Abstract: The subcellular localization of the epidermal growth factor receptor (EGFR) in polarized epithelial cells profoundly affects the activity of the intracellular signaling pathways activated after EGF ligand binding. Therefore, changes in EGFR localization and signaling are implicated in various human diseases, including different types of cancer. We have performed the first in vivo EGFR localization screen in an animal model by observing the expression of the EGFR ortholog LET-23 in the vulval epithelium of live C. elegans larvae. After systematically testing all genes known to produce an aberrant vulval phenotype, we have identified 81 genes regulating various aspects of EGFR localization and expression. In particular, we have found that ERM-1, the sole C. elegans Ezrin/Radixin/Moesin homolog, regulates EGFR localization and signaling in the vulval cells. ERM-1 interacts with the EGFR at the basolateral plasma membrane in a complex distinct from the previously identified LIN-2/LIN-7/LIN-10 receptor localization complex. We propose that ERM-1 binds to and sequesters basolateral LET-23 EGFR in an actin-rich inactive membrane compartment to restrict receptor mobility and signaling. In this manner, ERM-1 prevents the immediate activation of the entire pool of LET-23 EGFR and permits the generation of a long-lasting inductive signal. The regulation of receptor localization thus serves to fine-tune the temporal activation of intracellular signaling pathways.

Abstract

The subcellular localization of the epidermal growth factor receptor (EGFR) in polarized epithelial cells profoundly affects the activity of the intracellular signaling pathways activated after EGF ligand binding. Therefore, changes in EGFR localization and signaling are implicated in various human diseases, including different types of cancer. We have performed the first in vivo EGFR localization screen in an animal model by observing the expression of the EGFR ortholog LET-23 in the vulval epithelium of live C. elegans larvae. After systematically testing all genes known to produce an aberrant vulval phenotype, we have identified 81 genes regulating various aspects of EGFR localization and expression. In particular, we have found that ERM-1, the sole C. elegans Ezrin/Radixin/Moesin homolog, regulates EGFR localization and signaling in the vulval cells. ERM-1 interacts with the EGFR at the basolateral plasma membrane in a complex distinct from the previously identified LIN-2/LIN-7/LIN-10 receptor localization complex. We propose that ERM-1 binds to and sequesters basolateral LET-23 EGFR in an actin-rich inactive membrane compartment to restrict receptor mobility and signaling. In this manner, ERM-1 prevents the immediate activation of the entire pool of LET-23 EGFR and permits the generation of a long-lasting inductive signal. The regulation of receptor localization thus serves to fine-tune the temporal activation of intracellular signaling pathways.

Introduction

The formation of epithelial tissues involves the polarized distribution of growth factor receptors that determine cell proliferation and differentiation. Notably, changes in EGFR localization have a major impact on signaling and organogenesis [1–3].

In C. elegans, the let-23 gene encodes the sole member of the EGFR/ErbB family of receptor tyrosine kinases. let-23 is involved in a variety of developmental processes including the induction of the hermaphrodite vulva [4]. In early second stage (L2) larvae, LET-23 is expressed at equal levels in the six equivalent vulval precursor cells (VPCs) (P3.p through P8.p) (Figure 1A) [5,6]. Beginning in the L2 stage, the gonadal anchor cell (AC) secretes the EGFR ortholog LIN-3, which binds to LET-23 on the basolateral plasma membrane of the VPCs to activate the LET-60 RAS/MPK-1 MAPK signaling pathway [4] (Figure 1B). In order to reach high levels of receptor activity, LET-23 must be retained on the basolateral membrane of the VPCs by a ternary protein complex consisting of the PDZ-domain proteins LIN-2 CASK, LIN-10 MINT and LIN-7 VELIS. LIN-7 directly binds to the C-terminal PDZ binding motif of LET-23 [5]. The VPC that is nearest to the AC, P6.p, receives most of the inductive LIN-3 signal and hence adopts the primary (1’s) cell fate. P6.p then produces several DELTA ligands, which induce via the NOTCH pathway the secondary (2’s) cell fate in the neighboring VPCs P5.p and P7.p [7,8] (Figure 1B). NOTCH signaling blocks RAS/ MAPK signaling and results in the endocytosis and degradation of LET-23 in the 2’s VPCs [9–11]. The distal VPCs P3.p, P4.p and P8.p, which receive only little inductive signal, down-regulate LET-23 expression and adopt the tertiary (3’s), uninstructed cell fate. As the pathway components are conserved, the study of vulval induction of the worm can be used to find new core components or those required for fine-tune the signaling output. For this purpose, we performed the first systematic in vivo screen for regulators of LET-23 EGFR localization and expression in live C. elegans larvae.

Through this approach, we have identified 81 genes causing a variety of LET-23::GFP mislocalization phenotypes upon RNAi...
**Author Summary**

Abnormal signaling by the epidermal growth factor receptor (EGFR) contributes to the development of various human diseases, including different cancer types. One important mechanism that controls intracellular signal transduction is by regulation of the subcellular receptor localization in the signal-receiving cell. We are investigating the regulation of the EGFR homolog LET-23 in the Nematode *C. elegans* by observing the localization of the EGFR in the epithelial cells of live animals. This approach has allowed us to study the dynamics of receptor trafficking in cells embedded in their natural environment and receiving physiological concentrations of various extracellular signals. In a systematic RNA interference screen, we have identified 81 genes controlling EGFR localization and signaling in different subcellular compartments. One new regulator of EGFR signaling identified in this screen encodes the Ezrin Homolog ERM-1. We show genetic and biochemical evidence indicating that ERM-1 is part of a buffering mechanism to maintain a pool of immobile EGFR in the basolateral membrane compartment of the epithelial cells. This mechanism permits the generation of a long-lasting EGFR signal during multiple rounds of cell divisions. The control of receptor localization is thus necessary for the precise temporal regulation of signal transduction during animal development.

**Results**

**An In Vivo Screen Identifies Novel Regulators of LET-23 EGFR Localization and Expression**

We performed RNAi knock-down of all genes (705 clones) reported to exhibit a protruding vulva (Pvl) phenotype, which is indicative of a defect in vulval fate specification or execution (Table S1) and examined LET-23 localization and expression in the vulval epithelium of live L3 larvae expressing a functional LET-23::GFP reporter (Figure 1C–E). The LET-23::GFP reporter used showed the same vulval expression pattern as the translational reporter showed expression in the VPCs in perinuclear structures that resemble the ER [15]. An sft-4::gfp translational reporter showed expression in the VPCs in perinuclear structures that resemble the ER [15]. Thus, ER to Golgi transport might be involved in controlling LET-23 turnover in the VPCs.

RNAi of *C11H1.3* caused a complex mislocalization phenotype with a moderate apical enrichment, punctate LET-23::GFP accumulation at or close to the apical membrane [Figure 1J] and an increase in vulval induction in the *let-60(n1046gf)* background [Figure 1Q]. *C11H1.3* encodes a predicted E3 ubiquitin ligase that is expressed in the VPCs in intracellular vesicles [Figure 1O]. Therefore, *C11H1.3* may control LET-23 localization and stability through ubiquitination of the receptor itself or of an associated factor. A penetrant mislocalization phenotype with punctate cytoplasmic accumulation of LET-23::GFP was observed in *ego-2* RNAi treated animals (Figure 1M), and a translational *ego-2::gfp* reporter was expressed in the cytoplasm and nuclei of all the VPCs (Figure 1P). *ego-2* encodes a BRO1 domain protein that is related to mammalian PTPN23, which regulates the transport of ubiquitinated EGFR through the ESCRT III complex to the intraluminal vesicles of multivesicular bodies [16]. Interestingly, *ego-2* has also been reported to regulate GLP-1 NOTCH signaling during germ cell development and embryogenesis as well as LIN-12 NOTCH signaling during somatic gonad development [17]. Therefore, *ego-2* might be a general regulator of LET-23 EGFR and LIN-12/GLP-1 NOTCH via control of their endocytic transport.
Figure 1. Identification of genes regulating LET-23 EGFR localization and signaling. (A) Schematic drawing of an L2 larva with the location of the VPCs and AC. P5.p, P6.p, and P7.p get induced to form the mature vulva. P3.p, P4.p, and P8.p divide once and fuse to the hypodermis. (B) Overview of the LET-23 EGFR and NOTCH signaling network controlling 1° and 2° vulval fate specification. (C) LET-23::GFP expression (green) in P6.p of a late L2 larva during vulval induction. The AC is labeled with an mCherry::plcdPH reporter (magenta) [35]. Note the low LET-23::GFP levels in the 2° P5.p and P7.p. (D) Expression of the LET-23::GFP reporter in the 1° lineage at the Pn.px and (E) Pn.pxx stage. (F) Pie charts indicating the frequencies of the different classes of mislocalization phenotypes observed after RNAi and (G) the Clusters of Orthologous Groups (KOGs) of the 81 genes identified in the screen (H–M). Examples of different genes identified in the LET-23 localization screen. Left panels show the corresponding Nomarski images and right panels LET-23::GFP expression in the 1° cells and their neighbors (asterisks). (H) The negative empty vector control and (I) lin-7 RNAi as positive control. (J) erm-1 RNAi as an example for reduced basolateral (arrow) and increased apical localization (arrow head), (K) sft-4 RNAi with normal localization in P6.p but persistent expression in P7.p (asterisk), and (L) C11H1.3 RNAi (Pn.px stage) with punctate apical accumulation (arrow head). (M) ego-2 RNAi with cytoplasmic accumulation of LET-23::GFP in P6.p (arrow head) and P5.p (asterisk). (N) perinuclear localization of SFT-4::GFP in the vulval cells and the AC and (O) intracellular punctate expression of C11H1.3::GFP in P6.p. (P) Cytoplasmic and nuclear expression of EGO-2::GFP in P6.p. (Q) Vulval induction in let-60(n1046gf) larvae treated with different RNAi clones. Vulval induction (VI) indicates the average number of induced vulvae per larva.
ERM-1 Regulates EGFR Signaling

ERM-1 Controls LET-23 EGFR Trafficking

One of the strongest apical enrichment mislocalization phenotypes was observed in erm-1 RNAi treated animals (Figure 1F), prompting us to analyze the role of ERM-1 in LET-23 localization and signaling in more detail. erm-1 encodes the sole C. elegans member of the Ezrin, Radixin and Moesin (ERM) protein family. ERM proteins link the cortical actin cytoskeleton and the plasma membrane and recruit transmembrane proteins to specific membrane compartment [18]. In addition, C. elegans ERM-1 is required for apical lumen morphogenesis in the intestine [19] [20]. In contrast to the apical localization observed in the intestine, an erm-1::mCherry reporter showed basolateral and junctional localization and a partial overlap with LET-23::GFP in the VPCs and their descendants (Figure 2A–A’). Only after vulval invagination (at the Pn.pxxx stage), ERM-1 relocalized to the apical, luminal plasma membrane of the vulval torids (data not shown). To confirm the RNAi phenotype, we examined LET-23::GFP expression in erm-1(tm677) null mutants. Homozygous erm-1(tm677) larvae showed decreased basolateral and increased apical membrane localization of LET-23::GFP in the VPCs and their descendants, resulting in a significantly increased ratio of apical to basolateral LET-23::GFP signal intensity when compared to heterozygous erm-1(tm677)/+ controls (Figure 2B–D). The localization of the apical junction marker DLG-1::RFP [21] or the plasma membrane marker CED-10::GFP [22] were not changed, indicating that overall polarity of the VPCs was not altered in erm-1(tm677) mutants (data not shown and Figure S3). However, we detected a reduced basolateral staining of the F-actin reporter lifeAcc::GFP [23] in the VPCs of erm-1(tm677) mutants, which is consistent with the role of ERM proteins as membrane linkers for cortical F-actin (Figure 2D–F).

To test whether the reduced basolateral expression of LET-23::GFP is due to decreased basolateral secretion or to an increased membrane mobility and recycling rate of LET-23, we performed Fluorescence Recovery After Photobleaching (FRAP) experiments on the basal and lateral membranes of the vulval cells at the Pn.pxxx stage and calculated the mobile fraction and time half of recovery (t₁/₂) of LET-23::GFP (Figure 2G–L) [see materials and methods]. In erm-1(tm677) larvae, the total mobile fraction of LET-23::GFP was significantly higher than in heterozygous controls in both the basal and lateral compartments, while the t₁/₂ was not significantly changed (Figure 2L, t₁/₂ ≈ 76 sec in heterozygous erm-1(tm677)/+ vs. 81 sec in homozygous erm-1(tm677) mutants). Thus, erm-1(tm677) mutants exhibit an increased mobility of LET-23::GFP on the basolateral plasma membrane, rather than a decreased rate of basolateral secretion or retention.

ERM-1 Inhibits Ligand-Dependent Internalization of LET-23 EGFR

Changes in the ligand concentrations could alter the steady-state levels of LET-23 EGFR on the basolateral membrane. For example, reducing the dose of LIN-3 EGF may decrease receptor endocytosis and thus diminish the ratio of apical to basal EGFR, while increasing the dose of LIN-3 may promote receptor endocytosis on the basolateral membrane and therefore increase the apical to basal ratio. On the other hand, mutations in components of the LIN-2/LIN-7/LIN-10 complex that is necessary to retain the EGFR on the basolateral membrane also cause a strong reduction in basolateral EGFR localization, yet they result in reduced receptor activation [5]. To distinguish between these different scenarios, we tested if the increased apical LET-23::GFP localization in erm-1(tm677) mutants could be due to a higher rate of LET-23 endocytosis after binding to LIN-3 EGFR secreted from the AC. In lin-3(e1417) mutants, in which LIN-3 activity in the AC is strongly reduced [24], apical LET-23::GFP localization was nearly two-fold reduced (Figure 3A,C). However, in erm-1(tm677); lin-3(e1417) double mutants the apical to basolateral LET-23::GFP ratio was lower than in erm-1(tm677) but higher than in lin-3(e1417) single mutants (Figure 3B,C). Since the viable lin-3(e1417) allele used does not eliminate all LIN-3 activity, we conclude that the apical accumulation of LET-23::GFP in the absence of ERM-1 is at least in part ligand-dependent. On the other hand, a pulse of ectopic LIN-3 ubiquitously expressed under control of the heat-shock promoter hs::lin-3 [25] caused the almost complete disappearance of LET-23::GFP from the basolateral membrane and accumulation on the apical membrane within 230 minutes (Figure 3D,F). In homozygous erm-1(tm677) mutants, however, a LIN-3 pulse caused a smaller increase in the apical LET-23::GFP pool and persisting receptor expression on the basolateral membrane (Figure 3E,F). Thus, not only LET-23 endocytosis but also basolateral recycling are increased in erm-1(tm677) mutants, which is consistent with the increased mobile fraction of LET-23::GFP observed in the FRAP experiments (Figure 2L). By contrast, activation of the EGFR signaling pathway downstream of the receptor using for example the let-60(gf) mutation did not change LET-23::GFP localization (data not shown). Thus, the LIN-3 ligand stimulates and ERM-1 inhibits internalization and recycling of LET-23 on the basolateral membrane.

ERM-1 Acts as a Negative Regulator of the EGFR/RAS/MAPK Pathway

Enhanced receptor endocytosis could result in the attenuation of LET-23 signaling, while faster recycling to the plasma membrane could promote signaling [1]. To determine how the altered LET-23 dynamics in erm-1 mutants affects signaling, we performed epistasis analysis by combining erm-1(tm677) with mutations in different components of the EGFR/RAS/MAPK pathway [4] and quantifying vulval induction. In erm-1(tm677) single mutants, the three proximal VPCs were always induced as in the wild-type (Figure 4A). However, in let-60(gf); erm-1(tm677) double mutants, the average number of induced VPCs was significantly increased as compared to let-60(gf); lin-1(tm677)/+ controls, resulting in an enhanced Multivulva (Muv) phenotype (Figure 4A). Thus, ERM-1 negatively regulates RAS/MAPK signaling during vulval induction. Mutations in the lin-2/lin-7/lin-10 receptor localization complex or in the PDZ binding motif in let-23(gy1) cause a penetrant Vulvaless (Vul) phenotype because LET-23 mislocalized to the apical membrane cannot bind to LIN-3 [5]. Interestingly, erm-1(tm677) partially suppressed the lin-2(n397), lin-7(e1413), lin-10(e1439) and let-23(gy1) Vul phenotypes (Figure 4A), indicating that ERM-1 inhibits vulval induction independently of the LIN-2/LIN-7/LIN-10 receptor localization complex. However, the suppression of the lin-2(n397) Vul phenotype was not accompanied by a visible re-localization of LET-23::GFP to the basolateral membrane.
Table 1. Genes that control the localization or expression of LET-23::GFP.

| Gene         | KOG Information                                                                 | LET-23 localization | Known functions in vulval development                                                                 |

membrane (data not shown). In contrast,  

\textit{erm-1(tm677)} did not suppress the  

\textit{lin-3(e1417)} Vul phenotype, suggesting that vulval induction in  

\textit{erm-1(tm677)} mutants still depends on the AC signal (Figure 4A).

ERM-1 Forms a Complex with LET-23 EGFR Independently of the LIN-2/LIN-7/LIN-10 Complex

ERM proteins are composed of an N-terminal FERM domain and a C-terminal actin-binding domain [26]. They can switch from a closed, inactive conformation in the cytoplasm to an open, active conformation at the plasma membrane [27]. The FERM domain in the open conformation interacts with plasma membrane proteins either directly or indirectly through adaptor proteins [26], while binding of the actin cytoskeleton to the C-terminus of ERM proteins regulates the activity of the entire complex [28]. Since our genetic analysis indicated that ERM-1 controls LET-23 signaling independently of the LIN-2/LIN-7/LIN-10 complex, we tested if ERM-1 and LET-23 might exist in an alternate complex. For this purpose, different portions of purified recombinant ERM-1 tagged at the N-terminus with glutathione S-transferase (GST) were incubated with total worm lysates, and bound LET-23 was detected on Western-bLOTS. LET-23 from wild-type worm extracts bound to N-terminal fragments containing the entire FERM domain (GST::ERM-1 [240]) or truncated FERM domains (GST::ERM-1 [100] or GST::ERM-1 [167]) did not bind LET-23 (Figure 4B,C). Moreover, LET-23 extracted from 

\textit{sy1} mutants, in which LET-23 lacks the PDZ binding motif, or from  

\textit{lin-7(e1413)} mutants still bound to the ERM-1 FERM domain (Figure 4D,E). Thus, LET-23 and ERM-1 exist in a complex that is distinct from the LIN-2/LIN-7/LIN-10 localization complex.

ERM-1 Is a Temporal Regulator of EGFR Signaling

The increased basolateral LET-23 mobility in  

\textit{erm-1(tm677)} mutants may result in an overall elevated activity of the RAS/MAPK pathway, as more LET-23 molecules are available to interact with LIN-3. The co-localization of LET-23 and ERM-1 together with the  

\textit{in vitro} protein interaction experiments suggested that both proteins form a complex at the basolateral membrane of the VPCs. We thus hypothesized that ERM-1 may prevent the instant activation of the entire basolateral pool of LET-23 once the AC begins to secrete LIN-3 at the mid L2 stage, allowing the cells to maintain a high LET-23 activity after vulval induction. To test this model, we quantified the expression levels of the RAS/MAPK target  

\textit{egl-17::CFP} [29] in the descendants of the VPCs. In wild-type mid L3 larvae, we observed a peak of  

\textit{egl-17::CFP} expression after vulval induction in the 1L descendants of P6.p (Figure 5A–C). By contrast,  

\textit{erm-1(tm677)} mutants showed a gradual decrease rather than an increase in  

\textit{egl-17::CFP} expression (Figure 5A–G).

Table 1. Cont.

| Gene  | KOG Information | LET-23 localization | Known functions in vulval development |
|-------|-----------------|---------------------|---------------------------------------|

expression after vulval induction (Figure 5D–G). Thus, ERM-1 is required for the generation of a long-lasting RAS/MAPK signal in the 1° vulval cells after fate specification has occurred.

Discussion
Regulation of EGFR Localization Allows Pattern Formation
In order to systematically search for regulators of LET-23 EGFR trafficking and signaling, we performed an in vivo receptor localization screen in C. elegans larvae. There do exist certain limitations of this system, such as the inability to isolate individual cells for biochemical studies. However, an important advantage of our approach over previous studies performed with cultured epithelial cells [1] is the ability to observe the dynamics of receptor trafficking under normal conditions, in epithelial cells embedded in their natural environment and receiving physiological concentrations of various extracellular signals. The different regulators of LET-23 EGFR localization and signaling identified in our screen point at a complex network controlling LET-23 EGFR trafficking and signaling in different sub-cellular compartments. In a system, such as the VPCs, where ligand availability is limiting [8,30], these additional control mechanisms at the level of the receptor are necessary to prevent too many cells from engaging in signaling at the same time and to focus the inductive signal on a single cell (P6.p). A perturbation of LET-23 EGFR trafficking can lead to a multivulva phenotype because decreased ligand sequestering by the 1° VPC P6.p results in increased LET-23 EGFR activation in the distal VPCs [30]. The down regulation of the LET-23 EGFR in all but the 1° VPC is therefore an important mechanism to break the symmetry of the initially equivalent VPCs and select a single cell for the 1° fate. The most frequent phenotype we observed in our screen (31 genes) was persisting LET-23 EGFR expression in 2° VPCs, and for those genes that had significant effect on signaling we found increased rather than decreased vulval induction in the let-60 background. This suggests that a relatively large number of negative regulators of EGFR signaling is required to generate the invariant pattern of vulval cell fates with a single 1° cell flanked by two 2° cells.

Genes Regulating LET-23 EGFR Trafficking Are Conserved
A recent study has indicated that around 38% of all predicted protein coding genes in C. elegans possess at least one human homolog [31]. However, we found for 91% of the genes identified in our screen (74 of 81) at least one human homolog in the

Figure 2. ERM-1 controls LET-23::GFP localization at the basolateral membrane of the vulval cells. doi:10.1371/journal.pgen.1004341.g003
OrthoList, suggesting that the mechanisms regulating EGFR trafficking are strongly conserved. Further studies of these mammalian homologs may provide new means of interfering with deregulated EGFR signaling in human cells.

ERM-1 Is a Temporal Regulator of EGFR Signaling

We describe a new function of the *C. elegans* Ezrin homolog ERM-1 in regulating EGFR signaling on the basolateral membrane of the vulval cells. Based on the subcellular localization and dynamics and on genetic and biochemical data, we propose that ERM-1 forms a complex with the LET-23 EGFR at the basolateral plasma membrane to recruit the receptor into an actin-rich inactive membrane compartment and limit receptor activation (Figure 5H, I). A similar function has been proposed for mammalian NF2 Merlin, which shares similarity to Ezrin/Radixin/Moesin proteins. In confluent cultured epithelial cells, Merlin coordinates adherens junction stabilization with EGFR signaling by recruiting the EGFR into an apical membrane compartment, where the receptor cannot be activated [32]. In analogy, ERM-1 may link a fraction of the LET-23 EGFR pool at the basolateral membrane to cortical F-actin and restrict the access of the receptor to the activating LIN-2/LIN-7/LIN-10 complex [5]. In the absence of the tripartite LIN-2/LIN-7/LIN-10 complex, most of the residual basolateral LET-23 EGFR is probably bound and inactivated by ERM-1. The inhibitory ERM-1 complex thus antagonizes the activating LIN-2/LIN-7/LIN-10 complex to prevent the instant activation and subsequent degradation of the entire basolateral pool of LET-23 EGFR once the AC begins to secrete LIN-3 in the mid-L2 stage. This mechanism allows the vulval cells to maintain high LET-23 EGFR...

**Figure 4. ERM-1 negatively regulates vulval induction and binds to LET-23.** (A) Genetic epistasis analysis between *erm-1* and components of the egfr/ras/mapk pathway. Vulval induction (VI) indicates the average numbers of induced VPCs in different double mutant combinations scored in *erm-1(tm677)* heterozygous (white bars) versus homozygous (gray bars) animals. %Vul indicates the fraction of animals with VI<3 and % Muv the fraction of animals with VI>3. The numbers of animals scored for each genotype are indicated in brackets. N.S: no significant change. *Indicates p<0.05 as determined in a two tailed student’s t-test - two-sample unequal variance. (B) Structures of the GST:ERM-1 fusion proteins tested for LET-23 binding. (C) Interaction of LET-23 from wild-type extracts with different GST:ERM-1 fusion proteins detected on an anti-LET-23 Western blot. (D) Binding of LET-23 extracted from *lin-7(e1413)* and (E) from *let-23(sy1)* mutants to GST:ERM-1 proteins. The dashed lines indicate the approximate positions of the 180 kDa and 116 kDa protein standards.

doi:10.1371/journal.pgen.1004341.g004
activity at later time points after vulval induction. LET-23 EGFR may be released from the ERM-1 complex when the vulval lumen is formed and ERM-1 relocalizes to the apical plasma membrane of the toroids. Such a buffering mechanism may be important, as sustained RAS/MAPK signaling is required during the subsequent phase of vulval morphogenesis when RAS/MAPK activity induces the expression of genes required for the execution of the vulval fates [4,33]. Thus, the strength and duration of EGFR activation during development must be precisely controlled to achieve the correct levels of RAS/MAPK activity required for organogenesis.

**Materials and Methods**

**Strains and General Methods**

*C. elegans* strains were maintained at 20°C on standard nematode growth media [34] and the reference wild-type strain of *C. elegans* used was Bristol N2. Mutant strains used: LGI: *erm-1(tm677)/hT2[hli-4(e937) let(q782) qIs48] (I;III), *rd-1(ne219), lin-10(e1339). LGII: *let-23(sy1), lin-7(e1413), syIs12[hs::lin-3EGF][25]. LGIII: *unc-119(ed3), unc-119(e2498). LGIV: *lin-3(e1417), let-60(n397). LGX: *lin-2(n397). Integrated and extra-chromosomal arrays: *zhIs038[let-23::gfp, unc-119(+)] IV, zhIs396[Plin-48::gfp] [23], *zhEx486[let-7::gfp; Pmyo-2::mCherry], *zhEx487[ego-2::gfp; Pmyo-2::mCherry], *zhEx488[let-3::gfp; Pmyo-2::mCherry].

The construction of the translational reporter constructs used in this study is described in the **Text S1** and **Table S2** (see also Figure S4).

Extra-chromosomal arrays were obtained by microinjection of plasmids at 20 to 50 ng/µl along with the coinjection marker *Pmyo2::mCherry or unc-119(+) at 2 to 10 ng/µl and pBluescript to a final concentration of 150 to 200 ng/µl as described [36].

---

**Figure 5. Temporal regulation of LET-23 EGFR signaling by ERM-1.** (A, B, C) Nomarski images and (A’, B’, C’) EGL-17::CFP expression in *erm-1(tm677)+ controls versus (D through F’) homozygous *erm-1(tm677) mutants at the Pn.p (A’, D’), Pn.px (B’, E’) and Pn.pxx (C’, F’) stages. The scale bar is 10 µm. (G) Quantification of nuclear EGL-17::CFP intensities in P6.p and its descendants. The numbers of animals analyzed are indicated in brackets. *Indicates p<0.01 as determined in a two tailed student’s t-test - two-sample unequal variance. Error bars represent the standard error of the mean. (H) Two antagonistic complexes control LET-23 localization at the basolateral membrane of the VPCs. The ternary LIN-2/LIN-7/LIN-10 complex promotes receptor activation, while the ERM-1 complex (magenta) prevents LET-23 endocytosis and signaling from basolateral membrane. ERM-1 may sequester LET-23 in an actin-rich membrane compartment to prevent receptor activation. (I) In the absence of ERM-1, more LET-23 can be activated via the LIN-2/LIN-7/LIN-10 complex, resulting in enhanced receptor endocytosis and recycling, and ultimately an increased accumulation of LET-23 on the apical plasma membrane.

doi:10.1371/journal.pgen.1004341.g005
was obtained by bombardment of unc-119 mutants with plasmid coated gold particles as described [37]. Primers used and details on the construction of plasmids can be found in the Supplementary Material.

**GST Pull-down and Western Blots**

GST fusion proteins were purified from *E. coli* BL-21 with glutathione-sepharose beads, incubated with 500 µg total protein worm extracts, and bound LET-23 was detected on Western blots with affinity-purified rabbit anti-LET-23 antibodies (1:1000 dilution) raised against the C-terminal 196 amino acids [5].

**RNAi Screen and Microscopy**

RNAi was performed by bacterial feeding as described [38]. LET-23::GFP localization was scored in L3 larvae of the F1 generation mounted on 3% agarose pads supplemented with 5 mM tetramisol. For each RNAi clone, the vulval cells in 30 to 50 animals were observed at 40 to 63-fold magnification with a Leica DMRA wide-field microscope. Positive RNAi clones from the rescreen were verified by DNA sequencing. Images were recorded with a Hamamatsu ORCA-ER CCD camera controlled by the Openlab 5 software package (Improvision). Confocal images were recorded with a Olympus FV-1000 or a Zeiss LSM710 confocal microscope and analyzed with ImageJ [39]. Apical to basolateral intensity ratios were determined in mid-sagittal frames taken with the same illumination and same exposure settings by manually selecting the basal and apical membrane compartments and measuring total fluorescence intensities.

**Fluorescence Recovery after Photobleaching**

Larvae at the Pn.pxx stage were imaged at 20°C using a 63×/1.4 NA oil lens on an Zeiss LSM710 confocal microscope equipped with 458/488/514 nm argon and 405 nm diode lasers. A selected area of the basal or lateral membrane was bleached using the 488 nm argon laser at 85% power setting for 886.6 µsec to bleach around 70% of the signal, and fluorescence recovery was monitored over the following 296 seconds taking a frame every 8 seconds with a 488 nm laser excitation at 20% power intensity, a pinhole equivalent to 2.12 Airy units, a frame size of 256×256 dpi, and a pixel size of 0.53 µm. Data were analyzed in ImageJ by first registering the images with the StackReg plugin and then using the FRAP Norm plugin by Joris Meys [40] to measure recovery. Normalized curves were fitted to the formula I(t) = A(1-e^{-kt})+C using the solver function in MS Excel to calculate the total mobile fraction A and half time as $t_{1/2} = 1/k$.

**Heat Shock Treatment**

Synchronized L3 larvae were heat-treated at 33°C for 30 minutes in a water bath, transferred to 20°C, and imaged at 120, 180, 230 minute after induction under the same illumination and exposure conditions. Quantification of the apical to basal LET-23::GFP intensity ratio with and without heat-shock treatment as described in the results.

**Supporting Information**

**Figure S1** Characterization of the LET-23::GFP reporter. (A) Expression of endogenous LET-23 (aprox. 150 kDa) and LET-23::GFP (aprox. 177 kDa) in total worm lysates of L4 larvae and young adults detected on Western blots probed with anti-LET-23(left) and anti-GFP(right) antibodies. The upper band is LET-23::GFP and the lower band is endogenous LET-23. Integrated LET-23::GFP is expressed at similar levels as endogenous LET-23. (B) Complete rescue of the let-23(tm373) Vulvaless phenotype with an extra-chromosomal let-23::gfp array obtained by microinjection. The percentages of animals with a Vul phenotype in the presence an absence of the extra-chromosomal array are shown. The numbers of animals scored are indicated in brackets. (C) LET-23::GFP expressed from the integrated array used for the screen (JH0038) is localized at basolateral and apical plasma membrane of the vulval cells in wild-type larvae, but (D) mislocalized to the apical compartment in lin-2(n397) mutants. (D) shows the LET-23::GFP channel of (D) merged with the corresponding Nomarski picture. The scale bar is 10 µm.

**Figure S2** Additional examples of genes identified in the receptor localization screen. In each row, the left panels show the Nomarsi images and right panels the fluorescent images. (A) Nomarsi image and (A') Normal basolateral localization of the CED-10::GFP reporter in heterozygous erm-1(tm677)/+ and (B) Nomarsi image and (B') localization of the CED-10::GFP reporter in homozygous erm-1(tm677) mutants. The scale bar is 10 µm.
