the special form of $D^\alpha g$ in (35) that

$$
|(D^\alpha g)(y)|^p = \left[ - \int_{-\infty}^{\psi(y)} (D^\alpha \theta)(x, y) \rho(x_j) \, dx_j + \sum_{m=1}^{M|\alpha|} h_{\alpha, m}(y) \right]^p
\leq \left( \int_{-\infty}^{\psi(y)} |(D^\alpha \theta)(x, y)| \rho(x_j) \, dx_j + \sum_{m=1}^{M|\alpha|} |h_{\alpha, m}(y)| \right)^p
\leq (M|\alpha| + 1)^{p-1} \left( \int_{-\infty}^{\psi(y)} |(D^\alpha \theta)(x, y)| \rho(x_j) \, dx_j + \sum_{m=1}^{M|\alpha|} |h_{\alpha, m}(y)| \right)^p
\leq (M|\alpha| + 1)^{p-1} \left( \int_{-\infty}^{\psi(y)} |(D^\alpha \theta)(x, y)| \rho(x_j) \, dx_j + \sum_{m=1}^{M|\alpha|} |h_{\alpha, m}(y)| \right)^p.
$$

19
and thus
\[
\int_{U_j} |(D^{\alpha}g(y)|^p \zeta_{d-1,\alpha-j}(y) \, dy
\leq (M_{|\alpha|} + 1)^{p-1} \left( \int_{\mathbb{R}^d} |(D^{\alpha}\theta)(x)|^p \zeta_d(x) \, dx + \sum_{m=1}^{M_{|\alpha|}} \int_{U_j} |h_{\alpha,m}(y)|^p \zeta_{d-1,\alpha-j}(y) \, dy \right) < \infty,
\]
with the finiteness coming because \(\rho(x_j) = \zeta_0(x_j) = \zeta_{\alpha,j}(x_j)\) and \(\theta \in W_{d,p,\zeta}\), and because each integral involving \(h_{\alpha,m}\) is finite due to the condition (21). This proves that \(g \in W_{d-1,p,\zeta}\) as claimed.
