Beighton score, Joint hypermobility, Ligamentous laxity, Prevalence, Children, Saudi Arabia
Abstract

Background Generalized Joint Hypermobility (GJH) is common among schoolchildren and usually benign. However, progressively may lead to joint pain and developmental delay. Identifying the GJH at the school-age would facilitate to monitor early changes and to plan for early rehabilitative intervention. Hence, we aimed to determine the prevalence, pattern, and factors associated with the GJH among school-going children in the Majmaah region, Saudi Arabia.

Methods The school children of both genders aged 8 to 14 years from the Majmaah region of Saudi Arabia participated in this cross-sectional study. The Beighton’s score was used to assess the joint hypermobility. Personal characteristics like age, height, weight, Body mass index (BMI), and handedness was also collected. Descriptive statistics were produced for personal characteristics, the point prevalence of hypermobility, frequency of Beighton score distribution, and prevalence of GJH. The association between specific factors and the presence of GJH was analyzed using Chi-square tests and logistic regression measures.

Results The occurrence of GJH as defined by Beighton cutoff score ≥ 4 in the 303 participated primary school children was 15.2%. The prevalence of GJH was high among females (16.8%) compared to males (13.4%), but this difference is not statistically significant. Younger male children (age 8 to 11 years) were 16.7 times more probable to develop hypermobility (adjusted OR 0.06 [95% CI 0.01 – 0.56]) compared to older male children (age 12 to 14 years). No associations were observed among female children.

Conclusion The prevalence rate reported in this study among school-going children was in the lower range in comparison with the rates reported across the globe.
Beighton score of $\geq 4$ was adequate for use in identifying GJH among children in Saudi Arabia.

Background

The increase in mobility of one or more joints compared to the normal flexibility range is referred to as Joint hypermobility [1]. Ligament laxity is the primary cause of joint hypermobility [2]. Ligament laxity and the resulting joint hypermobility are cardinal features of genetic disorders like Marfan syndrome, Ehlers Danlos syndrome, or Osteogenesis imperfecta. However, in most cases, joint hypermobility is observed as a confined phenomenon and is referred to as the Generalised Joint Hypermobility (GJH). Rarely, in the absence of any genetic disorders joint hypermobility is associated with features like arthralgia, back pain, dislocation/subluxation, soft tissue rheumatic disorders, marfanoid habitus, skin abnormalities, eye signs, Incompetence of lower limb vessel valves or hernia or prolapse of rectum and is termed as joint hypermobility syndrome [3].

The reported occurrence of GJH in children with the age group of 6–15 years varies between 8.8% [4] and 64.6% [5]. The prevalence of GJH is high in girls and declines as the age increases [6–10]. Jansson et al. in their study among Swedish school children reported that regardless of age, the girls had presented with marked joint hypermobility. However, the presentation of joint laxity in boys declines as the age progress, whereas in the girls, the joint laxity is at its maximum with the age of 15 years [11]. Earlier researchers demonstrated an influence of ethnic background on GJH. There is a high prevalence of GJH among Asian and African populations compared to the Western population [12–15]. Nonetheless, literature is inadequate regarding the prevalence of GJH among children in the Gulf region.
Beighton score is a valid and reliable tool to screen the hypermobility of the joints and widely used across the globe [16,17]. Beighton’s method includes assessment of hypermobility in 9 joints (bilateral thumbs, bilateral little fingers, bilateral elbows, bilateral knees, and the trunk). The score ranges from zero (0) to nine (9); one (1) point has been awarded for the participant’s ability to carry out each component of the test [12]. All the nine tests were easy to perform and provides quantitative data. The most recommended cutoff score for GJH was ≥ 4 for GJH [3]. Juul et al. and Smits-Engelsman et al. recommended standard protocols to be administered in children [16,17].

GJH is common among school children and usually benign. However, progressively may lead to joint pain and developmental delay. Identifying the GJH at the school-age would facilitate to monitor early changes and to plan for early rehabilitative intervention [5]. Hence this study first of its kind in Saudi Arabia is focused on exploring the prevalence of GJH and associated factors amidst school-going children in the Majmaah region.

Methods

Study design, setting and participants

The school children of both genders aged 8 to 14 years from the Majmaah region of Saudi Arabia participated in this cross-sectional study. Permission was obtained from the Information and Planning Authority for Education—Majmaah, under the Ministry of Education, Saudi Arabia. A letter containing the description of study design and seeking the cooperation of Headteachers of Schools was sent. Children with any apparent or reported signs of disabilities such as cognitive, developmental, or bodily as per the medical data available in school were not included in this study.
Anthropometry measurements

The data related to personal characteristics like age (in years), gender, height (in centimeters), and weight (in kilograms) were collected. Height in standing and weight have been measured by a standard gold method (bare feet, measured to the approximate 1 cm and 100 g, respectively). BMI calculation was done with a metric formula, weight (in kg’s) divided by height (in meters squared) and children were sorted as underweight (BMI less than 18.5), ideal weight (BMI range between 18.5—24.9), overweight (BMI range between 25-29.9) or obese (BMI greater than 30) as per the recommended criteria [18].

Beighton score for Screening GJH

The screening criteria comprises five (5) clinical test, and each of them was awarded either zero (0) or one (1) based on their attempt. These test scores are summed at the end, which will be ranging from zero (0) to nine (9).

Researcher passively performs thumb apposition to the flexor side of the forearm and was performed on the right and left sides, the score of 1 is awarded if the whole thumb touches the flexor side of the forearm (900 of shoulder flexion with extended elbow and pronation of forearm);
Researcher passively performs dorsiflexion of the 5th metacarpophalangeal joint on the right and left sides ≥900 (sitting on chair, arm abducted to 800, elbow flexed 900, forearm rested on the table in pronation);
Researcher passively performs hyperextension of the elbow joint on the right and left sides ≥100 (The subjects were made to sit in a chair with shoulder positioned to 900 of flexion with forearm supinated);
Researcher passively performs hyperextension of the knee on the right and left sides ≥100 (The subjects were positioned in supine lying with legs supported on a table); and
The subjects have been asked to perform flexion of the trunk, with knees in the extended position, so that the palms rest easily on the ground [16].

The cutoff score of ≥ 4 was considered as GJH [3]. Also, a cutoff score ≥ of 6 was used to analyze any association. A 360° universal goniometer was used to measure the joint angles. The measurements and Beighton maneuvers were performed by
two Physical therapists with 15 years of experience in the area of Pediatric practice and research.

**Ethical consideration**

Approval was obtained from Majmaah University Ethical Committee (Approval. No. MUREC—Oct21/COM–2018/6). Children’s parents have been explained with the information (Oral / written) detailing the study, and they signed informed consent to permit their child to participate in the research. Moreover, assent was also obtained from the participating children before their enrollment in this research.

**Statistical analysis**

The data was recorded in the Microsoft Excel sheet and analyzed using SPSS (Version 17.0) for Windows. Descriptive statistics were produced for personal characteristics, the point prevalence of hypermobility, and frequency of Beighton score distribution. The prevalence of GJH was calculated by taking the number of children diagnosed for GJH (Beighton cutoff score of ≥ 4 or ≥ 6) and dividing it by the total number of students who participated in the study. Chi-square statistic was used to compute the association between binary variables and the presence/absence of GJH. Trend analysis was done using logistic regression to find out the associations between categorical variables and the presence or absence of GJH. The level of probability of 5% was used to indicate statistical significance.

**Results**

A total of 303 children participated in this study. The details regarding the personal characteristics are presented in Table 1. The majority of the participated children were females (53.1%) compared to males (46.9%). Nearly 69.3% of the children belonged to the 8—11 age group. Concerning BMI, the majority of the children were
underweight (53.1%) whereas 34.7%, 7.9% and 4.3% of them were normal weight, overweight and obese respectively. Most of the participants were right-hand dominants (95.7%).

The distribution of the total Beighton score of the participants is presented in Table 2. The majority of the participants (75.6%) did not exhibit hypermobility in any of the joints tested in the Beighton score (Score—0). None of the participants in this present study demonstrated hypermobility in all sites tested in the Beighton score.

The occurrence of GJH as formulated by Beighton cutoff score ≥ 4 in the 303 participated primary school children was 15.2% (Males—13.4% and Females—16.8%). When a more vigorous cutoff (≥ 6) was used, the prevalence was 7.6% (Males—4.5% and Females—9.9%).

Table 3 represents the distribution of the participants’ joint hypermobility. The occurrence of hypermobility is high in the elbows (17.2%), then by the thumbs (12.5%), little fingers (12.5%), knees (8.6%) and trunk (0.7%). In females, hypermobility of thumb was more predominant than elbow, knee, finger and trunk hypermobility (19.2%, 16.8%, 10.6%, 8.1%, and 1.2% respectively). In males, hypermobility of the fingers was more predominant than elbow, knee, thumb and trunk hypermobility (18.3%, 17.6%, 6.3%, 4.9%, and 0% respectively). The trunk hypermobility in males was unusual as none of the 142 males could place the palms together completely on the ground with knee in full extension.

The association between personal characteristics and GJH is summarized in Table 4. In males, the relationship between age and presence of GJH (cutoff of ≥ 4) have shown a positive association, both with or without adjustment of other variables (BMI and hand dominance). Males aged 8 to 11 years were 16.7 times more probable for having hypermobility (adjusted OR 0.06 [95% CI 0.01—0.56]) compared
to males aged 12 to 14 years (Table 5). There were no other associations seen when
cutoff of ≥ 4 is used to define GJH in both sexes. No associations have been found
with GJH for the variables assessed by using the cutoff of ≥ 6 in both genders.

Discussion

This is the first study in the entire Gulf region, reflecting the Arab ethnicity to
report the prevalence of GJH among school children aged 8 to 14 years. In the
present study, the prevalence of GJH was 15.2%, when using the cutoff score of
greater than or equal to 4 hypermobile joints from the 9-point scoring system of
Beighton. The prevalence reported in our study is comparable with the prevalence
reported among children at Denmark (9.4%), Egypt (16%), United Kingdom (19.2%)
and less compared to rates reported from Iceland (27.7%), Italy (35.4%) and India
(61.2%) [3,19–23]. The prevalence of GJH was high among females (16.8%)
compared to males (13.4%), but this difference is not statistically significant (P <
0.05). This finding is consistent with the rates reported by El-Garf et al. among
Egyptian children (males - 14.4% and females—18%) [20]. Gyldenkerne et al.
reported a statistically significant high occurrence of GJH among females (16.6%)
compared males (3%) among Children in Denmark [19]. None of the earlier studies
reported a high incidence of GJH among males compared to females [3,19–23].
Female children in our study predominantly presented with hypermobility at the
thumb and elbow, whereas males were commonly presented with hypermobility at
the fingers and elbows. It was fascinating that our participants have shown
considerably less hypermobility with the joint of the lumbar spine. This may be
better described by the factuality that the most of the range of flexion of the
lumbar spine is a conjoint of extensibility of hamstrings and actual vertebral flexion
short hamstrings would be one of the factors that are associated with reduced lumbar flexion in males [25]. Perhaps, a perceived reduction in flexion of the lumbar spine would have been caused by tight hamstrings and this, in turn, could be a reason for low occurrence of hypermobility of the lumbar spine among the boys in the present study.

In our study, the rate of hypermobility declined with an increase in age among males and not in females. The researches among Egyptian and Swedish children reported the inverse age-related decrease in the prevalence of GJH in both males and females [11,20]. The degree of collagen cross-linking is related to hypermobility of the joints as this is believed to increase the collagen ability to attract and hold water and thereby increases the mobility of the joints: as the age increases there is a decrease in body water content and increase in cross-linking of collagen molecules, this accounts for the decrease in joint hypermobility. Another factor that would reduce joint mobility at an older age is increased diameters of muscle fibers [5,16]. Beighton et al. states that the joint laxity is at its maximum at birth, then reduces more quickly during the span of childhood, less quickly in the span of adolescents and more slowly during the span of adulthood [26].

The presence of GJH was not associated with Body mass index (BMI) and Hand dominance both in males and females. Clinch et al. reported a positive association between GJH and BMI among females and not in males. Obese females were 2.7 times more prone to develop hypermobility compared to females who were underweight [3]. Contrastingly, a previous study from India reported an association between hypermobility and moderate and severe malnutrition [23]. No association was found among the variables assessed in GJH when laxity of the joint was scored using a cutoff of greater than or equal to 6 both in males and females. A previous
study in the United Kingdom using Beighton score cutoff of greater than or equal to 6 compared with greater than or equal to 4 to measure generalized joint laxity, have reported that there is stronger evidence of associations between physical activity and maternal education. The authors also suggested raising the cutoff from \( \geq 4 \) to \( \geq 6 \) to determine GJH [3].

Study limitations

One of the limitations of the present study is that the clinical symptoms studied by previous researchers is not assessed [20–23,27]. The correlations between GJH and clinical symptoms are not clear. Al-Rawi et al. (a study over the university students aged between 20—24 years) have found a correlation between joint hypermobility and the symptoms/signs including joint complaints and ligamentous sprains [28]. A study conducted by Mikkelson and Qvindesland among 12-year old children have discussed that hypermobility is not associated with any kind of joint symptoms [21,29]. Grahame’s study concludes that “it is not yet known whether there are a variety of hypermobilities (symptomatic or otherwise) that are not part of a connective tissue disorder” [30]. A further limitation of the present study is that parental or sibling hypermobility, which could be an added “risk” factor for hypermobility is not assessed. Like the limitations encountered in any other observational studies, we can neither rule out the confounding and chance nor establish causal or temporal relationship for the associations reported.

Conclusion

Using the criteria of standard cutoff of \( \geq 4 \) on Beighton score, 46 of the 303 school children (15.2%) in our research was currently diagnosed as having GJH. The prevalence rate reported in this study among school-going children was in the lower
range in comparison with the rates reported across the globe. This recommends that a Beighton score of ≥4 is appropriate to identify children present with a pathologic entity. Raising the Beighton score to increase the threshold for diagnosis would end up in diagnosing only the tiny proportion of children in whom it is difficult to find out the risk factors and pathologic sequel. Stronger evidence of associations was found in this study with the age of the male students when using the Beighton score cutoff of ≥4 compared with ≥6 to define generalized joint laxity. Finally, it is very important to formulate a new and specific tool for a thorough evaluation of laxity of the joint in the growing musculoskeletal system—which can be administered to distinguish children with risk factors such as pain and pathologies of connective tissues from minor cases, who don’t require further medical attention.
