Sensitive dependence on initial conditions in transition to turbulence in pipe flow

By Holger Faisst and Bruno Eckhardt

Fachbereich Physik, Philipps-Universität Marburg, D-35032 Marburg, Germany

(Received ??)

The experiments by Darbyshire and Mullin (J. Fluid Mech. 289, 83 (1995)) on the transition to turbulence in pipe flow show that there is no sharp border between initial conditions that trigger turbulence and those that do not. We here relate this behaviour to the possibility that the transition to turbulence is connected with the formation of a chaotic saddle in the phase space of the system. We quantify a sensitive dependence on initial conditions and find in a statistical analysis that in the transition region the distribution of turbulent lifetimes follows an exponential law. The characteristic mean lifetime of the distribution increases rapidly with Reynolds number and becomes inaccessible for Reynolds numbers exceeding about 2200. Suitable experiments to further probe this concept are proposed.

1. Introduction

The transition to turbulence in pipe flow has been the subject of many investigations since the first documentation of its phenomenology in (Reynolds 1883). Reynolds already noticed that there was no sharp transition, that the transition could be delayed to very high Reynolds number when perturbations to the laminar profile were carefully avoided and that sometimes turbulence appeared without clear evidence for a perturbation that may have triggered it. His findings have been confirmed and expanded on in many subsequent experiments, e.g. (Wygnanski & Champagne 1973; Wygnanski et al. 1975; Rubin et al. 1980; Eggels et al. 1994; Ma et al. 1999; Darbyshire & Mullin 1995). On the theoretical side, no linear instability could be found (see Schmid & Henningson (1994); Meseguer & Trefethen (2003) and references therein) but analysis of the consequences of the non-normality of the linearized problem has led to the identification of efficient amplification mechanisms that can explain the sensitivity to small perturbations of the laminar profile (Boberg & Brosa 1988; Schmid & Henningson 1994; Trefethen et al. 2000, 1993; Grossmann 2000; Hof et al. 2001). On the other hand the simulations in (Brosa 1989) and the experiments in (Darbyshire & Mullin 1995) suggest that even if the perturbations are large enough to trigger turbulence, the flow can re-laminarize without any previous indication. Similar behaviour has been found in plane Couette flow (Schmiegel & Eckhardt 1995, 2000; Bottin et al. 1993; Faisst & Eckhardt 2000; Eckhardt et al. 2002).

Decay of the turbulent flow must follow from the dynamics of the fully developed 3-d turbulent state and cannot be explained by linearization around the laminar flow. The dynamical system concept compatible with such a behaviour is that of a chaotic saddle, a transient object with chaotic dynamics (Tel 1991; Ott 1993). The simplest example of a chaotic saddle arises for a particle in a box with a tiny hole: the dynamics inside the box can be chaotic, as measured by positive Lyapunov exponents, but it is transient and ends when the particle leaves through the hole. The escape through the hole is a
global event, and its rate is not related to the Lyapunov exponent. The analogy then is that the turbulent state is motion in the box, and escape from the box is related to relaminarization. The characteristic signatures of a chaotic saddle are: (a) a sensitive dependence of lifetimes on initial conditions, (b) an exponential distribution of lifetimes for initial conditions around the chaotic saddle, (c) a positive Lyapunov exponent in the chaotic phase, and (d) an independence of the variations of Lyapunov exponents and the escape rates with parameters. We will show here that the transition to turbulence in pipe flow shows all these characteristics and is thus compatible with the formation of a chaotic saddle.

Our analysis is based on numerical simulations of the time evolution of perturbations in circular pipe flow with periodic boundary conditions in the downstream direction. The axial periodicity length will be too short to simulate localized turbulent structures, such as puffs and slugs (Wygnanski & Champagne 1973; Wygnanski et al. 1975), but long enough to capture the local turbulent structures. Following the simulations of Eggels et al. (1994) we take a length $10R$, with $R$ the pipe radius. The turbulence will then typically fill the entire volume and we do not have to consider the advection of the turbulent state by the mean profile: lifetimes can be defined locally. The Reynolds number $Re$ is based on the mean streamwise flow velocity $U$ and the pipe diameter $2R$,

$$Re = 2RU/\nu,$$  

and the units of time are $2R/U$. As in the experiments (Darbyshire & Mullin 1995) we keep the volume flux constant in time: this simplifies the analysis and prevents decay due to a reduction of flux that could occur in pressure driven situations when the flow becomes turbulent.

2. Numerical considerations

We use cylindrical coordinates and employ a pseudo-spectral method with Fourier modes in the periodic azimuthal and downstream direction and Legendre collocation radially (Canuto et al. 1988). Various linear constraints on the velocity field are treated together by the method of Lagrange multipliers: the rigid boundary condition, the solenoidality, and the analyticity in the neighbourhood of the coordinate singularity at the center line (Privman & Miyazaki 1998). We verified our numerical scheme in various ways. For the linearized dynamics we reproduced the literature data on the eigenvalue spectrum of the linearized Navier-Stokes operator with full spectral precision (Schmid & Henningson 1994). For the non-normal linear dynamics and nonlinear 2D dynamics we reproduced Zikanov’s results (Zikanov 1996). At $Re = 5000$ a long, fully nonlinear 3D turbulent trajectory was analysed and its statistical properties agreed with previous numerical and experimental results (Eggels et al. 1994; Quadrio & Sibilla 2000).

The results presented here are obtained with azimuthal and axial resolution of $|n/17| + |m/15| < 1$, where $n$ and $m$ are the azimuthal and streamwise wavenumbers, respectively, and 50 Legendre polynomials radially. This resolution is not the maximal that could be integrated for a single run but reflects a compromise between the mutually exclusive requirements of maximal resolution, maximal integration time for a single run and a large number of sample runs for the statistical evaluations. It is justified by comparisons with lower and higher resolutions which show no significant differences for the range of Reynolds numbers $Re < 2300$ to which we restrict our computations. The maximal integration time after which we terminate a turbulent trajectory is 2000, sometimes 3000 natural time units. This by far exceeds the values accessible in the longest currently available experimental set up (Ma et al. 1999; Hof et al. 2003). For the statistical analysis
and the calculations of Lyapunov exponents more than 1000 runs were needed, adding up to several years of CPU time on a single 2.2 GHz Pentium4/Xeon processor.

The initial conditions for each run are the parabolic profile \( \mathbf{u}_{HP} \) to which a three-dimensional perturbation \( \mathbf{u}_p \) is added. The specific form of \( \mathbf{u}_p \) should not matter, as long as it triggers a transition to turbulence, since the dynamics of the turbulent state has positive Lyapunov exponents and leads to a quick elimination of any details and memory of the initial conditions. Furthermore, experiments with different kinds of wall-normal or azimuthal jets or other perturbations lead to very similar results [Darbyshire & Mullin 1995], so that we can safely assume that there is only one turbulent state to which all initial conditions are attracted. Therefore, we take as initial condition an uncorrelated random superposition of all available spectral modes. Changes in the initial conditions are then limited to variations in the amplitude of the perturbation, not in the form, i.e., throughout this paper we scan the behaviour along a one-dimensional subset in the space of all velocity fields, \( \mathbf{u}(0) = \mathbf{u}_{HP} + a\mathbf{u}_p \).

We define the amplitude \( A \) of an initial disturbance as its kinetic energy in units of the energy of the laminar Hagen-Poiseuille profile \( \mathbf{u}_{HP} \),

\[
A = a^2 \int dV \frac{u_p^2}{u_{HP}^2}.
\]  

The measures that we apply to the turbulent runs are the pressure gradient required to maintain a constant mean flux and the energy variable \( E_{3d} \), the kinetic energy in the streamwise modulated part of the velocity field,

\[
E_{3d} = \sum_n \sum_{m \neq 0} \int_0^R |u_{n,m}(r)|^2 r \, dr.
\]
Figure 2. Turbulent lifetime vs. perturbation amplitude for different Reynolds numbers. For all Reynolds numbers a smooth region with short-lived states can be observed for small amplitudes. For larger Reynolds numbers this is followed by a ragged region of highly fluctuating lifetimes. The threshold amplitude that divides the two regions decreases with Reynolds number. The little rectangle at amplitudes of about $0.03$ at $Re = 2000$ is further magnified in Fig. 3.

The significance of $E_{3d}$ is that if it becomes too small, then the flow is too close to an axially translation invariant flow field and will eventually decay (Zikanov 1996). We therefore terminate integration if it drops below a threshold of $10^{-4}$.

3. Turbulent lifetimes

Typical trajectories are shown in Fig. 1. Within about 150 time units they relax towards the turbulent state. The dashed trace belongs to an initial condition for which the lifetime of the turbulent state is about 2000: there is no indication of the decay until the energy $E_{3d}$ drops so low that turbulence cannot recover.

Scanning the lifetimes of turbulent states as a function of initial amplitude for different Reynolds number we obtain the results shown in Fig. 2. For sufficiently small amplitudes all states decay and the lifetimes are short. Beginning with a Reynolds number of 1800 sharp peaks with very long lifetimes appear. Beyond $Re = 2000$ several initial conditions reach lifetimes up to the integration cut-off of $t_{max} = 2000$. Moreover, the variations in lifetimes between neighboring sampling points in amplitude increase.

The transition between the short lifetimes for the initial conditions that decay quickly towards the laminar state and the longer ones for trajectories that show some turbulent behaviour is a very rapid one. Successive magnifications of a small region in amplitude for $Re = 2000$ are shown in Fig. 3. The increase is not monotonic, with modulations and structures superimposed.

Fig. 4 compares the energy traces for four initial conditions in two ranges of amplitude. Fig. 4a for the smaller mean amplitude shows that in an interval of width about 3% of the mean amplitude the lifetimes increase by about 40%. At a slightly higher amplitude Fig. 4b shows that in an interval of relative width $3 \cdot 10^{-4}$ the lifetimes increase by a factor of almost 4!

Figure 3. Successive magnifications of the lifetime variations with amplitude in the transition region for \( Re = 2000 \). The left panel is a magnification of the box indicated in Fig. 2, the right one a magnification of the interval indicated in the left panel. Note the increased ordinate scale in the right panel.

Figure 4. Energy traces for trajectories in small intervals of amplitude close to the transition region at \( Re = 2000 \), marked by open circles in the corresponding panel in Fig. 3. The small differences in initial conditions are amplified and lead to noticeable differences in their evolution. For panel (b) the lifetimes are larger and the dynamics shows several large amplitude oscillations connected with the turbulent regeneration dynamics.

The strong fluctuations in lifetimes are not limited to variations with amplitude alone, they also occur when changing the Reynolds number for fixed amplitude, as shown in Fig. 5. Such fractal behaviour in the variations of lifetimes under parameter variation has previously been observed in plane Couette flow (Schmiegel & Eckhardt 1997), Taylor-Couette flow for large radii (Faisst & Eckhardt 2000; Eckhardt et al. 2002), and in models with a sufficient number of degrees of freedom (Eckhardt & Mersmann 1999).

4. Lyapunov exponents

The sensitive dependence on variations of initial conditions can also be quantified in terms of Lyapunov exponents. For a trajectory \( u(t) \) and deviations \( \delta u(t) \) the largest Lyapunov exponent is defined as

\[
\lambda = \lim_{||\delta u(0)|| \to 0} \lim_{T \to \infty} \frac{1}{T} \log \frac{||\delta u(T)||}{||\delta u(0)||},
\]

where \( ||\cdot|| \) denotes the Euclidian norm. Instead of a single \( \lambda \) from an infinite time interval we calculate ensembles of finite-time Lyapunov exponents, extracted from the integration of a small deviation from the reference trajectory. The separation was measured after
time intervals of $T = 200$ units, and then rescaled to $||\delta u|| = 10^{-9}$. An initial time interval of 200 units was omitted because of the transient relaxation of the initial conditions onto the turbulent state. Similarly, the last 200 time units were omitted to avoid the decay to the laminar state. The infinite-time Lyapunov exponent was then approximated as the average of the finite-time Lyapunov exponents.

The instantaneous changes in the separation between neighboring trajectories can be used to define local Lyapunov exponents (Eckhardt & Yao 1993). They correlate strongly with large energy fluctuations, see Fig. 6a. When new large scale structures are generated the energy grows strongly and the Lyapunov exponent increases. Towards the end of a nonlinear regeneration cycle the energy goes down and the Lyapunov exponent decreases as well. Therefore, the fluctuations in the exponent are large and averages over at least $10^4$ time units are needed for the determination of reliable numbers. Obviously, this is very difficult to achieve for Reynolds numbers below $Re = 2000$, where only very few trajectories stay turbulent for sufficiently long times.

The largest Lyapunov exponent is shown in Fig. 6b. Its typical value is about $6.5 \times 10^{-2}$ at Reynolds numbers around 2000. For predictability this Lyapunov exponent implies that an uncertainty doubles after a time of $(\ln 2)/\lambda \approx 10$ units. Over a time interval of 200 units a perturbation grows $10^6$-fold! Note that 200 units is about the separation between two oscillations in the mean energy in Figs. 1 and 6a, and is the typical duration
of the regeneration cycle proposed in Hamilton et al. (1995; Waleffe 1995, 1997). Thus, the Lyapunov exponent is small in absolute value, but fairly large on the intrinsic time scales of the turbulent dynamics.

The extreme sensitivity of turbulent lifetimes to variations in initial conditions will make it next to impossible to prepare experimental perturbations sufficiently accurately to reproduce a run. A statistical analysis of, e.g., the distribution of lifetimes obtained by collecting data for several nearby initial conditions, should be more reliable. We therefore study $P(t)$, the probability that a flow started with some initial condition will still be turbulent after a time $t$. A related kind of statistics was proposed in Darbyshire & Mullin (1995): they analyzed the fraction $p$ of initial conditions that remained turbulent over the time $T$ it took for the perturbation to transit the distance between perturbation and detection. (Recall that we do not need to take this advection into account since our periodicity length is so short that the turbulence fills the entire volume.) In terms of our $P(t)$, this probability is $p = P(T)$. However, because of the unknown relation between the initial relaxation times in our simulations and the experiment we cannot compare values.

For the lifetime statistics we used more than 50 initial amplitudes each for eight Reynolds numbers in the range from 1600 to 2200. The amplitudes were fairly high, $\approx 1$, in order to assure transition to turbulence at least for a short time interval. The results for different Reynolds numbers are shown in Fig. 7.

The data support an exponential decay $P(t) \sim \exp(-\epsilon t)$ for large times, with $\epsilon$ the rate of escape from the turbulent state. An exponential distribution of turbulent lifetimes is a characteristic signature for escape from a chaotic saddle (Kadanoff & Tang 1984; Tel 1991; Ott 1993). They have previously been seen in experiments (Bottin & Chat 1993; Bottin et al. 1998) and numerical studies on plane Couette flow (Schmiegel 1999), as well as in Taylor-Couette flow (Eckhardt et al. 2002). They seem to be a generic feature of the transition in shear flows that are not dominated by linear instabilities.
Another measure that can be extracted from the lifetime distributions is the median, \( \tau = \frac{\ln 2}{\epsilon} \). The median is the time up to which half the states have decayed. It is also well suited for numerical studies since it is not affected by the cut-off in integration time. The median increases rapidly with Reynolds number as shown in Fig. 7b. Below \( Re = 1800 \) the increase is mainly due to non-normal transient linear dynamics. When the Reynolds number is increased above \( Re = 2000 \) the median of the turbulent lifetimes as well as the fluctuations rise rapidly until the median reaches the cut-off lifetime of 2000 at \( Re \approx 2200 \). The inset in Fig. 7 shows the inverse median lifetime vs. \( Re \) and among the possible fits for these data the most satisfactory ones supports a divergence like \( (Re_c - Re)^{-1} \), with \( Re_c \approx 2250 \). Such a divergence would be connected with a transition from the chaotic saddle for lower \( Re \) to an attractor for larger \( Re \).

However, it is known from other models that the lifetimes can increase rapidly without a true singularity (Tel 1991; Crutchfield & Kaneko 1988). The question of whether we will arrive at a turbulent attractor cannot be answered here. But from the rapid increase it is clear that it will become an attractor for all practical purposes: for a setup with length 1000 diameters the median will exceed this value for Reynolds number about 2130. For this observation time the fraction of states with shorter lifetimes drops from 80% of all initial conditions for \( Re = 2000 \) to 40% for \( Re = 2150 \) and to zero for \( Re = 2200 \). These numbers are obtained from the numerical simulations and include the initial transient; numbers in other simulations and experiments may be different, but the rapid increase will remain the same.

5. Conclusions

An exponential distribution of lifetimes can be obtained for a constant probability of decaying. In view of the internal dynamics and the characteristic times connected with it, one can interpret this as the probability of decaying towards the laminar state at the end of each turbulent regeneration cycle. The conclusion from the exponential distribution of lifetimes is that this probability remains constant during the evolution, independent of the ‘age’ of the trajectory.

It is worthwhile pointing out that the strong variation of the median lifetimes with \( Re \) is not reflected in the Lyapunov exponent, which increases only linearly with \( Re \): this shows that the chaotic dynamics on the turbulent saddle and the escape from it are two different processes with independent characteristics.

There are two predictions that should be accessible to experimental investigation: the behaviour near the boundary between laminar and turbulent and the exponential distribution of lifetimes. The increase in lifetime for increasing perturbation amplitude can be analyzed with a series of sensors along the pipe. The oscillations in Fig. 6 have a period of about 200 time units, which translates into 200 diameters. Thus, if a perturbation can be localized within a few radii, detectors that are further and further downstream might be able to reproduce some of the oscillations in Figure 4 as the perturbation amplitude is increased. Similarly, it might be possible to experimentally detect the Lyapunov exponents in the flow: with a Lyapunov exponent of about 0.07, a 5% uncertainty in the preparation of initial conditions will increase to 100% in a time of about 40 units, i.e. 40 diameters. Thus, placing detectors at spacings of several diameters apart should allow a determination of the separation between flow states starting from similar initial conditions.

The second measurement is more easily performed: repeated runs with similar perturbations give the probability of finding a turbulent state that exists at least up to time \( t \). The time can be varied again by placing detectors at different locations along the pipe.
As explained, the exponential distribution of lifetimes is a property of the turbulent state in the transition region and will not depend critically on the type of initial conditions used. Exact reproduction of an initial condition is hence not essential here since all initial conditions relax to the same turbulent state. The median lifetime increases rapidly with Reynolds number, from about 220 at $Re = 1800$ to 750 at $Re = 2100$. Given the experimental limitations on the length of the pipe this region looks like a promising range for experiments. The mechanism studied here, the formation of a chaotic saddle, is fairly independent of the boundary conditions, but the quantitative characteristics may depend on it. Since the experiments will not have periodic boundary conditions in downstream direction and since the turbulence may be localized in puffs or slugs it will be interesting to see whether this will affect the lifetimes or its distribution.

A detailed analysis of the distribution of lifetimes is a task which is still much better suited for experiments than for numerics: it is not necessary to prepare the initial disturbance with highest precision, and the experimental observation time is of the order of 1 minute for an experimental run, followed by about half an hour for the water to return to rest in the head-tank. On the other hand, a single trajectory in our computation takes up to 10 days.

The picture that emerges from these data is that the transition to turbulence in pipe flow is connected with the formation of a chaotic saddle. The turbulent dynamics is chaotic, the lifetimes are exponentially distributed and the transition depends sensitively on the initial state. The same characteristics have been found in other shear flows without a linear instability as well (Schmiegel & Eckhardt 1997; Eckhardt et al. 2002; Bottin et al. 1998; Faisst & Eckhardt 2000). The recent discovery of travelling waves in pipe flow for Reynolds numbers as low as 1250 (Faisst & Eckhardt 2003; Wedin & Kerswell 2003) strengthens this picture by providing some of the states around which the network of homoclinic and heteroclinic connections that carry the chaotic saddle may form.
