Beyond UCB:
Optimal and Efficient Contextual Bandits with Regression Oracles

Dylan J. Foster  Alexander Rakhlin

{dylanf,rakhlin}@mit.edu

Abstract

A fundamental challenge in contextual bandits is to develop flexible, general-purpose algorithms with computational requirements no worse than classical supervised learning tasks such as classification and regression. Algorithms based on regression have shown promising empirical success, but theoretical guarantees have remained elusive except in special cases. We provide the first universal and optimal reduction from contextual bandits to online regression. We show how to transform any oracle for online regression with a given value function class into an algorithm for contextual bandits with the induced policy class, with no overhead in runtime or memory requirements. We characterize the minimax rates for contextual bandits with general, potentially nonparametric function classes, and show that our algorithm is minimax optimal whenever the oracle obtains the optimal rate for regression. Compared to previous results, our algorithm requires no distributional assumptions beyond realizability, and works even when contexts are chosen adversarially.

1 Introduction

We consider the design of practical, provably efficient algorithms for contextual bandits, where a learner repeatedly receives contexts and makes decisions on the fly so as to learn a policy that maximizes their total reward. Contextual bandits have been successfully applied in user recommendation systems (Agarwal et al., 2016) and mobile health applications (Tewari and Murphy, 2017), and in theory they are perhaps simplest reinforcement learning problem that embeds the full complexity of statistical learning with function approximation.

A key challenge in contextual bandits is to develop flexible, general purpose algorithms that work for arbitrary, user-specified classes of policies and come with strong theoretical guarantees on performance. Depending on the task, a user might wish to try decision trees, kernels, neural nets, and beyond to get the best performance. General-purpose contextual bandit algorithms ensure that the user doesn’t have to design a new algorithm from scratch every time they encounter a new task.

Oracle-based algorithms constitute the dominant approach to general-purpose contextual bandits. Broadly, these algorithms seek to reduce the contextual bandit problem to basic supervised learning tasks such as classification and regression so that off-the-shelf algorithms can be applied. However, essentially all oracle-based contextual bandit algorithms suffer from one or more of the following issues:

1. Difficult-to-implement oracle.
2. Strong assumptions on hypothesis class or distribution.
3. High memory and runtime requirements.
Agnostic oracle-efficient algorithms (Langford and Zhang, 2008; Dudik et al., 2011; Agarwal et al., 2014) require few assumptions on the distribution, but reduce contextual bandits to cost-sensitive classification. Cost-sensitive classification is intractable even for simple hypothesis classes (Klivans and Sherstov, 2009), and in practice implementations are forced to resort to heuristics to implement the oracle (Agarwal et al., 2014; Krishnamurthy et al., 2016).

Foster et al. (2018) recently showed that a variant of the UCB algorithm for general function classes (Russo and Van Roy, 2014) can be made efficient in terms of calls to an oracle for supervised regression. Regression alleviates some of the practical issues with classification because it can be solved in closed form for simple classes and is amenable to gradient-based methods. Indeed, Foster et al. (2018) and Bietti et al. (2018) found that this algorithm typically outperformed algorithms based on classification oracles across a range of datasets. However, the theoretical analysis of the algorithm relies on strong distributional assumptions that are difficult to verify in practice, and it can indeed fail pathologically when these assumptions fail to hold.

All of the provably optimal general-purpose algorithms described above—both classification- and regression-based—are memory hungry: they keep the entire dataset in memory and repeatedly augment it before feeding it into the oracle. Even if the oracle itself is online in the sense that it admits streaming or incremental updates, the resulting algorithms do not have this property. At this point it suffices to say that—to our knowledge—no algorithm with provably optimal regret has made it into a large-scale contextual bandit deployment in the real world (e.g., Agarwal et al. (2016)).

In this paper, we address issues (1), (2), and (3) simultaneously: We give a new contextual bandit algorithm which is efficient in terms of queries to an online oracle for regression, and which requires no assumptions on the data-generating process beyond a standard realizability assumption.

1.1 Setup

We consider the following contextual bandit protocol, which occurs over \( T \) rounds. At each round \( t \in [T] \), Nature selects a context \( x_t \in \mathcal{X} \) and loss function \( \ell_t : \mathcal{A} \to [0, 1] \), where \( \mathcal{A} = [K] \) is the learner’s action space. The learner then selects an action \( a_t \in \mathcal{A} \) and observes \( \ell_t(a_t) \). We allow the contexts \( x_t \) to be chosen arbitrarily by an adaptive adversary, but we assume that each loss \( \ell_t \) is drawn independently from a fixed distribution \( \mathbb{P}_{\ell_t} \), where \( \mathbb{P}_{\ell_1}, \ldots, \mathbb{P}_{\ell_T} \) are selected a-priori by an oblivious adversary.

We assume that the learner has access to a class of value functions \( \mathcal{F} \subset (\mathcal{X} \times \mathcal{A} \to [0, 1]) \) (such as linear models or neural networks) that models the mean of the reward distribution. Specifically, we make the following standard realizability assumption (Chu et al., 2011; Agarwal et al., 2012; Foster et al., 2018).

Assumption 1 (Realizability). There exists a regressor \( f^* \in \mathcal{F} \) such that for all \( t \), \( f^*(x, a) = \mathbb{E}[\ell_t(a) \mid x_t = x] \).

The learner’s goal is to compete with the class of policies induced by the model class \( \mathcal{F} \). For each regression function \( f \in \mathcal{F} \), we let \( \pi_f(x) = \arg\min_{a \in \mathcal{A}} f(x, a) \) be the induced policy. Then aim of the learner is to minimize their regret to the optimal policy:

\[
\text{Reg}_{\text{CB}}(T) = \sum_{t=1}^{T} \ell_t(a_t) - \sum_{t=1}^{T} \ell_t(\pi^*(x_t)),
\]

where \( \pi^* := \pi_{f^*} \). Going forward, we let \( \Pi_f = \{ \pi_f \mid f \in \mathcal{F} \} \) denote the induced policy class.

1.2 Contributions

We introduce the notion of an online regression oracle. At each time \( t \), an online regression oracle, which we denote \( \text{SqAlg} \) (for “square loss regression algorithm”), takes as input a tuple \( (x_t, a_t) \), produces a real-valued prediction \( \hat{y}_t \in \mathbb{R} \), and then receives the true outcome \( y_t \). The goal of the oracle is to predict the outcomes as
well as the best function in a class $\mathcal{F}$, in the sense that for every sequence of outcomes the square loss regret is bounded:

$$
\sum_{t=1}^{T} (\hat{y}_t - y_t)^2 - \inf_{f \in \mathcal{F}} \sum_{t=1}^{T} (f(x_t, a_t) - y_t)^2 \leq \text{Reg}_{\text{Sq}}(T).
$$

(2)

Our main algorithm, SquareCB (Algorithm 1), is a reduction that efficiently and optimally turns any online regression oracle into an algorithm for contextual bandits in the realizable setting.

**Theorem 1 (informal).** Suppose Assumption 1 holds. Then SquareCB, when invoked with an online regression oracle with square loss regret $\text{Reg}_{\text{Sq}}(T)$, ensures that with high probability

$$
\text{Reg}_{\text{CB}}(T) \leq C \cdot \sqrt{KT \cdot \text{Reg}_{\text{Sq}}(T)},
$$

where $C > 0$ is a small numerical constant. Moreover, SquareCB inherits the memory and runtime requirements of the oracle.

We show (Section 3) that SquareCB is optimal, in the sense that for every class $\mathcal{F}$, there exists a choice for the oracle SqAlg such that SquareCB attains the minimax optimal rate for $\mathcal{F}$. For example, when $|\mathcal{F}| < \infty$, one can choose SqAlg such that $\text{Reg}_{\text{Sq}}(T) \leq 2 \log |\mathcal{F}|$, and so SquareCB enjoys the optimal rate $\text{Reg}_{\text{CB}}(T) \leq C \sqrt{KT \log |\mathcal{F}|}$ for finite classes (Agarwal et al., 2012). On the other hand, the reduction is black-box in nature, so on the practical side one can simply choose SqAlg to be whatever works best.

An advantage of working with 1) regression and 2) online oracles is that we can instantiate SquareCB reduction to give new provable end-to-end regret guarantees for concrete function classes of interest. In Section 2 we flesh this direction out and provide new guarantees for high-dimensional linear classes, generalized linear models, and kernels. SquareCB is also robust to model misspecification: we show (Section 5.1) that the performance gracefully degrades when the realizability assumption is satisfied only approximately.

Compared to previous methods, which either maintain global confidence intervals, version spaces, or distributions over feasible hypotheses, our method applies a simple mapping proposed by Abe and Long (1999) from scores to action probabilities at each step. This leads to the method’s efficient runtime guarantee. In Section 5.2 we show that this type of reduction extend beyond the finite actions by designing a variant of SquareCB that has $\text{Reg}_{\text{CB}}(T) \leq C \sqrt{d_A T \cdot \text{Reg}_{\text{Sq}}(T)}$ for the setting where actions live in the $d_A$-dimensional unit ball in $\ell_2$.

### 1.3 Towards learning-theoretic guarantees for contextual bandits

The broader goal of this work is to develop a deeper understanding of the algorithmic principles and statistical complexity of contextual bandit learning in the “large-$\mathcal{F}$, small-$A$” regime, where the goal is to learn from a rich, potentially nonparametric function class with a small number of actions. We call this setting “Contextual Bandits with Rich Classes of Hypotheses”, or RichCBs.

Beyond providing a general algorithmic principle for RichCBs (SquareCB), we resolve two central questions regarding the statistical complexity of RichCBs.

1. What are the minimax rates for RichCBs when $|\mathcal{F}| = \infty$?
2. Can we achieve logarithmic regret for RichCBs when the underlying instance has a gap?

Recall that for general finite classes $\mathcal{F}$, the gold standard here is $\text{Reg}_{\text{CB}}(T) \leq \sqrt{KT \log |\mathcal{F}|}$, with an emphasis on the logarithmic scaling in $|\mathcal{F}|$. For the first point, we characterize (Section 3) the minimax rates for infinite classes $\mathcal{F}$ as a function of metric entropy, a fundamental complexity measure in learning theory. We also
show that SquareCB is universal, in the sense that it can always be instantiated with a choice of SqAlg to achieve the minimax rate. Interestingly, we show that for general classes with metric entropy $H(F, \varepsilon)$, the minimax rate is $\tilde{\Theta}(T \cdot \varepsilon_T)$, where $\varepsilon_T$ satisfies the classical balance

$$\varepsilon_T^2 \propto H(F, \varepsilon_T)/T,$$

found throughout the literature on nonparametric estimation (Yang and Barron, 1999; Tsybakov, 2008).

For the second point, we show (Section 4), that for general function classes $F$ with $|F| < \infty$, obtaining logarithmic regret when there is a gap between the best and second-best action is impossible if we insist that regret scales with $\text{polylog}|F|$: There exist instances with constant gap and polynomially large hypothesis class for which any algorithm must experience $\sqrt{T}$-regret.

This last point suggests that designing optimal algorithms for RichCBs seems to require new algorithmic ideas. Indeed, two of the dominant strategies for the realizable setting, generalized UCB and Thompson sampling (Russo and Van Roy, 2013), always adapt to the gap to get logarithmic regret, but without strong structural assumptions on $F$ they can have regret $\Omega(|F|)$.

### 1.4 Related work

Our algorithm builds off of the work of Abe and Long (1999) (see also Abe et al. (2003)). Our key insight is that a particular action selection scheme used in these works for linear contextual bandits actually yields an algorithm for general function classes when combined with the idea of an online regression oracle. Interestingly, while Abe and Long (1999) contains essentially the first formulation of the contextual bandit problem, the techniques used within seem to have been forgotten by time in favor of more recent approaches to linear contextual bandits (Abbasi-Yadkori et al., 2011; Chu et al., 2011); see further discussion in Section 2.

As discussed in the introduction, our results build on a long line of work on oracle-efficient contextual bandit class algorithms. We discuss some important points of comparison below.

**Agnostic algorithms.** The longest line of research on oracle-efficient CBs focuses on the agnostic i.i.d. setting (Langford and Zhang, 2008; Dudik et al., 2011; Agarwal et al., 2014). All of these algorithms assume access to an offline cost-sensitive classification oracle for the policy class which, given a dataset $(x_1, \ell_1), \ldots, (x_n, \ell_n)$, solves

$$\arg \min_{\pi \in \Pi} \sum_{t=1}^n \ell_t(\pi(x_t)).$$  

In particular, the ILOVECONBANDITS (ILTCB) algorithm (Agarwal et al., 2014) enjoys optimal $\sqrt{KT \log |\Pi|}$ regret given such an oracle. This type of oracle has two drawbacks. First, classification for arbitrary datasets is intractable for most policy classes, so implementations typically resort to heuristics to implement (3). Second, because the oracle is offline, the memory required by ILTCB scales linearly with $T$ (the algorithm repeatedly generates augmented versions of the dataset and feeds them into the oracle). To deal with this issue the implementation of ILTCB in Agarwal et al. (2014) resorts to heuristics in order to make use of an online oracle classification, but the resulting algorithm has no guarantees, and analyzing it was left as an open problem.

A parallel line of work focuses on algorithms for the adversarial setting where losses are also arbitrary (Rakhlin and Sridharan, 2016; Syrgkanis et al., 2016a,b). Notably, the BISTRO algorithm (Rakhlin and Sridharan, 2016) essentially gives a reduction from adversarial CBs to a particular class of “relaxation-based” online learning algorithms for cost-sensitive classification, but the algorithm has sub-optimal $T^{3/4}$ regret for finite classes.
Realizability-based algorithms. Under the realizability assumption, Foster et al. (2018) provide a version of the UCB strategy for general function classes (Russo and Van Roy, 2014) that makes use of an offline regression oracle that solves
\[
\arg\min_{f \in \mathcal{F}} \sum_{t=1}^{n} (f(x_t, a_t) - \ell_t(a_t))^2. \tag{4}
\]
While this is typically an easier optimization problem than (3)—it can be solved in closed form for linear classes and is amenable to gradient-based methods—the algorithm only attains optimal regret under strong distributional assumptions (beyond just realizability) or when the class \( \mathcal{F} \) has bounded eluder dimension (Russo and Van Roy, 2013), and it can have linear regret when these assumptions fail to hold (Foster et al., 2018, Proposition 1).

Thompson sampling and posterior sampling are closely related to UCB and have similar regret guarantees (Russo and Van Roy, 2014). These algorithms are only efficient for certain simple classes \( \mathcal{F} \), and implementations for general classes resort to heuristics such as bootstrapping, which do not have strong theoretical guarantees except in special cases (Vaswani et al., 2018; Kveton et al., 2019).

We mention in passing that under our assumptions (realizability, online regression oracle), one can design an online oracle-efficient variant of \( \varepsilon \)-Greedy with \( T^{2/3} \)-type regret; SquareCB appears to be strictly superior.

Other square loss-related reductions. Abernethy et al. (2013) consider the related problem reducing realizable contextual bandits with general function classes \( \mathcal{F} \) and large action spaces to knows-what-it-knows (KWIK) learning oracles (Li et al., 2011). KWIK learning is much stronger property than regret minimization, and KWIK learners only exist for certain structured hypotheses classes. Interestingly though, this work also provides a computational lower bound which suggests that efficient reductions of the type we provide here (SquareCB) are not possible if one insists on \( \log K \) dependence rather than \( \text{poly}(K) \) dependence.

Abbasi-Yadkori et al. (2012) develops contextual bandit algorithms that use online regression algorithms to form confidence sets for use within UCB-style algorithms. Ultimately these algorithms inherit the usual drawbacks of UCB, namely that they require either strong assumptions on the structure of \( \mathcal{F} \) or strong distributional assumptions.

1.5 Additional notation

We adopt non-asymptotic big-oh notation: For functions \( f, g : \mathcal{X} \to \mathbb{R}_+ \), we write \( f = O(g) \) if there exists some constant \( C > 0 \) such that \( f(x) \leq C g(x) \) for all \( x \in \mathcal{X} \). We write \( f = \tilde{O}(g) \) if \( f = O(g \max\{1, \text{polylog}(g)\}) \).

For a vector \( x \in \mathbb{R}^d \), we let \( \|x\|_2 \) denote the euclidean norm and \( \|x\|_\infty \) denote the element-wise \( \ell_\infty \) norm. For a matrix \( A \), we let \( \|A\|_{\text{op}} \) denote the operator norm. If \( A \) is symmetric, we let \( \lambda_{\text{min}}(A) \) denote the minimum eigenvalue. When \( P \succ 0 \) is a positive definite matrix, we let \( \|x\|_P = \sqrt{\langle x, Px \rangle} \) denote the induced weighted euclidean norm.

2 The reduction: SquareCB

We now describe our main algorithm, SquareCB, and prove its regret guarantees along with some consequences for concrete function classes. To state the guarantees, we first formalize the idea of an online regression oracle sketched in the introduction.
2.1 Online regression oracles

We assume access to an oracle $\text{SqAlg}$ for the standard online learning setting with the square loss (Cesa-Bianchi and Lugosi, 2006, Chapter 3). The oracle performs real-valued online regression with features in $Z := \mathcal{X} \times \mathcal{A}$, and is assumed to have a prediction error guarantee relative to the regression function class $\mathcal{F}$. We consider the following model:

For $t = 1, \ldots, T$:

- Nature chooses input instance $z_t = (x_t, a_t)$.
- Algorithm chooses prediction $\hat{y}_t$.
- Nature chooses outcome $y_t$.

Formally, we model the algorithm as a sequence of mappings $\text{SqAlg}_t : Z \times (Z \times \mathbb{R})^{t-1} \rightarrow [0, 1]$, so that $\hat{y}_t = \text{SqAlg}_t(z_t; (z_1, y_1), \ldots, (z_{t-1}, y_{t-1}))$ in the protocol above. Each such algorithm induces a mapping $\hat{y}_t(x, a) := \text{SqAlg}_t(x, a; (z_1, y_1), \ldots, (z_{t-1}, y_{t-1}))$,

which corresponds to the prediction the algorithm would make at time $t$ if we froze its internal state and fed in the feature vector $(x, a)$.

The simplest condition under which our reduction works posits that $\text{SqAlg}$ enjoys a regret bound for individual sequence prediction.

**Assumption 2a.** The algorithm $\text{SqAlg}$ guarantees that for every (possibly adaptively chosen) sequence $z_{1:T}, y_{1:T}$, regret is bounded as

$$\sum_{t=1}^{T} (\hat{y}_t - y_t)^2 - \inf_{f \in \mathcal{F}} \sum_{t=1}^{T} (f(z_t) - y_t)^2 \leq \text{Reg}_{\text{Sq}}(T).$$

(6)

While there is a relatively complete theory characterizing what regret bounds $\text{Reg}_{\text{Sq}}(T)$ can be achieved for this setting for general classes $\mathcal{F}$ (Rakhlin and Sridharan, 2014), the requirement that the regret bound holds for arbitrary sequences $y_{1:T}$ may be restrictive for some classes, at least as far as efficient algorithms are concerned. The following relaxed assumption also suffices.

**Assumption 2b.** Under Assumption 1, the algorithm $\text{SqAlg}$ guarantees that for every (possibly adaptively chosen) sequence $\{({x_t, a_t})\}_{t=1}^{T}$, we have

$$\sum_{t=1}^{T} (\hat{y}_t - f^*(x_t, a_t))^2 \leq \text{Reg}_{\text{Sq}}(T).$$

(7)

Assumption 2b holds with high probability whenever Assumption 2a holds and the problem is realizable, but it is a weaker condition that allows for algorithms tailored toward realizability; we shall see examples of this in the sequel. The assumption shows that the choice of square loss in (6) does not actually play a critical role: Any algorithm that attains a regret bound of the form (6) with the square loss replaced by a strongly convex loss such as the log loss implies a bound of the type (7) under realizability.

2.2 The algorithm

Our main algorithm, SquareCB, is presented in Algorithm 1. At time $t$, the algorithm receives the context $x_t$ and computes the oracle’s predicted scores $\hat{y}_t(x_t, a)$ for each action. Then, following the probability selection scheme of Abe and Long (1999), it computes the action with the lowest score ($b_t$) and assigns a probability to every other action inversely proportional to the gap between the action’s score and that of $b_t$. Finally, the algorithm samples its action $a_t$ from this distribution, observes the loss $\ell_t(a_t)$, and feeds the tuple $((x_t, a_t), \ell_t(a_t))$ into the oracle. The main guarantee for the algorithm is as follows.
Algorithm 1 SquareCB

1: **parameters:**
   - Learning rate $\gamma > 0$, exploration parameter $\mu > 0$.
   - Online regression oracle $\text{SqAlg}$.
2: **for** $t = 1, \ldots, T$ **do**
3:   - Receive context $x_t$.
   - // **Compute oracle’s predictions** (Eq. (5)).
4:   - For each action $a \in \mathcal{A}$, compute $\hat{y}_{t,a} := \hat{y}_t(x_t, a)$.
5:   - Let $b_t = \arg \min_{a \in \mathcal{A}} \hat{y}_{t,a}$.
6:   - For each $a \neq b_t$, define $p_{t,a} = \frac{1}{\mu + \gamma(\hat{y}_{t,a} - \hat{y}_{t,b_t})}$, and let $p_{t,b_t} = 1 - \sum_{a \neq b_t} p_{t,a}$.
7:   - Sample $a_t \sim p_t$ and observe loss $\ell_t(a_t)$.
8:   - Update $\text{SqAlg}$ with example $((x_t, a_t), \ell_t(a_t))$.

**Theorem 1.** Suppose Assumption 1 and Assumption 2a/b hold. Then for any $\delta > 0$, by setting $\mu = K$ and $\gamma = \sqrt{KT/(\text{Reg}_{\text{SqAlg}}(T) + \log(2\delta^{-1}))}$, SquareCB guarantees that with probability at least $1 - \delta$,

$$\text{Reg}_{\text{CB}}(T) \leq 4\sqrt{KT \cdot \text{Reg}_{\text{SqAlg}}(T)} + 8\sqrt{KT \log(2\delta^{-1})}.$$  (8)

Let us discuss some key features of the algorithm and its regret bound.

- The algorithm enjoys $\tilde{O}(\sqrt{T})$-regret whenever the oracle $\text{SqAlg}$ gets a fast $\log T$-type rate for online regression. This holds for finite classes ($\text{Reg}_{\text{SqAlg}}(T) = \log|\mathcal{F}|$) as well as parametric classes such as linear functions in $\mathbb{R}^d$ ($\text{Reg}_{\text{SqAlg}}(T) = d \log (T/d)$). We sketch some more examples below, and we show in Section 3 that the regret is optimal whenever $\text{SqAlg}$ is optimal.

- The algorithm inherits the runtime and memory requirements of the oracle $\text{SqAlg}$ up to lower order terms. If $\mathcal{T}_{\text{SqAlg}}$ denotes per-round runtime for $\text{SqAlg}$ and $\mathcal{M}_{\text{SqAlg}}$ denotes the maximum memory, then the per-round runtime of SquareCB is $O(\mathcal{T}_{\text{SqAlg}} + K)$, and the maximum memory is $O(\mathcal{M}_{\text{SqAlg}} + K)$.

- The regret scales as $\sqrt{K}$ in the number of actions. This is near-optimal in the sense that any algorithm that works uniformly for all oracles must pay a $\tilde{O}(\sqrt{K})$ factor: For multi-armed bandits, one can achieve $\text{Reg}_{\text{sq}}(T) = \log K$, yet the optimal bandit regret is $\Omega(\sqrt{KT})$. However, for specific function classes, the dependence on $K$ may be suboptimal (e.g., for linear classes, regret can be made to scale only with $\log K$ (Chu et al., 2011)).

At a conceptual level, the proof (which, beyond the idea of using a generic regression oracle and taking advantage of modern martingale tail bounds, closely follows Abe and Long (1999)) is interesting because it is agnostic to the structure of the class $\mathcal{F}$. We show that at each timestep, the instantaneous bandit regret is upper bounded by the instantaneous square loss regret of $\text{SqAlg}$. No structure is shared across timesteps, and all of the heavy lifting regarding generalization is taken care of by Assumption 2a/Assumption 2b.

One important point to discuss is the assumption that the bound (7) holds for every sequence $\{(x_t, a_t)\}_{t=1}^T$.

While the assumption that the bound holds for adaptively chosen contexts $x$ can be removed if contexts are i.i.d., the analysis critically uses that the regret bound holds when the actions $a_1, \ldots, a_T$ are chosen adaptively (since actions selected in early rounds are used by SquareCB to determine the action distribution at later rounds). On a related note, even when contexts are i.i.d., it is not clear that one can implement an online regression oracle that satisfies the requirements of Theorem 1 via calls to an offline regression oracle, and

---

1This can be achieved through Vovk’s aggregating algorithm (Vovk, 1995).
offline versus online regression oracles appear to be incomparable assumptions. Whether optimal regret can be attained via reduction to an offline oracle remains an interesting open question.

2.3 Examples and applications

Online square loss regression is a well-studied problem, and efficient algorithms with provable regret guarantees are known for many classes (Vovk, 1998; Azoury and Warmuth, 2001; Vovk, 2006; Gerchinovitz, 2013; Rakhlin and Sridharan, 2014; Gaillard and Gerchinovitz, 2015). Here we take advantage of these results by instantiating SqAlg within SquareCB to derive end-to-end regret guarantees for various classes—some new, some old.

Low-dimensional linear classes. We first consider the familiar LinUCB setting, where

$$\mathcal{F} = \{(x, a) \mapsto \langle \theta, x_a \rangle \mid \theta \in \mathbb{R}^d, \|\theta\|_2 \leq 1\},$$

and $x = (x_a)_{a \in A}$, where $x_a \in \mathbb{R}^d$ has $\|x_a\|_2 \leq 1$. Here LinUCB obtains $\text{Reg}_{\text{CB}}(T) \leq O(\sqrt{dT \log \langle K T \rangle})$ (Chu et al., 2011). By choosing SqAlg to be the Vovk-Azoury-Warmuth forecaster, which has $\text{Reg}_{\text{Sq}}(T) \leq d \log (T/d)$ (Vovk, 1998; Azoury and Warmuth, 2001), SquareCB has $\text{Reg}_{\text{CB}}(T) \leq O(\sqrt{d K T \log (T/d)})$. This has worse dependence on $K$ (square root rather than logarithmic), the resulting algorithm works when contexts are chosen by an adaptive adversary, whereas LinUCB requires an oblivious adversary. It would be interesting to understand whether such a tradeoff is optimal. We also remark that—ignoring dependence on $K$—the algorithm precisely matches a recently established lower bound of $\Omega(\sqrt{d T \log (T/d)})$ for this setting (Li et al., 2019).

High-dimensional linear classes and Banach spaces. In the same setting as above, by choosing SqAlg to be Online Gradient Descent, we obtain $\text{Reg}_{\text{Sq}}(T) \leq O(\sqrt{T})$, and consequently $\text{Reg}_{\text{CB}}(T) \leq O(K^{1/2}T^{3/4})$.

For a more general version of this result, we let $(\mathcal{B}, \|\cdot\|)$ be a separable Banach space and take

$$\mathcal{F} = \{(x, a) \mapsto \langle \theta, x_a \rangle \mid \theta \in \mathcal{B}, \|\theta\| \leq 1\},$$

where $x_a$ belongs to the dual space $(\mathcal{B}^*, \|\cdot\|_*)$ and has $\|x_a\|_* \leq 1$. For this setting, whenever $\mathcal{B}$ is $(2, D)$-uniformly convex, Online Mirror Descent can be configured to have $\text{Reg}_{\text{Sq}}(T) \leq \sqrt{T/D}$ (Srebro et al., 2011), and SquareCB consequently has $\text{Reg}_{\text{CB}}(T) \leq O(K^{1/2}T^{3/4}D^{-1/4})$. This leads to linear time algorithms with nearly dimension-free rates for, e.g., $\ell_1$- and nuclear norm-constrained linear classes.

Kernels. Suppose that $\mathcal{F}$ is a reproducing kernel Hilbert space with RKHS norm $\|\cdot\|_\mathcal{H}$ and kernel $K$. Let $\|f\|_\mathcal{H} \leq 1$ for all $f \in \mathcal{H}$, and assume $K(x_a, x_a) \leq 1$ for all $x \in \mathcal{X}$. A simple observation is that, since Online Gradient Descent kernelsizes, the $O(T^{3/4})$ regret bound from the previous example immediately extends to this setting. This appear to be a new result; Previous work on kernel-based contextual bandits (Valko et al., 2013) gives regret bounds of the form $\sqrt{d_{\text{eff}} T}$, assuming that the effective dimension $d_{\text{eff}}$ of the empirical design matrix is bounded. Again there is a tradeoff, since our result requires no assumptions on the data beyond bounded RKHS norm, but has worse (albeit optimal under these assumptions) dependence on the time horizon.
**Generalized linear models.** Let $\sigma : \mathbb{R} \to [0, 1]$ be a fixed non-decreasing 1-Lipschitz link function, and let

$$\mathcal{F} = \{(x, a) \mapsto \sigma(\langle \theta, x_a \rangle) \mid \theta \in \mathbb{R}^d, \|\theta\|_2 \leq 1\};$$

where we again take $\|x_a\|_2 \leq 1$. For this setting, under the realizability assumption, the GLMtron algorithm (Kakade et al., 2011) satisfies Assumption 2b, in the sense that is has

$$\sum_{t=1}^{T} (\hat{g}_t - \sigma(\langle \theta^*, x_{a_t} \rangle))^2 \leq O(\sqrt{T}),$$

where $f^*(x, a) = \sigma(\langle \theta^*, x_a \rangle)$; see Proposition 2 in Appendix B.2 for details. This leads to a dimension-free regret bound $\text{Reg}_{\text{CB}}(T) \leq O(T^{3/4})$, similar to the linear setting. If we have a lower bound on the link function derivative (i.e., $\sigma' \geq c_\sigma > 0$), then a second-order variant of GLMtron (Proposition 3) satisfies Assumption 2b with $\text{Reg}_{\text{Sq}}(T) = O(d \log T / c_\sigma^2)$. Plugging this into SquareCB gives regret $O(\sqrt{dT \log T / c_\sigma^2})$. This matches the dependence on $d$ and $T$ in previous results for generalized linear contextual bandits with finite actions (Li et al., 2017), but unlike these results the algorithm does not require stochastic contexts, and requires no assumptions on the design matrix $\frac{1}{T} \sum_{t=1}^{T} x_t a_t x_t^T$ or its population analogue.

### 2.4 Minimax perspective

The analysis of SquareCB is interesting because the reduction from square loss regret to contextual bandit regret completely ignores the structure of the function class $\mathcal{F}$. At a high level, the proof proceeds by showing that the probability selection strategy ensures that

$$\sum_{t=1}^{T} \mathbb{E}_{a \sim p_t} \left[ f^*(x_t, a) - f^*(x_t, \pi^*(x_t)) \right] \leq \frac{2KT}{\gamma} + \frac{\gamma}{4} \sum_{t=1}^{T} \mathbb{E}_{a \sim p_t} \left[ (\hat{g}_{t,a} - f^*(x_t, a))^2 \right]. \quad (10)$$

at which point we can bound the right-hand side by using the regret bound for SqAlg. In fact, the probability selection strategy in SquareCB actually gives a stronger guarantee than (10). Consider the following *per-round minimax* problem:

$$\text{Val}(\gamma) := \max_{g \in [0,1]^K} \min_{p \in \Delta_K} \max_{f^* \in [0,1]^K} \max_{a^* \in [K]} \mathbb{E}_{a \sim p} \left[ f^*_a - f^*_a - \frac{\gamma}{4} (\hat{g}_a - f^*_a)^2 \right]. \quad (11)$$

If $\text{Val}(\gamma) \leq c$, we can interpret this as saying, “For every choice of $\hat{g}$, there exists an action distribution such that regardless of the value of $f^*$, the immediate regret with respect to $f^*$ is bounded by the squared prediction error of $\hat{g}$, plus a constant $c$.” The probability selection rule used in SquareCB with parameter $\gamma$ certifies that $\text{Val}(\gamma) \leq \frac{2K}{\gamma}$. The takeaway is that, at the level of the reduction, $f^*(x_t, a)$ might as well be chosen adversarially at each round rather than realized by a specific function $f^* \in \mathcal{F}$ chosen a-priori. We are hopeful that this per-round minimax approach to reductions will be more broadly useful, and indeed our extension to infinite actions in Section 5.2 uses similar per-round reasoning. To close the section, we give a lower bound on the minimax value which shows that the action selection strategy used in SquareCB is near-optimal for the minimax problem (11).

**Proposition 1.** For any $\gamma \geq 2$, we have $\text{Val}(\gamma) \geq \frac{(1-1/K)}{\gamma}$.

### 3 Optimality and universality

In light of Theorem 1, a natural question is whether one can always instantiate SquareCB such that its regret is optimal for the class $\mathcal{F}$ under consideration. More broadly, we seek to understand the minimax rate for the
RichCB setting where $\mathcal{F}$ is a large, potentially nonparametric function class and the problem is realizable. In this section we first prove a lower bound on minimax regret achievable for any function class $\mathcal{F}$. We then show that SquareCB is universal, in the sense that there always exist a choice for SqAlg that achieves the lower bound (up to dependence on the number of actions, which is not our focus).

For technical reasons, we make two simplifying assumptions in this section. First, we focus on the setting where $(x_t, \ell_t)$ are drawn i.i.d. from a joint distribution $\mu$. Second, we assume that the regression function class $\mathcal{F}$ tensorizes: There is a base function class $\mathcal{G} \subseteq (\mathcal{X} \to [0, 1])$ such that $\mathcal{F} = \mathcal{G}^K$, in the sense $\mathcal{F}$ consists of functions of the form

$$f(x, a) = g_a(x),$$

where $g_a \in \mathcal{G}$.

Our upper and lower bounds are stated in terms of the metric entropy of the base class $\mathcal{G}$. For a sample set $S = \{x_1, \ldots, x_n\}$, let $N_2(\mathcal{G}, \varepsilon, S)$ denote the size of the smallest set $\mathcal{G}'$ such that

$$\forall g \in \mathcal{G}, \exists g' \in \mathcal{G}' \text{ s.t. } \left(\frac{1}{n} \sum_{t=1}^{n} (g(x_t) - g'(x_t))^2\right)^{1/2} \leq \varepsilon.$$

The empirical entropy of $\mathcal{G}$ is then defined as

$$\mathcal{H}^{\text{iid}}(\mathcal{G}, \varepsilon) = \sup_{n \geq 1, S \subseteq \mathcal{X}^n} \log N_2(\mathcal{G}, \varepsilon, S).$$

Empirical entropy is a fundamental quantity in statistical learning that is both necessary and sufficient for learnability, as well as polynomially related to other standard complexity measures such as (local) Rademacher complexity and fat-shattering dimension (Rakhlin and Sridharan, 2012). We give concrete examples in the sequel, but for now we make the following assumption.

**Assumption 3.** Contexts and losses are drawn i.i.d. from a joint distribution $\mu$, and there exists a constant $p > 0$ such that for all $\varepsilon > 0$, the empirical entropy for $\mathcal{G}$ grows as

$$\mathcal{H}^{\text{iid}}(\mathcal{G}, \varepsilon) \leq \varepsilon^{-p}.$$

Our upper and lower bounds characterize the optimal regret for RichCBs as a function of the growth rate parameter $p > 0$ in Assumption 3. We first state the lower bound.

**Theorem 2** (Lower bound). Let $\mathcal{G}$ be any function class for which $\mathcal{H}^{\text{iid}}(\mathcal{G}, \varepsilon) = \Theta(\varepsilon^{-p})$ for some $p > 0$. Then there exists a slightly modified class $\mathcal{G}'$ with $\mathcal{H}^{\text{iid}}(\mathcal{G'}, \varepsilon) = \Theta(\varepsilon^{-p})$ for which the corresponding function class $\mathcal{F}$ (with $K = 2$) is such that any algorithm must have

$$\mathbb{E}[\text{Reg}_{\text{CB}}(T)] \geq \tilde{\Omega}\left(T^{\frac{1+p}{2+p}}\right), \quad (13)$$

on some realizable instance for $\mathcal{F}$.

We now show that SquareCB can always be instantiated to match the lower bound (13) in terms of dependence on $T$.

**Theorem 3** (Universality of SquareCB). Whenever Assumption 3 holds, there exists a choice for the base regret minimization algorithm SqAlg such that with probability at least $1 - \delta$, SquareCB has

$$\text{Reg}_{\text{CB}}(T) \leq \tilde{O}\left((KT)^{\frac{1+p}{2+p}} + \sqrt{K^2 T \log(\delta^{-1})}\right).$$

The idea behind the proof of Theorem 3 is to choose SqAlg to run Vovk’s aggregating algorithm over an empirical cover for $\mathcal{G}$. The main technical difficulty is that we must find a cover that is close on the distribution $\mu$, which the algorithm has no prior knowledge of. To get around this issue, the algorithm continually refines a cover based on data collected so far.
Examples. Let us make matters slightly more concrete and show how to extract some familiar regret bounds from Theorem 2 and Theorem 3. First, for linear classes (9) (specifically, the tensorized variants), one has \( H_{\text{iid}}^\text{lin}(G, \varepsilon) \propto d \log(1/\varepsilon) \wedge \varepsilon^{-2} \) (Zhang, 2002), and hence the theorems recover the \( \sqrt{dT} \) and \( T^{3/4} \) regret bounds for linear classes described in the previous section.

Slivkins (2011) derives fairly general results for nonparametric contextual bandits. As one example, their results imply that when \( G \) is the set of all 1-Lipschitz functions over \([0, 1]^d\), the optimal regret is \( T^{\frac{1}{2+d}} \). Since such classes have \( H_{\text{iid}}^\text{lin}(G, \varepsilon) \propto \varepsilon^{-d} \), our theorems recover this result. Similarly, for Hölder-smooth functions of order \( \beta \), we have \( p = d/\beta \) which yields the rate \( T^{\frac{1}{d+1}} \) (Rigollet and Zeevi, 2010).

As a final example, Bartlett et al. (2017) show that neural networks with appropriately bounded spectral norm enjoy a gap between the optimal and second-best action. More ambitiously, can the algorithm achieve similar instance-dependent regret bounds for rich function classes \( F \)?

Technical discussion. The assumptions made in this section (tensorization, stochastic contexts) can be relaxed, but we do not have a complete picture of the optimal regret for all values of \( p \) in this case. For adversarial contexts and without the tensorization assumption, if \( \mathcal{F} \) has bounded sequential metric entropy then Theorem 1 of Rakhlin and Sridharan (2014) implies that there exists a choice for \( \text{SqAlg} \) such that \( \text{Reg}_{\text{SqAlg}}(T) \leq T^{1 - \frac{2}{p+2}} \) and thus \( \text{SquareCB} \) has \( \text{Reg}_{\text{CB}}(T) \leq O(T^{\frac{1}{p+2}}) \) as in Theorem 3, but only for \( p \leq 2 \). On the other hand, for stochastic contexts it is also possible to show that a variant of the algorithm in Theorem 3 using slightly different concentration arguments matches the regret bound \( O(T^{\frac{1}{p+2}}) \) without the tensorization assumption, but only for \( p \geq 1 \).

Resolving the optimal dependence on \( K \) for \( \text{RichCBs} \) seems challenging and likely requires more refined complexity measures; see also discussion in Daniely et al. (2015b).

Previous works have given regret bounds for infinite policy classes that depend on the complexity (e.g., VC dimension) of the policy class (Beygelzimer et al., 2011; Foster and Krishnamurthy, 2018). These guarantees are somewhat different than the ones we provide here, which depend on the complexity of the regression function class \( \mathcal{F} \) rather than the class of policies it induces (but require realizability).

4 On gap-dependent regret bounds

In this section we give some negative results regarding instance-dependent regret bounds for \( \text{RichCBs} \). Since Theorem 1 recovers the usual \( \widetilde{O}(\sqrt{KT}) \) bound for multi-armed bandits, a natural question is whether the algorithm can recover instance-dependent regret bounds of the form \( \mathcal{O}\left(\frac{K}{\Delta}\log T\right) \) when there is a gap \( \Delta \) between the best and second-best action. More ambitiously, can the algorithm achieve similar instance-dependent regret bounds for rich function classes \( \mathcal{F} \)?

To address this question, we assume Bayes regressor \( f^\ast \) enjoys a gap between the optimal and second-best action for every context. The following definition is adapted from Dani et al. (2008).

**Definition 1** (Uniform gap). A contextual bandit instance is said to have uniform gap \( \Delta \) if for all \( x \in \mathcal{X} \),

\[
f^\ast(x, a) - f^\ast(x, \pi^\ast(x)) > \Delta \quad \forall a \neq \pi^\ast(x).
\]

We would like to understand whether Theorem 1 can be improved when the uniform gap condition holds. For example, is it possible to select the learning rate \( \gamma \) such that \( \text{SquareCB} \) has

\[
\text{Reg}_{\text{CB}}(T) \leq \frac{K \text{Reg}_{\text{Sq}}(T)}{\Delta} \cdot \text{polylog}(T) \quad (14)
\]

As a special case, such a regret bound would recover the \( \widetilde{O}\left(\frac{K}{\Delta}\right) \)-type regret bound for multi-armed bandits by choosing \( \text{SqAlg} \) with the exponential weights strategy. More generally, for any finite class \( \mathcal{F} \), the hypothesized
bound (14) would imply a regret bound of

$$\text{Reg}_{\text{CB}}(T) \leq \tilde{O}\left(\frac{K \log |\mathcal{F}|}{\Delta}\right)$$

(15)

by taking SqAlg to be Vovk’s aggregating algorithm, which has Reg_{Sq}(T) = \log |\mathcal{F}|. Here we give an information-theoretic lower bound which shows that such a regret bound is not possible, not just for SquareCB but for any contextual bandit algorithm.

**Theorem 4.** For every T, there exists a function class \(\mathcal{F}\) with two arms and \(|\mathcal{F}| \leq \sqrt{2T}\) such that for any (potentially randomized) contextual bandit algorithm, there exists a realizable and noiseless contextual bandit instance with uniform gap \(\Delta = \frac{1}{4}\) on which

$$\mathbb{E}[\text{Reg}_{\text{CB}}(T)] \geq \frac{1}{16} \sqrt{T}.$$ 

The function class in Theorem 4 has \(|\mathcal{F}| = O(\sqrt{T})\), and all instances considered in the theorem have constant gap. For such setups, the hypothesized regret bound (15) would give \(\text{Reg}_{\text{CB}}(T) \leq \tilde{O}(1)\). Hence, Theorem 4 rules out (15) and (14), and in fact rules out any regret bound of the form \(\text{Reg}_{\text{CB}}(T) \leq \tilde{O}\left(\frac{K \log |\mathcal{F}|}{\Delta} \cdot T^{1/2-\varepsilon}\right)\) for constant \(\varepsilon\).

In essence, the theorem shows that to obtain instance-dependent regret guarantees, one can at best hope for regret bounds that scale with \(\frac{|\mathcal{F}|}{\Delta}\) rather than \(\frac{\log |\mathcal{F}|}{\Delta}\). In other words, instance-dependent regret is at odds with learning from rich function classes (RichCBs), where regret scaling with \(|\mathcal{F}|\) is unacceptable. It is known that for linear function classes \(\mathcal{F}\), and more broadly function classes that satisfy certain structural assumptions such as bounded eluder dimension (Russo and Van Roy, 2013), gap-dependent logarithmic regret bounds are achievable through variants of UCB and Thompson sampling. However, bounded eluder dimension is a rather strong assumption which is essentially only known to hold for linear models, generalized linear models, and classes for which the domain size \(|\mathcal{X}|\) is bounded.² Theorem 4 shows that such assumptions are qualitatively required for instance-dependent logarithmic regret guarantees.

Langford and Zhang (2008) consider a different gap notion we refer to as a *policy gap* which, in the stochastic setting, posits that \(L(\pi^*) < L(\pi) - \Delta_{\text{policy}}\), where \(L(\pi) = \mathbb{E}_{x, t} \ell_t(\pi(x))\). For instances with policy gap \(\Delta_{\text{policy}}\), they show that the Epoch-Greedy algorithm achieves regret \(\text{poly}(\log |\Pi|, \log T, \Delta_{\text{policy}}^{-2})\). There is no contradiction between this result and Theorem 4, as the construction in the theorem has policy gap \(\frac{1}{\sqrt{T}}\).

## 5 Extensions

In this setting we provide two useful generalizations of SquareCB and its analysis. The first concerns the setting where the realizability assumption holds only approximately, and the second concerns the setting where the action set is infinite.

### 5.1 Misspecified models

In practice, the realizability assumption (Assumption 1) may be restrictive. In this section we show that the performance of SquareCB gracefully degrades when the assumption fails to hold, so long as the learning rate is changed appropriately. We consider the following relaxed notion of realizability.

**Assumption 4.** There exists a regressor \(f^* \in \mathcal{F}\) such that for all \(t\), \(f^*(x, a) = \mathbb{E}[\ell_t(a) \mid x_t = x] + \varepsilon_t(x, a)\), where \(|\varepsilon_t(x, a)| \leq \varepsilon\).

²There is no contradiction with Theorem 4, as the construction in the theorem scales \(|\mathcal{X}|\) as \(\sqrt{T}\).
The main theorem for this section shows that when Assumption 4 holds, the performance of SquareCB degrades by an additive $\varepsilon \cdot \sqrt{KT}$ factor. We state the result in terms of Assumption 2a, since this assumption is typically easier to satisfy than Assumption 2b when the model is misspecified.

**Theorem 5.** Suppose the adversary satisfies Assumption 4 and SqAlg satisfies Assumption 2a. Then SquareCB with $\gamma = 2\sqrt{KT}/(\text{Reg}_{\text{Sq}}(T) + \varepsilon^2 T)$ and $\mu = K$ ensures that

$$\sup_{\pi} \mathbb{E} \left[ \sum_{t=1}^{T} \ell_t(a_t) - \sum_{t=1}^{T} \ell_t(\pi(x_t)) \right] \leq 2\sqrt{KT \cdot \text{Reg}_{\text{Sq}}(T)} + \varepsilon \cdot 4\sqrt{KT},$$

where $\sup_{\pi}$ ranges over all policies $\pi : \mathcal{X} \to \mathcal{A}$.

**Theorem 5** gives a pseudoregret bound not just to $\pi_f^*$, but against any policy $\pi : \mathcal{X} \to \mathcal{A}$. The theorem also extends to contextual bandits with an adaptive adversary. The formal setting here is as follows.

For $t = 1, \ldots, T$:

- Adversary chooses $x_t \in \mathcal{X}$.
- Learner chooses action distribution $p_t$.
- Adversary chooses loss $\ell_t : \mathcal{A} \to [0, 1]$.
- Learner samples $a_t \sim p_t$ and observes $\ell_t(a_t)$.

We make the following assumption on the adversary.

**Assumption 5.** The adaptive adversary is constrained such that for every sequence, there exists $f^* \in \mathcal{F}$ such that $|\ell_t(a) - f^*(x_t, a)| \leq \varepsilon$ for all $a \in \mathcal{A}$.

The following theorem shows that this assumption suffices to attain the same guarantee as **Theorem 5**.

**Theorem 6.** Suppose the adversary satisfies Assumption 5 and SqAlg satisfies Assumption 2a. Then SquareCB with $\gamma = \sqrt{8KT/(\text{Reg}_{\text{Sq}}(T) + \varepsilon^2 T)}$ and $\mu = K$ ensures that

$$\sup_{\pi} \mathbb{E} \left[ \sum_{t=1}^{T} \ell_t(a_t) - \sum_{t=1}^{T} \ell_t(\pi(x_t)) \right] \leq 2\sqrt{2KT \cdot \text{Reg}_{\text{Sq}}(T)} + \varepsilon \cdot \sqrt{2KT}.$$

**Examples and discussion.** Regret bounds for misspecified linear bandits have recently gathered interest (Van Roy and Dong, 2019; Lattimore and Szepesvari, 2019; Neu and Olkhovskaya, 2020) due to their connection to reinforcement learning with misspecified linear feature maps (Du et al., 2019). Consider again the LinUCB-type setting where

$$\mathcal{F} = \{ (x, a) \mapsto \langle \theta, x_a \rangle \mid \theta \in \mathbb{R}^d, \|\theta\|_2 \leq 1\},$$

so that $x_t = (x_t, a)_{a \in \mathcal{A}}$ is a finite collection of contexts that varies from round to round. Neu and Olkhovskaya (2020) recently gave the first efficient algorithm for this setting. With adversarial losses as in Assumption 5 and stochastic contexts, their algorithm has regret $\widetilde{O}((dK)^{1/3}T^{2/3} + \varepsilon \sqrt{d}T)$. By instantiating SquareCB with the Vovk-Azoury-Warmuth forecaster, which has $\text{Reg}_{\text{Sq}}(T) \leq d \log(T/d)$ (Vovk, 1998; Azoury and Warmuth, 2001) and appealing to **Theorem 6**, we get an efficient algorithm with an improved regret bound,

$$\widetilde{O}(\sqrt{dKT} + \varepsilon \sqrt{KT}).$$

The new algorithm also allows for adversarially selected contexts rather than well-conditioned stochastic contexts. Interestingly, as remarked by Lattimore and Szepesvari (2019), the lower bounds of Du et al. (2019)
imply that when $K \gg d$, the “price” of $\varepsilon$-misspecification must grow as $\Omega(\varepsilon \sqrt{dT})$. On the other hand, our result shows that the price can be improved to $O(\varepsilon \sqrt{KT})$ in the small-$K$ regime.

Theorem 5 and Theorem 6 show that we can be robust to misspecification efficiently whenever online regression is possible efficiently. More broadly, these theorems give the first result we are aware of that considers $\varepsilon$-misspecification for arbitrary classes $\mathcal{F}$. The theorems imply that $O(\varepsilon \sqrt{KT})$ bounds the price of misspecification for general classes; the complexity of $\mathcal{F}$ is only reflected in $\text{Reg}_{\text{Sq}}(T)$.

5.2 Infinite actions

While the finite-action setting in which SquareCB works is arguably the most basic and fundamental contextual bandit setting, it is desirable to have algorithms that work for large or infinite sets of actions. As a proof of concept, we extend SquareCB to an infinite-action setting where the action space $\mathcal{A}$ is $d_{\mathcal{A}}$-dimensional unit $\ell_2$ ball $\mathbb{B}_{d_{\mathcal{A}}}$.

For this result, we assume that the regression functions in $\mathcal{F}$ take the form $f(x, a) = \langle f(x), a \rangle$, where $a \in \mathbb{B}_{d_{\mathcal{A}}}$ and $f(x) \in \mathbb{B}_{d_{\mathcal{A}}}$. We likewise assume that the predictions of the sub-algorithm SqAlg have the form $\hat{y}_t(x, a) = \langle \hat{g}_t(x), a \rangle$. Under these assumptions, we design a variant of SquareCB called SquareCB.Hilbert (Algorithm 2, deferred to Appendix E.2 for space). The regret guarantee for the algorithm is as follows.

**Theorem 7.** Suppose Assumption 1 and Assumption 2a/b hold. Then for any $\delta > 0$, SquareCB.Hilbert with parameter $\beta = \sqrt{d_{\mathcal{A}}(\text{Reg}_{\text{Sq}}(T) + 8 \log(\delta^{-1}))/T}$ ensures that with probability at least $1 - \delta$,

$$
\text{Reg}_{\text{CB}}(T) \leq 18 \sqrt{d_{\mathcal{A}}T \cdot \text{Reg}_{\text{Sq}}(T)} + 90 \sqrt{d_{\mathcal{A}}T \log(\delta^{-1})}.
$$

As a simple example, consider the setting where $\mathcal{F} = \{(x, a) \mapsto \langle \theta, a \rangle \mid \theta \in \mathbb{B}_{d_{\mathcal{A}}} \}$; this is a special case of the well-studied infinite-action linear contextual bandit setting (Abbasi-Yadkori et al., 2011) in which the action set is constant across all rounds. For this setting, choosing Vovk-Azoury Warmuth forecaster for SqAlg gives $\text{Reg}_{\text{Sq}}(T) \leq d_{\mathcal{A}} \log(T/d_{\mathcal{A}})$. By Theorem 7, we see that SquareCB.Hilbert has $\text{Reg}_{\text{CB}}(T) \leq d_{\mathcal{A}} \sqrt{T \log(T/d_{\mathcal{A}})}$ which matches the rate obtained by the OFUL strategy (Abbasi-Yadkori et al., 2011) for this setting.

Conceptually, the proof of Theorem 7 is similar to Theorem 1, in the sense that we show that the action selection scheme—by carefully balancing probability placed on the best action for $\hat{y}_t$ versus other
actions—ensures that the immediate bandit regret is upper bounded by the immediate square loss regret on a round-by-round basis. The regret guarantee extends to the misspecified case in the same fashion in the finite-action case, though the additive error in this here scales as $O(\varepsilon \sqrt{dA_T})$ rather than $O(\varepsilon \sqrt{KT})$.

6 Discussion

We have presented the first optimal reduction from contextual bandits to online square loss reduction. Conceptually, we showed that online oracles are a powerful primitive for designing contextual bandit algorithms, both in terms of computational and statistical efficiency. Beyond our algorithmic contribution, we have shed light on the fundamental limits of algorithms for RichCBs, including minimax rates and gap-dependent regret guarantees. We are hopeful that our techniques will find broader use, and that our results will inspire further research on provably efficient contextual bandits with flexible function approximation. We outline a few natural directions below. Going forward, some natural questions are:

Reinforcement learning. Can the SquareCB strategy be adapted to give regret bounds for reinforcement learning or continuous control with unknown dynamics and function approximation (where $\mathcal{F}$ is either a class of dynamics models or value functions)? A key challenge here is that SquareCB is not optimistic, which seems to play a more important role in the full RL setting.

Adaptivity. Compared to full-information learning, adaptive and data-dependent guarantees are notoriously difficult to come by for contextual bandits (Agarwal et al., 2017; Allen-Zhu et al., 2018; Foster et al., 2019). Can the SquareCB strategy or a variant be adapted to better take advantage of nice data?

Further technical directions. There are likely many concrete classes of interest for which SquareCB can be instantiated to give provable guarantees beyond those in Section 2. On the practical side, it would be useful to extend the continuous action variant of our algorithm from Section 5.2 to arbitrary action sets; we intend to pursue this in future work. Finally, we mention that while SquareCB works whenever we have access to an online regression oracle, it remains open whether there exists an optimal oracle-based contextual bandit algorithm that uses either 1) an offline regression oracle, or 2) an online classification oracle. Both of these are interesting problems.

A Basic technical results

Lemma 1 (Freedman’s inequality (e.g., Agarwal et al. (2014))). Let \((Z_t)_{t \in T}\) be a real-valued martingale difference sequence adapted to a filtration \(\mathcal{F}_t\), and let \(\mathbb{E}_t[\cdot] := \mathbb{E}[\cdot | \mathcal{F}_t]\). If \(|Z_t| \leq R\) almost surely, then for any \(\eta \in (0, 1/R)\) it holds that with probability at least \(1 - \delta\),

\[
\sum_{t=1}^{T} Z_t \leq \eta \sum_{t=1}^{T} \mathbb{E}_{t-1}[Z_t^2] + \frac{R \log(\delta^{-1})}{\eta T}.
\]

B Proofs from Section 2

B.1 Proof of Theorem 1

Proof of Theorem 1. We first appeal to the following lemma, proven at the end of the section, which relates the contextual bandit regret and square loss regret to their conditional expectation counterparts under our assumptions on the data-generating process and oracle model.

Lemma 2. If Assumption 1 and Assumption 2a/b hold, then with probability at least \(1 - \delta\),

\[
\text{Reg}_{\text{CB}}(T) \leq \sum_{t=1}^{T} \sum_{a \in A} p_{t,a} (f^*(x_t, a) - f^*(x_t, \pi^*(x_t))) + \sqrt{2T \log(2\delta^{-1})},
\]

and

\[
\sum_{t=1}^{T} \sum_{a \in A} p_{t,a} (\bar{y}_t(x_t, a_t) - f^*(x_t, a_t))^2 \leq 2\text{Reg}_{\text{Sq}}(T) + 16\log(2\delta^{-1}).
\]

Observe that by the lemma, we have that with probability at least \(1 - \delta\),

\[
\begin{align*}
\text{Reg}_{\text{CB}}(T) &\leq \sum_{t=1}^{T} \sum_{a \in A} p_{t,a} \left[(f^*(x_t, a) - f^*(x_t, \pi^*(x_t))) - \frac{\gamma}{4} (\bar{y}_t(x_t, a) - f^*(x_t, a))^2\right] \\
&\quad + \frac{\gamma}{2} \text{Reg}_{\text{Sq}}(T) + 16\eta \log(2\delta^{-1}) + \sqrt{2T \log(2\delta^{-1})}.
\end{align*}
\]

From here, our goal is to show that

\[
\sum_{t=1}^{T} \sum_{a \in A} p_{t,a} \left[(f^*(x_t, a) - f^*(x_t, \pi^*(x_t))) - \frac{\gamma}{4} (\bar{y}_t(x_t, a) - f^*(x_t, a))^2\right] \leq \frac{2KT}{\gamma}.
\]

Let the time \(t\) be fixed, and introduce the abbreviations \(f^*_{a} := f^*(x_t, a), \bar{y}_{a} := \bar{y}_t(x_t, a), p_{a} := p_{t,a}, a^* := \pi^*(x_t),\) and \(b := b_t\). The remainder of the proof is dedicated to proving the following per-timestep inequality, which will imply the result.

Lemma 3. For any vector \(\bar{y} \in [0, 1]^K\), the corresponding probability distribution \(p \in \Delta(K)\) on Line 6 of SquareCB ensures that for any vector \(f^* \in [0, 1]^K\), we have

\[
\sum_{a \in A} p_{a} \left[(f^*_{a} - f^*_a) - \frac{\gamma}{4} (\bar{y}_a - f^*_a)^2\right] \leq \frac{2K}{\gamma}.
\]

Proof of Lemma 3. Let \(\eta > 0\) be a free parameter to be determined at the end of the proof, and consider

\[
\sum_{a \in A} p_{a} \left[(f^*_{a} - f^*_a) - \eta (\bar{y}_a - f^*_a)^2\right].
\]
As a first step, we have
\[
\sum_{a \in A} p_a \left[ (f_a^* - f_a^*) - \eta (\bar{y}_a - f_a^*) \right] = \sum_{a \in A^*} p_a \left[ (f_a^* - f_a^*) - \eta (\bar{y}_a - f_a^*) \right] - \eta p_a \left( \bar{y}_a^* - f_a^* \right)^2
\]
\[
= \sum_{a \in A^*} p_a \left[ (\bar{y}_a - f_a^*) + (f_a^* - \bar{y}_a) - \eta (\bar{y}_a - f_a^*) \right] - \eta p_a \left( \bar{y}_a^* - f_a^* \right)^2
\]
\[
\leq \sum_{a \in A^*} p_a (\bar{y}_a - f_a^*) - \eta p_a \left( \bar{y}_a^* - f_a^* \right)^2 + \frac{(1 - p_a^*)}{4\eta},
\]
where the last inequality uses that \((f_a^* - \bar{y}_a) - \eta (\bar{y}_a - f_a^*)^2 \leq \frac{1}{4\eta}\) by AM-GM. For the next step, we similarly upper bound as
\[
\sum_{a \in A^*} p_a (\bar{y}_a - f_a^*) - \eta p_a \left( \bar{y}_a^* - f_a^* \right)^2 + \frac{1}{4\eta}
\]
\[
= \sum_{a \in A^*} p_a (\bar{y}_a - \bar{y}_a^*) + (1 - p_a^*) (\bar{y}_a^* - f_a^*) - \eta p_a \left( \bar{y}_a^* - f_a^* \right)^2 + \frac{1}{4\eta}
\]
\[
\leq \sum_{a \in A^*} p_a (\bar{y}_a - \bar{y}_a^*) + (1 - p_a^*) \frac{1}{4\eta p_a} + \frac{1}{4\eta}
\]
\[
\leq \sum_{a \in A^*} p_a (\bar{y}_a - \bar{y}_a^*) + \frac{1}{4\eta p_a} + \frac{1}{4\eta},
\]
where the first inequality again uses AM-GM. Now, for each \(a\), define \(u_a = \bar{y}_a - \bar{y}_b \geq 0\). Then we have
\[
\sum_{a \in A^*} p_a (\bar{y}_a - \bar{y}_a^*) = \sum_{a \in A^*} p_a (u_a - u_a^*)
\]
\[
= \sum_{a \in A^*} p_a u_a - (1 - p_a^*) u_a^*
\]
\[
= \sum_{a \in \{a, \ b\}} p_a u_a - (1 - p_a^*) u_a^*
\]
\[
= \sum_{a \in b} p_a u_a - u_a^*
\]
\[
= \sum_{a \in b} \frac{u_a}{\mu + \gamma u_a} - u_a^*
\]
\[
\leq \frac{K - 1}{\gamma} - u_a^*.
\]
It remains to bound
\[
-u_a^* + \frac{1}{4\eta p_a^*} + \frac{K - 1}{\gamma} + \frac{1}{4\eta},
\]
We consider two cases. First, if \(a^* = b\), then we have \(p_a^* = 1 - \sum_{a \in A^*} \frac{1}{\mu + \gamma u_a} \geq 1 - \frac{K - 1}{\mu} \geq \frac{1}{K}\), using the choice \(\mu = K\). Dropping the negative \(-u_a^*\) term, this leads to an upper bound of
\[
\frac{K}{4\eta} + \frac{K - 1}{\gamma} + \frac{1}{4\eta}.
\]
On the other hand, if \(a^* \neq b\), we have
\[
-u_a^* + \frac{1}{4\eta p_a^*} = -u_a^* + \frac{(\mu + \gamma u_a^*)}{4\eta} = \frac{K}{4\eta} + u_a^* \left( \frac{\gamma}{4\eta} - 1 \right).
\]
By choosing $\eta = \gamma/4$, we again get an upper bound of

$$\frac{K}{4\eta} + \frac{K - 1}{\gamma} + \frac{1}{4\eta} = \frac{2K}{\gamma}.$$ 

Summing Lemma 3 across all rounds and putting everything together, we have

$$\text{Reg}_{\text{CB}}(T) \leq \frac{3}{2} \text{Reg}_{\text{Sq}}(T) + 4\gamma \log(2\delta^{-1}) + \frac{2KT}{\gamma} + \sqrt{2T \log(2\delta^{-1})}.$$ 

The prescribed choice for $\gamma$ now gives the regret bound in the theorem statement.

**Proof of Lemma 2.** We define a filtration:

$\mathcal{F}_{t-1} = \sigma((x_1, a_1, \ell_1(a_1)), \ldots, (x_{t-1}, a_{t-1}, \ell_{t-1}(a_{t-1})), x_t).$ (17)

Note that for any $a$, the online regression algorithm’s prediction $\overline{y}_t(x_t, a)$ is a measurable with respect to $\mathcal{F}_{t-1}$. We apply Azuma-Hoeffding, which implies that with probability at least $1 - \delta$,

$$\text{Reg}_{\text{CB}}(T) = \sum_{t=1}^{T} \ell_t(a_t) - \ell_t(\pi^*(x_t)) \leq \sum_{t=1}^{T} \mathbb{E}[\ell_t(a_t) - \ell_t(\pi^*(x_t)) | \mathcal{F}_{t-1}] + \sqrt{2T \log(\delta^{-1})}$$

$$= \sum_{t=1}^{T} \sum_{a \in \mathcal{A}} p_t(a) (f^*(x_t, a) - f^*(x_t, \pi^*(x_t))) + \sqrt{2T \log(\delta^{-1})}.$$ 

Now, suppose Assumption 2a holds, so that SqAlg guarantees that with probability $1$,

$$\sum_{t=1}^{T} (\overline{y}_t(x_t, a_t) - \ell_t(a_t))^2 - \sum_{t=1}^{T} (f^*(x_t, a_t) - \ell_t(a_t))^2 \leq \text{Reg}_{\text{Sq}}(T)$$

Define $M_t = (\overline{y}_t(x_t, a_t) - \ell_t(a_t))^2 - (f^*(x_t, a_t) - \ell_t(a_t))^2$ and $Z_t = \mathbb{E}[M_t | \mathcal{F}_{t-1}] - M_t$.

**Lemma 4.** The following properties hold:

- $|Z_t| \leq 1$.
- $\mathbb{E}[M_t | \mathcal{F}_{t-1}] = \mathbb{E}[(\overline{y}_t(x_t, a_t) - f^*(x_t, a_t))^2 | \mathcal{F}_{t-1}] = \sum_{a \in \mathcal{A}} p_t(a) (\overline{y}_t(x_t, a) - f^*(x_t, a))^2$
- $\mathbb{E}[Z_t^2 | \mathcal{F}_{t-1}] \leq 4 \mathbb{E}[M_t | \mathcal{F}_{t-1}]$.

We now apply Lemma 1 with $\gamma = 1/8$, which implies that with probability at least $1 - \delta$,

$$\sum_{t=1}^{T} \mathbb{E}[M_t | \mathcal{F}_{t-1}] \leq \sum_{t=1}^{T} M_t + \frac{1}{8} \sum_{t=1}^{T} \mathbb{E}[Z_t^2 | \mathcal{F}_{t-1}] + 8 \log(\delta^{-1}) \leq \text{Reg}_{\text{Sq}}(T) + \frac{1}{2} \sum_{t=1}^{T} \mathbb{E}[M_t | \mathcal{F}_{t-1}] + 8 \log(\delta^{-1}),$$

or in other words, with probability at least $1 - \delta$,

$$\sum_{t=1}^{T} \sum_{a \in \mathcal{A}} p_t(a) (\overline{y}_t(x_t, a_t) - f^*(x_t, a_t))^2 \leq 2\text{Reg}_{\text{Sq}}(T) + 16 \log(\delta^{-1}).$$

Finally, we handle the case where Assumption 2b holds. Define $X_t = (\overline{y}_t(x_t, a_t) - f^*(x, a_t))^2$, and observe that

$$\mathbb{E}_{t-1}[(X_t - \mathbb{E}_{t-1}[X_t])^2] \leq \mathbb{E}_{t-1}[X_t^2] \leq \mathbb{E}_{t-1}[X_t].$$
We now apply Lemma 1 with $\eta = 1/2$, which implies
\[
\frac{1}{T} \sum_{t=1}^{T} E[X_t | \mathcal{F}_{t-1}] \leq \frac{1}{2} \sum_{t=1}^{T} E[X_t | \mathcal{F}_{t-1}] + 2 \log(\delta^{-1}),
\]
and consequently
\[
\sum_{t=1}^{T} \sum_{a \in A} p_t(a) (\tilde{y}_t(x_t, a_t) - f^*(x_t, a_t))^2 \leq 2 \text{Reg}_\text{Sq}(T) + 4 \log(\delta^{-1}).
\]

**Proof of Lemma 4.** That $|Z_t|$ is bounded by 1 is immediate. For the second property, we have
\[
\mathbb{E}[\tilde{y}_t(x_t, a_t) - \ell_t(a_t)]^2 - (f^*(x_t, a_t) - \ell_t(a_t))^2 | \mathcal{F}_{t-1}
\]
\[
= \mathbb{E}[2(\tilde{y}_t(x_t, a_t) - \ell_t(a_t))(\tilde{y}_t(x_t, a_t) - f^*(x_t, a_t)) - (\tilde{y}_t(x_t, a_t) - f^*(x_t, a_t))^2 | \mathcal{F}_{t-1}]
\]
\[
= \mathbb{E}[2(\tilde{y}_t(x_t, a_t) - f^*(x_t, a_t))^2 - (\tilde{y}_t(x_t, a_t) - f^*(x_t, a_t))^2 | \mathcal{F}_{t-1}]
\]
\[
= \mathbb{E}[(\tilde{y}_t(x_t, a_t) - f^*(x_t, a_t))^2 | \mathcal{F}_{t-1}],
\]
where we have used that $\mathbb{E}[\ell(a) | x, a] = f^*(x, a)$, and that $\tilde{y}_t(x_t, a_t)$ is independent of $\ell_t$ given $\mathcal{F}_{t-1}$. For the third property, we have
\[
\mathbb{E}[Z_t^2 | \mathcal{F}_{t-1}] \leq \mathbb{E}[M_t^2 | \mathcal{F}_{t-1}]
\]
\[
= \mathbb{E}[(\tilde{y}_t(x_t, a_t) - f^*(x_t, a_t))^2(\tilde{y}_t(x_t, a_t) + f^*(x_t, a_t) - 2\ell_t(a_t))^2 | \mathcal{F}_{t-1}]
\]
\[
\leq 4 \mathbb{E}[(\tilde{y}_t(x_t, a_t) - f^*(x_t, a_t))^2 | \mathcal{F}_{t-1}],
\]
since $|\tilde{y}_t(x_t, a_t) + f^*(x_t, a_t) - 2\ell_t(a_t)| \leq 2$. 

**Proof of Proposition 1.** We first make the choice $\tilde{y} = 0$, so that the value is lower bounded by
\[
\min_{p \in \Delta_K} \max_{f^* \in [0,1]^K} \max_{a^* \in [K]} \mathbb{E}_{a \sim p}[f^*_a - f^*_a - \frac{2}{\gamma}(f^*_a)^2].
\]
For a given action distribution $p$, we choose $a^* \in \arg\min_{a \in A} p_a$ and set $f^*_a = 0$ and $f^*_a = \frac{2}{\gamma}$ for all $a \neq a^*$. The condition that $\gamma \geq 2$ ensures that $f^* \in [0,1]^K$. The value is now lower bounded by
\[
\sum_{a \neq a^*} p_a \left( \frac{2}{\gamma} - \frac{2}{\gamma} \left( \frac{2}{\gamma} \right)^2 \right) = (1 - p_{a^*}) \frac{1}{\gamma} \geq (1 - 1/K) \frac{1}{\gamma},
\]
where we have used that $p_{a^*} \leq 1/K$. 

**B.2 Details for specific algorithms**

**B.2.1 Generalized linear models**

Consider the setting where $\mathcal{F} = \{x \mapsto \sigma(\theta, x) | \theta \in \Theta\}$, where $\sigma : [-1, +1] \rightarrow [0, 1]$ is a known, non-decreasing 1-Lipschitz link function and $\Theta = \{\theta \in \mathbb{R}^d | \|\theta\|_2 \leq 1\}$. We consider two variants of the GLMtron algorithm (Kakade et al., 2011) and show that they enjoy slow and fast rates for online prediction, respectively. We only sketch the arguments, as they are fairly standard.

We analyze both variants in the following online learning setting:
For $t = 1, \ldots, T$:

- Nature chooses input instance $x_t$.
- Algorithm chooses prediction $\widehat{y}_t$.
- Nature chooses outcome $y_t$.

We allow $x_t$ to be selected by an adaptive adversary, but assume that there exists some $\theta^*$ such that

$$E[y | x] = \sigma(\langle \theta^*, x \rangle) = f^*(x, a).$$

We also assume that $\|x_t\|_2 \leq 1$ for all $t$.

The first GLMtron variant is based on online gradient descent. Define a “pseudo-gradient”

$$g_t(\theta) = 2(\sigma(\langle \theta, x_t \rangle) - y_t)x_t$$

Starting from $\theta_1 = 0$, we update the iterates via

- $\tilde{\theta}_{t+1} \leftarrow \theta_t - \eta g_t(\theta_t)$.
- $\theta_{t+1} \leftarrow \arg \min_{\theta \in \Theta} \|\theta - \tilde{\theta}_{t+1}\|^2_2$.

At each time $t$ we predict using $\widehat{y}_t = \sigma(\langle \theta_t, x_t \rangle)$.

**Proposition 2.** By setting $\eta = \frac{1}{\sqrt{T}}$, the strategy above guarantees that with probability at least $1 - \delta$,

$$\sum_{t=1}^{T} (\widehat{y}_t - f^*(x_t))^2 \leq O(\sqrt{T \log(\delta^{-1})}).$$

**Proof of Proposition 2.** Define a filtration.

$$\mathcal{G}_{t-1} = \sigma(x_1, y_1, \ldots, x_{t-1}, y_{t-1}, x_t),$$

Observe since $\sigma$ is Lipschitz and non-decreasing, we have

$$\sum_{t=1}^{T} (\widehat{y}_t - f^*(x_t))^2 = \sum_{t=1}^{T} (\sigma(\langle \theta_t, x_t \rangle) - \sigma(\langle \theta^*, x_t \rangle))^2$$

$$\leq \sum_{t=1}^{T} (\sigma(\langle \theta_t, x_t \rangle) - \sigma(\langle \theta^*, x_t \rangle))(\langle \theta_t, x_t \rangle - \langle \theta^*, x_t \rangle)$$

$$= \frac{1}{2} \sum_{t=1}^{T} \mathbb{E}[(g_t(\theta_t), \theta_t - \theta^*) | \mathcal{G}_{t-1}].$$

By Azuma-Hoeffding, we are guaranteed that with probability at least $1 - \delta$,

$$\sum_{t=1}^{T} \mathbb{E}[(g_t(\theta_t), \theta_t - \theta^*) | \mathcal{G}_{t-1}] \leq \sum_{t=1}^{T} (g_t(\theta_t), \theta_t - \theta^*) + O(\sqrt{T \log(\delta^{-1})}).$$

Finally, the standard analysis for online gradient descent (Hazan, 2016) guarantees that with probability 1,

$$\sum_{t=1}^{T} (g_t(\theta_t), \theta_t - \theta^*) \leq O(\sqrt{T}).$$

We next consider an online Newton variant of GLMtron. Starting from $\theta_1 = 0$, and $\Sigma_0 = \varepsilon I$, we update the iterates via
• \( \Sigma_{t+1} = \Sigma_t + x_t x_t^\top \).
• \( \tilde{\theta}_{t+1} \leftarrow \theta_t - \eta \Sigma_t^{-1} g_t(\theta_t) \).
• \( \theta_{t+1} \leftarrow \text{arg min}_{\theta \in \Theta} \| \theta - \tilde{\theta}_{t+1} \|^2_{\Sigma_{t+1}} \).

As before, at each time \( t \) we predict using \( \hat{y}_t = \sigma(\langle \theta_t, x_t \rangle) \).

**Proposition 3.** Suppose that \( \sigma' \geq c_\sigma > 0 \). Then for an appropriate choice of \( \eta \) and \( \varepsilon \), the algorithm above ensures that with probability at least \( 1 - \delta \),

\[
\sum_{t=1}^T (\hat{y}_t - f^*(x_t))^2 \leq \widetilde{O} \left( \frac{d \log T + \log(\delta^{-1})}{c_\sigma^2} \right).
\]

**Proof of Proposition 3.** Consider the filtration

\[ \mathfrak{F}_{t-1} = \sigma(x_1, y_1, \ldots, x_{t-1}, y_{t-1}, x_t), \]

Since \( \sigma \) is Lipschitz and increasing, we have

\[
\sum_{t=1}^T (\hat{y}_t - f^*(x_t))^2 = \sum_{t=1}^T 2(\sigma(\langle \theta_t, x_t \rangle) - \sigma(\langle \theta^*, x_t \rangle))^2 - (\sigma(\langle \theta_t, x_t \rangle) - \sigma(\langle \theta^*, x_t \rangle))^2
\]

\[
\leq \sum_{t=1}^T 2(\sigma(\langle \theta_t, x_t \rangle) - \sigma(\langle \theta^*, x_t \rangle))(\theta_t, x_t - \theta^*, x_t) - (\sigma(\langle \theta_t, x_t \rangle) - \sigma(\langle \theta^*, x_t \rangle))^2
\]

\[
= \sum_{t=1}^T \mathbb{E}[(g_t(\theta_t), \theta_t - \theta^*) | \mathfrak{F}_{t-1}] - (\sigma(\langle \theta_t, x_t \rangle) - \sigma(\langle \theta^*, x_t \rangle))^2
\]

\[
\leq \sum_{t=1}^T \mathbb{E}[(g_t(\theta_t), \theta_t - \theta^*) | \mathfrak{F}_{t-1}] - c_\sigma^2(\theta - \theta^*, x_t)^2
\]

Let \( X_t = (g_t(\theta_t), \theta_t - \theta^*) \) and \( Z_t = \mathbb{E}[X_t | \mathfrak{F}_{t-1}] - Z_t \). Note that \( |X_t| \leq 4, |Z_t| \leq 8 \), and

\[
\mathbb{E}[Z_t^2 | \mathfrak{F}_{t-1}] \leq \mathbb{E}[X_t^2 | \mathfrak{F}_{t-1}] \leq 4(\theta_t - \theta^*, x_t)^2.
\]

Next, using **Lemma 1** with \( \eta = c_\sigma^2/8 \), we are guaranteed that with probability at least \( 1 - \delta \),

\[
\sum_{t=1}^T \mathbb{E}[(g_t(\theta_t), \theta_t - \theta^*) | \mathfrak{F}_{t-1}] \leq \sum_{t=1}^T (g_t(\theta_t), \theta_t - \theta^*) + \frac{c_\sigma^2}{2} \sum_{t=1}^T (\theta_t - \theta^*, x_t)^2 + \frac{64 \log(\delta^{-1})}{c_\sigma^2},
\]

and consequently

\[
\sum_{t=1}^T (\hat{y}_t - f^*(x_t))^2 \leq \sum_{t=1}^T (g_t(\theta_t), \theta_t - \theta^*) - \frac{c_\sigma^2}{2} (\theta - \theta^*, x_t)^2 + \frac{64 \log(\delta^{-1})}{c_\sigma^2}.
\]

From here, an argument identical to the usual analysis of Online Newton Step (with the only difference being that \( \Sigma_t \) is updated with \( x_t x_t^\top \) rather than \( g_t g_t^\top \); see Hazan (2016)) implies that when \( \eta \) and \( \varepsilon \) are chosen appropriately,

\[
\sum_{t=1}^T (g_t(\theta_t), \theta_t - \theta^*) - \frac{c_\sigma^2}{2} (\theta - \theta^*, x_t)^2 \leq O \left( \frac{1}{c_\sigma^2} \sum_{t=1}^T \| g_t \|^2_{\Sigma_t} \right) \leq O \left( \frac{1}{c_\sigma^2} \sum_{t=1}^T \| x_t \|^2_{\Sigma_t} \right) \leq O \left( \frac{d \log T}{c_\sigma^2} \right).
\]

\( \square \)
### C  Proofs from Section 3

#### C.1  Proof of Theorem 2

**Proof of Theorem 2.** Recall that $\mathcal{G} \subseteq (\mathcal{X} \to [0, 1])$ is said to shatter $x_1, \ldots, x_n$ at scale $\gamma$ if there exists a sequence $s_1, \ldots, s_n \in [0, 1]$ such that

$$\forall \epsilon \in \{\pm 1\}^n \ \exists g \in \mathcal{G} \text{ such that } \epsilon_t \cdot (g(x_t) - s_t) \geq \frac{\gamma}{2} \ \forall t.$$  

The fat-shattering dimension (Alon et al., 1997; Bartlett and Long, 1998) is then defined via

$$\text{fat}_{\gamma}(\mathcal{G}) = \max\{n \mid \exists x_1, \ldots, x_n \text{ such that } \mathcal{G} \gamma\text{-shatters } x_1, \ldots, x_n\}.$$  

We first invoke the following lemma.

**Lemma 5** (Mendelson and Vershynin (2003)). There exist constants $0 < c < 1$ and $C \geq 0$ such that for all $\epsilon \in (0, 1)$,

$$\mathcal{H}^{\text{id}}(\mathcal{G}, \epsilon) \leq C \cdot \text{fat}_{c\epsilon}(\mathcal{G}) \log(1/\epsilon).$$

Let $\gamma > 0$ be fixed. Then Lemma 5, along with our assumption on the entropy growth implies that

$$\text{fat}_{\gamma}(\mathcal{G}) \geq \tilde{O}(\gamma^{-2})$$

In particular, we are guaranteed that there exists a set of distinct examples $x(1), \ldots, x(m)$ and shifts $s(1), \ldots, s(m) \in [0, 1]$ with $m = \tilde{O}(\gamma^{-2})$ such that

$$\forall \epsilon \in \{\pm 1\}^m \ \exists g \in \mathcal{G} \text{ such that } \epsilon_t \cdot (g(x(t)) - s(t)) \geq \frac{\gamma}{2} \ \forall t.$$  

(18)

For each sign pattern $\epsilon \in \{\pm 1\}^m$, let $g$ be a function that shatters the sequence in the sense of (18). We let $g_\epsilon$ be the same function everywhere except on $x(1), \ldots, x(m)$, where it is truncated so that shattering holds with equality, i.e.

$$\forall \epsilon \in \{\pm 1\}^m : \epsilon_t \cdot (g_\epsilon(x(t)) - s(t)) = \frac{\gamma}{2} \ \forall t.$$  

(19)

We form a class $\mathcal{H}$ by taking one such function for each $\epsilon \in \{\pm 1\}^m$, as well as adding a function $s : \mathcal{X} \to [0, 1]$ that has $s(x(i)) = s(i)$ for each $t$ and is arbitrary elsewhere. We take our augmented function class to be $\mathcal{G}' = \mathcal{G} \cup \mathcal{H}$. Since $|\mathcal{H}| \leq 2^m + 1$, we have $\mathcal{H}^{\text{id}}(\mathcal{G}', \gamma) \leq \mathcal{H}^{\text{id}}(\mathcal{G}, \gamma) + m = O(\gamma^{-2})$, so the metric entropy is preserved as desired.

We now construct a collection of problem instances. We choose $\mu$ to be the uniform distribution over $x_1, \ldots, x_m$, and for each $\epsilon \in \{\pm 1\}^m$, we define a corresponding Bayes regression function

$$f_\epsilon^*(x, 1) := g_\epsilon(x), \text{ and } f_\epsilon^*(x, 2) := s(x).$$

Finally, for each $a \in \mathcal{A} = \{a(1), a(2)\}$, we take $\ell(a)$ to be a Bernoulli random variable with mean $f^*(x, a)$ conditioned on $x$.

We define a distribution $\mathcal{D}$ over problem instances by choosing $\epsilon$ uniformly at random. Since (19) holds with equality, the mean reward functions on different shattered examples $x(i)$ and $x(j)$ are independent under $\mathcal{D}$. In particular, we may treat data as generated via the following process

- Sample $x_1, \ldots, x_T$ i.i.d. from $\mu$, and let $S_t = \{t \mid x_t = x(i)\}$.
- For each $i \in [m]$, independently sample a Bernoulli multi-armed bandit instance $\mathcal{P}_i$ with arm means $\mu(a(1))$ and $\mu(a(2))$, such that with probability $1/2$,

  $$\mu(a(1)) = s(i) + \frac{\gamma}{2}, \text{ and } \mu(a(2)) = s(i),$$

  and otherwise

  $$\mu(a(1)) = s(i) - \gamma, \text{ and } \mu(a(2)) = s(i),$$

  and
Note that \( \{S_i\}_{i \in \lbrack m \rbrack} \) and the instances \( \{P_i\}_{i \in \lbrack m \rbrack} \) are independent under this process. For a given instance \( P_i \), let \( a_i^* \) denote the optimal arm for this instance. Now, note that regret decomposes as

\[
\text{Reg}_{CB}(T) = \sum_{i \in \lbrack M \rbrack} \sum_{t \in S_i} \ell_t(a_t) - \ell_t(a_i^*).
\]

By Theorem 5.7 of Kleinberg et al. (2019),\(^3\) we have that for any \( \gamma < 1/24 \), for each \( i \in \lbrack m \rbrack \)

\[
\mathbb{E}_{P_i} \mathbb{E}_{(\ell_t)_{t \in S_i}} \left[ \sum_{t \in S_i} \ell_t(a_t) - \ell_t(a_i^*) \right] \geq \frac{\gamma}{60} N_i \mathbbm{1} \left\{ N_i < \frac{1}{64} \gamma^{-2} \right\},
\]

where \( \mathbb{E}_{P_i} \) denotes the draw of the instance \( P_i \) itself. Now, note that \( \mathbb{E}[N_i] = T/m \) and \( \mathbb{E}[N_i^2] \leq (T/m)^2 \). Hence, by Markov’s inequality and Paley-Zygmund, there exist constants \( c_1 < c_2 \) such that with constant probability (say, 1/2), we have \( c_1 \frac{T}{m} < N_i < c_2 \frac{T}{m} \). It follows that if we select \( \gamma \) such that \( \frac{T}{m} = c_2 \gamma^{-2} \) for a sufficiently small constant \( c \), i.e. \( \gamma \approx T^{-\frac{1}{2p}}/\text{polylog}(T) \), then we are guaranteed that with probability at least 1/2 over the draw of \( S_i \),

\[
\mathbb{E}_{P_i} \mathbb{E}_{(\ell_t)_{t \in S_i}} \left[ \sum_{t \in S_i} \ell_t(a_t) - \ell_t(a_i^*) \right] \geq \Omega \left( \gamma \cdot \frac{T}{m} \right).
\]

In particular, since the expected regret is non-negative, we have

\[
\mathbb{E}_{S_i} \mathbb{E}_{P_i} \mathbb{E}_{(\ell_t)_{t \in S_i}} \left[ \sum_{t \in S_i} \ell_t(a_t) - \ell_t(a_i^*) \right] \geq \Omega \left( \gamma \cdot \frac{T}{m} \right).
\]

To conclude, we sum this bound over all \( i \in \lbrack m \rbrack \) which, by linearity of expectation, gives

\[
\mathbb{E}[\text{Reg}_{CB}(T)] \geq \Omega(\gamma \cdot T) = \Omega(T^{\frac{1-p}{2p}}).
\]

### C.2 Proof of Theorem 3

To prove the upper bound, we exhibit an online regression algorithm \( \text{SqAlg} \) for which \( \text{Reg}_{Sq}(T) \leq \widetilde{O} \left( T^{\frac{1+p}{2p}} \right) \) under i.i.d. contexts and the realizability assumption. The result follows by appealing to Theorem 1.

To describe the algorithm, we introduce additional notation. For a dataset \( S = x_1, \ldots, x_n \), we let \( d_S(g, g') = \left( \frac{1}{n} \sum_{t=1}^{n} (g(x_t) - g'(x_t))^2 \right)^{1/2} \) denote the empirical \( L_2 \) distance on \( S \).

Our strategy for \( \text{SqAlg} \) is described below. The algorithm proceeds in epochs of doubling length. At the beginning of each epoch, the algorithm forms a cover for \( \mathcal{G} \) using all the data collected so far. For the remainder of the epoch, it runs a variant of the exponential weights algorithm (Vovk’s aggregating algorithm) over the cover to produce the square loss predictions (\( \tilde{y}_t \)).

In more detail, the algorithm is as follows:

- Parameters: \( \varepsilon > 0 \).
- Let \( M = \lceil \log T \rceil \), and let \( \tau_m = e^{m-1} \wedge T \) for each \( m \in \lbrack M + 1 \rbrack \).

\(^{3}\)See also Theorem A.2 of Auer et al. (2002).
• For each epoch \( m = 1, \ldots, M \):
  - Let \( S_m = x_1, \ldots, x_{\tau_m-1} \).
  - Let \( G_m \) be a minimal \( L_2 \) cover for \( G \) on \( S_m \), at scale \( \varepsilon \).
  - Let \( \mathcal{F}_m = \{(x, a) \mapsto g_a(x) \mid g \in G_m\} \).
  - Select predictions \( \bar{y}_t \) for rounds \( t = \tau_m, \ldots, \tau_m+1-1 \) by running the exponential weights algorithm over \( \mathcal{F}_m \) with the loss function \( \ell_t(\bar{y}) := (\bar{y} - \ell_t(a_t))^2 \), as described in Lemma 6.

Let \( I_m = \tau_m, \ldots, \tau_m+1-1 \), and let \( n_m = |I_m| \). To analyze the performance of the algorithm, we require two standard lemmas. The first lemma shows that the aggregating algorithm has regret \( \log |\mathcal{F}| \) for a finite class.

**Lemma 6** (Cesa-Bianchi and Lugosi (2006), Proposition 3.2). Let \( \mathcal{F} \subseteq (\mathcal{Z} \rightarrow [0, 1]) \) be a finite function class. Consider an exponential weights algorithm variant with loss \( \ell_t(\bar{y}) := (\bar{y} - y_t)^2 \), uniform prior and learning rate \( \eta = 1/2 \), which follows the update rule

1. Select \( P_t(g) \propto e^{-\eta \sum_{i=1}^{t-1} (g(z_i) - y_i)^2} \).
2. Choose \( \bar{y}_t \) such that \( (\bar{y}_t - y)^2 \leq \frac{1}{\eta} \log \left( \mathbb{E}_{g \sim P_t} e^{-\eta (g(z_t) - y)^2} \right) \) for all \( y \in [0, 1] \).

This strategy guarantees that for any adaptively chosen sequence \((z_1, y_1), \ldots, (z_T, y_T)\)

\[
\sum_{t=1}^{T} (\bar{y}_t - y_t)^2 - \min_{f \in \mathcal{F}} \sum_{t=1}^{T} (f(z_t) - y_t) \leq 2 \log |\mathcal{F}|. \quad (20)
\]

The second lemma quantifies the rate at which empirical \( L_2 \) distance concentrate around their population counterparts, and is used to prove that the covers for \( \mathcal{F} \) the algorithm forms at the beginning of epoch are also accurate on future examples under the i.i.d. assumption.

**Lemma 7** (Rakhlin et al. (2017)). Let \( \mathcal{P} \in \Delta(\mathcal{X}) \), and let \( S = x_1, \ldots, x_n \), where \( x_t \sim \mathcal{P} \) i.i.d. for all \( t \). If \( \mathcal{G} \) has range \([0, 1] \) and \( \mathcal{H}^{bd}(\mathcal{G}, \varepsilon) \propto \varepsilon^{-p} \), then with probability at least \( 1 - \delta \),

\[
\mathbb{E}_{x \sim \mathcal{P}} (g(x) - g'(x))^2 \leq 2d_\mathcal{G}^2(g, g') + O\left( \log^3 n \cdot n^{-\left(1 + \frac{2}{p}\right)} + \log \left( \log n / \delta \right) \cdot n^{-1} \right), \quad \text{for all } g, g' \in \mathcal{G}. \quad (21)
\]

The last auxiliary result we require is a basic concentration lemma for the square loss.

**Lemma 8.** Let the epoch \( m \in [M] \) and a function \( f \in \mathcal{F} \) be fixed. Then with probability at least \( 1 - \delta \),

\[
\sum_{t \in I_m} \ell_t(\bar{y}_t) - \ell_t(f^*(z_t)) \leq \sum_{t \in I_m} \ell_t(\bar{y}_t) - \ell_t(f(z_t)) + 2Kn_m \max_{a \in A} \mathbb{E}_{x \sim \mu}\left[ (f(x, a) - f^*(x, a))^2 \right] + 16 \log(\delta^{-1}).
\]

**Proof of Lemma 8.** To begin, we have

\[
\sum_{t \in I_m} \ell_t(\bar{y}_t) - \ell_t(f^*(z_t)) = \sum_{t \in I_m} \ell_t(\bar{y}_t) - \ell_t(f(z_t)) + \sum_{t \in I_m} \ell_t(f(z_t)) - \ell_t(f^*(z_t)).
\]

It remains to bound the second term. Define a filtration

\[
\mathcal{G}_{t-1} = \sigma((x_1, a_1, \ell_1(a_1)), \ldots, (x_{t-1}, a_{t-1}, \ell_{t-1}(a_{t-1}))),
\]

and let \( M_t = \ell_t(f(z_t)) - \ell_t(f^*(z_t)) \) and \( Z_t = \mathbb{E}[M_t | \mathcal{G}_{t-1}] - Z_t \). The following lemma shows that these random variables are both bounded and self-bounding.
Lemma 9. The following properties hold:

- \(|Z| \leq 1.\)
- \(\mathbb{E}[M_t \mid \mathcal{G}_{t-1}] = \mathbb{E}_{x_t \sim \mu}[E_{a_t}[(f(x_t, a_t) - f^*(x_t, a_t))^2 \mid \mathcal{G}_{t-1}, x_t]]\)
- \(\mathbb{E}[Z^2_t \mid \mathcal{G}_{t-1}] \leq 4 \mathbb{E}[M_t \mid \mathcal{G}_{t-1}].\)

Proof. See proof of Lemma 4.

We now apply Lemma 1 with \(\eta = 1/8\), which implies that with probability at least \(1 - \delta\),

\[
\sum_{t \in \mathcal{I}_m} \mathbb{E}[M_t \mid \mathcal{G}_{t-1}] \leq \sum_{t \in \mathcal{I}_m} M_t + \frac{1}{8} \sum_{t \in \mathcal{I}_m} \mathbb{E}[Z^2_t \mid \mathcal{G}_{t-1}] + 8 \log(\delta^{-1}) \leq \sum_{t \in \mathcal{I}_m} M_t + \frac{1}{2} \sum_{t \in \mathcal{I}_m} \mathbb{E}[M_t \mid \mathcal{G}_{t-1}] + 8 \log(\delta^{-1}),
\]

or, rearranging, with probability at least \(1 - \delta\), we have

\[
\sum_{t \in \mathcal{I}_m} \ell_t(f(z_t)) - \ell_t(f^*(z_t)) \leq 2 \sum_{t \in \mathcal{I}_m} \mathbb{E}[M_t \mid \mathcal{G}_{t-1}] + 16 \log(\delta^{-1}).
\]

The result follows by observing that

\[
\mathbb{E}[M_t \mid \mathcal{G}_{t-1}] = \mathbb{E}_{x_t \sim \mu}[E_{a_t}[(f(x_t, a_t) - f^*(x_t, a_t))^2 \mid \mathcal{G}_{t-1}, x_t]] \\
\leq \mathbb{E}_{x_t \sim \mu}[\max_{a \in A} (f(x, a) - f^*(x, a))^2] \\
\leq K \cdot \max_{a \in A} \mathbb{E}_{x_t \sim \mu}[(f(x, a) - f^*(x, a))^2].
\]

Proof of Theorem 3. The strategy for this proof is as follows. We first show that the choice for SqAlg described above enjoys an upper bound on \(\text{Reg}_{\text{Sq}}(T)\) with high probability. We then appeal to Theorem 1 and tune the parameters to achieve the final bound.

We will prove a high-probability regret for each epoch \(m\) separately, then union bound and add these regret bounds to get the final bound on \(\text{Reg}_{\text{Sq}}(T)\). Let the epoch \(m \in [M]\) be fixed. Let \(g^*_a\) be such that

\(f^*(x, a) = g^*_a(x)\).

By the definition of \(\mathcal{G}_m\), for each \(a\) there exists \(\overline{g}_a \in \mathcal{G}_m\) such that \(d_{S_m}(\overline{g}_a, g^*_a) \leq \varepsilon\). We apply Lemma 7, which implies that with probability at least \(1 - \delta\), for all \(a \in A\),

\[
\mathbb{E}_{x \sim \mathcal{P}}(\overline{g}_a(x) - g^*_a(x))^2 \leq 2d^2_{S_m}(\overline{g}_a, g^*_a) + O\left(\log^3 T \cdot |S_m|^{-\frac{1}{2}} + \log(\log T/\delta) \cdot |S_m|^{-\frac{1}{2}}\right).
\]

(22)

Let \(\overline{f}(x, a) = \overline{g}_a(x)\) denote the corresponding regression function in \(\mathcal{F}_m\). Since contexts are i.i.d.—in particular, contexts in \(I_m\) are independent of those in \(S_m\)—we have by Lemma 8 that conditioned on the event in (22), with probability at least \(1 - \delta\),

\[
\sum_{t \in I_m} \ell_t(\overline{y}_t) - \ell_t(f^*(z_t)) \leq \sum_{t \in I_m} \ell_t(\overline{y}_t) - \ell_t(\overline{f}(z_t)) + 2Km \cdot \max_{a \in A} \mathbb{E}_{x \sim \mu}[(\overline{f}(x, a) - f^*(x, a))^2] + 16 \log(\delta^{-1}).
\]

regret to \(\overline{f}\)

bias of \(\overline{f}\)
We take \( X \) and union bound over the events with probability \( \frac{1}{2} \). This proof uses arguments similar to a lower bound against strongly adaptive regret. Hence, we can simplify to \( \varepsilon \). Choosing \( \log(2) \) for all \( m \in [M] \) and sum the bound \( (23) \) over each round. Since there are at most \( \log T + 1 \) epochs, we are guaranteed (after simplifying) that with probability at least \( 1 - \delta \),

\[
\text{Reg}_{\text{Sq}}(T) = \sum_{t=1}^{T} \ell_t(\hat{y}_t) - \ell_t(f^*(z_t)) \leq \mathcal{O}
\left( \varepsilon - p + K T \cdot \varepsilon^2 + K T^{1 - \frac{2}{p}} + K \log(\delta^{-1}) \right).
\]

Choosing \( \varepsilon \propto (KT)^{-\frac{1}{2+p}} \) ensures that \( \text{Reg}_{\text{Sq}}(T) \leq \mathcal{O}
\left( (KT)^{-\frac{2}{2+p}} + K T^{1 - \frac{2}{p}} + K \log(\delta^{-1}) \right) \). However, note that \( K T^{1 - \frac{2}{p}} \leq (KT)^{-\frac{2}{2+p}} \) whenever \( K \leq T^\frac{2}{p} \), and if \( K \geq T^\frac{2}{p} \) then \( (KT)^{-\frac{2}{2+p}} \geq T \), so the regret bound is vacuous. Hence, we can simplify to \( \text{Reg}_{\text{Sq}}(T) \leq \mathcal{O}
\left( (KT)^{-\frac{2}{2+p}} + K \log(\delta^{-1}) \right) \). To finish, we appeal to Theorem 1 and union bound, which gives

\[
\text{Reg}_{\text{CB}}(T) \leq \mathcal{O}
\left( \sqrt{KT \text{Reg}_{\text{Sq}}(T)} + \sqrt{K^2 T \log(\delta^{-1})} \right) = \mathcal{O}
\left( (KT)^{\frac{1+p}{2+p}} + \sqrt{K^2 T \log(\delta^{-1})} \right).
\]

\[\square\]

## D Proofs from Section 4

**Proof of Theorem 4.** This proof uses arguments similar to a lower bound against strongly adaptive regret for (non-contextual) multi-armed bandits in given in Daniely et al. (2015a).

Let \( N \in [T] \) be fixed; throughout the proof we assume without loss of generality that \( T \) is divisible by \( N \). We take \( \mathcal{X} = [N], \mathcal{A} = \{a^{(1)}, a^{(2)}\} \) and \( \mathcal{F} = \{f_i\}_{i=0}^{N} \), where for each \( i \leq 1 \leq N \), \( f_i \) is defined as follows:

\[
f_i(j, a^{(1)}) = \frac{1}{2} - \Delta, \quad \text{and} \quad f_i(j, a^{(2)}) = \frac{1}{2}, \quad \forall j \neq i.
\]

\[
f_i(i, a^{(1)}) = \frac{1}{2}, \quad \text{and} \quad f_i(i, a^{(2)}) = \frac{1}{2} - 2\Delta.
\]

The regressor \( f_0 \) is defined via

\[
f_0(j, a^{(1)}) = \frac{1}{2} - \Delta, \quad \text{and} \quad f_0(j, a^{(2)}) = \frac{1}{2}, \quad \forall j.
\]

For each \( i \in \{0, \ldots, N\} \) we define a problem instance \( \mathcal{P}_i \) as follows:
• Choose \( f^* = f_i \).

• For each context \( x \), set \( \ell(a) = f^*(x,a) \) with probability 1 conditioned on \( x \) (i.e., the instances are noiseless).

• Play \( x_t = 1 \) for rounds \( 1, \ldots , T/N \), \( x_t = 2 \) for rounds \( T/N + 1, \ldots , 2T/N \), and so on.

Each instance has uniform gap parameter \( \Delta \). Observe that for each instance \( \mathcal{P}_i \) above, we have

\[
\text{Reg}_{\text{CB}}(T) = \sum_{t=1}^{T} f_i(x_t, a_t) - f_i(x_t, \pi_i(x_t)),
\]

where \( \pi_i := \pi_{f_i} \) is the optimal policy for \( f_i \).

Formally, we model the contextual bandit algorithm \( A \) as a sequence of measurable functions \( A_t : [0, 1]^{t-1} \times \mathcal{R} \to \mathcal{A} \), such that

\[
a_t = A_t(\ell_1(a_1), \ldots , \ell_{t-1}(a_{t-1}); r),
\]

where \( r \sim P_r \) is a random seed.

Henceforth, let the algorithm \( A \) be fixed. We consider two cases. The goal will be to show that in each case there exists some \( i \) such that \( \mathbb{E}_{\mathcal{P}_i}[\text{Reg}_{\text{CB}}(T)] \geq \Delta T \). We then show that this quantity grows as \( \sqrt{T} \) for an appropriate choice of \( N \), even for \( \Delta \) constant.

**Case 1:** \( \mathbb{E}_{\mathcal{P}_0}[\text{Reg}_{\text{CB}}(T)] > \Delta T \). For the first case, we assume \( \mathbb{E}_{\mathcal{P}_0}[\text{Reg}_{\text{CB}}(T)] > \Delta T \), so the desired statement follows immediately by taking \( i = 0 \).

**Case 2:** \( \mathbb{E}_{\mathcal{P}_0}[\text{Reg}_{\text{CB}}(T)] \leq \Delta T \). For the second case, suppose \( A \) has \( \mathbb{E}_{\mathcal{P}_0}[\text{Reg}_{\text{CB}}(T)] \leq \Delta T \). Under \( \mathcal{P}_0 \), we have

\[
\text{Reg}_{\text{CB}}(T) = \sum_{t=1}^{T} \Delta \cdot \mathbb{1}\{a_t = a^{(2)}\},
\]

so if we define \( U = \{ t \mid a_t = a^{(2)} \} \), this implies that \( \mathbb{E}_{\mathcal{P}_0}[U] \leq \Delta T \). For each \( i \), let \( \mathcal{I}_i \) denote the rounds in which \( x_t = i \). Since these sets form a partition, i.e. \( \mathcal{I}_1 \cup \ldots \cup \mathcal{I}_N = [T] \), we have

\[
\sum_{i=1}^{N} \mathbb{E}_{\mathcal{P}_0}[\mathcal{I}_i \cap U] = \mathbb{E}_{\mathcal{P}_0}[U] \leq \frac{T}{N},
\]

and in particular, \( N \cdot \min_i \mathbb{E}_{\mathcal{P}_0}[\mathcal{I}_i \cap U] \leq \frac{T}{N} \). If \( N = \sqrt{2T} \), this implies that for some index \( i^* \), \( \mathbb{E}_{\mathcal{P}_0}[\mathcal{I}_{i^*} \cap U] \leq \frac{1}{2} \), and consequently \( P_{\mathcal{P}_0}(\mathcal{I}_{i^*} \cap U = \emptyset) \geq \frac{1}{2} \). We emphasize that \( i^* \) is not a random variable; it is a deterministic property of \( A \). To proceed, we use the following lemma, which implies we also have \( P_{\mathcal{P}_{i^*}}(\mathcal{I}_{i^*} \cap U = \emptyset) \geq \frac{1}{2} \).

**Lemma 10.** For any every instance \( i \), \( P_{\mathcal{P}_0}(\mathcal{I}_i \cap U = \emptyset) = P_{\mathcal{P}_{i^*}}(\mathcal{I}_{i^*} \cap U = \emptyset) \).

Observe that under instance \( i^* \), we have

\[
\text{Reg}_{\text{CB}}(T) = \sum_{t=1}^{T} f_{i^*}(x_t, a_t) - f_{i^*}(x_t, \pi_{i^*}(x_t)) \geq \sum_{t \in \mathcal{I}_{i^*}} \Delta \mathbb{1}\{a_t = a^{(2)}\},
\]

and in particular \( \mathbb{E}_{\mathcal{P}_{i^*}}[\text{Reg}_{\text{CB}}(T)] \geq \Delta \mathbb{E}_{\mathcal{P}_{i^*}}[\mathcal{I}_{i^*} \cap U = \emptyset] \). Since we showed that \( P_{\mathcal{P}_{i^*}}(\mathcal{I}_{i^*} \cap U = \emptyset) \geq \frac{1}{2} \), we conclude that \( \mathbb{E}_{\mathcal{P}_{i^*}}[\text{Reg}_{\text{CB}}(T)] \geq \frac{1}{2} \Delta T \). \(^4\)

\(^4\)Note that since losses are noiseless, the expectation here only reflects the randomization over the algorithm’s actions under instance \( \mathcal{P}_i \).
We first observe that
\[ r = \mathbb{E}[\min_{a \in A} f_i(x_t, a)] - \mathbb{E}[f_i(x_t, \pi(x_t))] \]

where we used the previous observation that the law of \( t \). Proceeding forwards in the same fashion for \( t \), we have

\[ \max_{i \in [N]} \mathbb{E}[\text{Reg}_{CB}(T)] = \frac{1}{2} \Delta \frac{T}{N}. \]

Recalling that \( N = \sqrt{2T} \) and making the somewhat arbitrary choice \( \Delta = \frac{1}{4} \), we have

\[ \max_{i \in [N]} \mathbb{E}[\text{Reg}_{CB}(T)] \geq \frac{1}{16} \sqrt{T}. \]

\[ \square \]

**Proof of Lemma 10.** Let \( M = T/N \), and let \( t_1, \ldots, t_M = \{M(i - 1) + 1, Mi\} \) denote the (consecutive) rounds in block \( I_i \). Let \( H = \ell_1(a_t), \ldots, \ell_{t-1}(a_{t-1}) \) denote the history prior to \( I_i \).

Let \( \ell_t^i(a) = f_i(x_t, a) \) for each \( a \). For all \( t < t_1 \), we have \( \ell_t^i(a) = \ell_0^i(a) \) (since \( f_i(j, a) = f_0(j, a) \) for all \( j < i \) and losses are noiseless). Consequently, the history is a measurable function of \( r \) that does not depend on whether the underlying instance is \( \mathcal{P}_I \) or \( \mathcal{P}_0 \); we will denote the value it take for each choice of \( r \) by \( H_r \).

Now, observe that we have

\[ \mathbb{P}_{\mathcal{P}_I}(I_i \cap U = \emptyset) = \mathbb{P}_{\mathcal{P}_I}(a_{t_1} = a^{(1)}) \mathbb{P}_{\mathcal{P}_I}(a_{t_2} = a^{(1)} | a_{t_1} = a^{(1)}) \cdots \mathbb{P}_{\mathcal{P}_I}(a_{t_M} = a^{(1)} | a_{t_1}, \ldots, a_{t_{M-1}} = a^{(1)}). \]

We first observe that \( \mathbb{P}_{\mathcal{P}_I}(a_{t_1} = a^{(1)}) = \mathbb{P}_{\mathcal{P}_0}(a_{t_1} = a^{(1)}) \), since

\[ \mathbb{P}_{\mathcal{P}_I}(a_{t_1} = a^{(1)}) = \mathbb{P}_{\mathcal{P}_I}(A_{t_1}(H_r; r) = a^{(1)}) = \mathbb{P}_{\mathcal{P}_0}(A_{t_1}(H_r; r) = a^{(1)}) = \mathbb{P}_{\mathcal{P}_0}(a_{t_1} = a^{(1)}), \]

where we used the previous observation that the law of \( r \) and \( H_r \) does not depend on the underlying instance. For the next timestep, we use that \( \ell_{t_1}^i(a^{(1)}) = \ell_0^i(a^{(1)}) = \frac{1}{2} - \Delta \). That is, if the algorithm pulls arm \( a^{(1)} \) at time \( t_1 \), the feedback is identical for both instances. Consequently, we have

\[ \mathbb{P}_{\mathcal{P}_I}(a_{t_2} = a^{(1)} | a_{t_1} = a^{(1)}) = \mathbb{P}_{\mathcal{P}_I}(A_{t_2}(H_r, \ell_{t_1}^i(a^{(1)}); r) = a^{(1)} | a_{t_1} = a^{(1)}) = \mathbb{P}_{\mathcal{P}_0}(a_{t_2} = a^{(1)} | a_{t_1} = a^{(1)}). \]

Proceeding forwards in the same fashion for \( t = t_3, \ldots, t_M \) yields the result. \[ \square \]

## E  Proofs from Section 5

### E.1  Proofs from Section 5.1

**Proof of Theorem 5.** Let a policy \( \pi \) be fixed, and let the filtration \( \mathcal{F}_t \) be as in (17). We begin with the sum of (conditional expectations of) immediate regrets of to \( \pi \).

\[
\sum_{t=1}^{T} \mathbb{E}[\ell_t(a_t) - \ell_t(\pi(x_t)) | \mathcal{F}_{t-1}] \\
\leq \sum_{t=1}^{T} \mathbb{E}[f^*(x_t, a_t) - f^*(x_t, \pi(x_t)) | \mathcal{F}_{t-1}] + 2\varepsilon T \\
\leq \sum_{t=1}^{T} \mathbb{E}[f^*(x_t, a_t) - f^*(x_t, \pi f^*(x_t)) | \mathcal{F}_{t-1}] + 2\varepsilon T \\
= \sum_{t=1}^{T} \sum_{a \in A} p_t(a) (f^*(x_t, a) - f^*(x_t, \pi f^*(x_t))) + 2\varepsilon T.
\]
Applying Lemma 3 at each round and summing, we can upper bound by

\[
\frac{\gamma}{4} \sum_{t=1}^{T} \sum_{a \in A} p_t(a) (\hat{y}_t(x_t, a) - f^*(x_t, a))^2 + \frac{2KT}{\gamma} + 2\varepsilon T
\]

where we have used Assumption 2a. Now, observe that we have

\[
\frac{\gamma}{4} \sum_{t=1}^{T} \mathbb{E}\left[ (\hat{y}_t(x_t, a_t) - f^*(x_t, a_t))^2 \mid \mathcal{F}_{t-1} \right] + \frac{2KT}{\gamma} + 2\varepsilon T.
\]

By the law of total expectation, this implies that the following inequality holds marginally.

\[
\mathbb{E}\left[ \sum_{t=1}^{T} \ell_t(a_t) - \ell_t(\pi(x_t)) \right] \leq \frac{\gamma}{4} \mathbb{E}\left[ \sum_{t=1}^{T} (\hat{y}_t(x_t, a_t) - f^*(x_t, a_t))^2 \mid \mathcal{F}_{t-1} \right] + \frac{2KT}{\gamma} + 2\varepsilon T. \tag{24}
\]

In the remainder of the proof we bound the squared prediction error on the right-hand side. Observe that for any fixed timestep \( t \), strong convexity of the square loss implies

\[
(\hat{y}_t(x_t, a_t) - \ell_t(a_t))^2 \geq (f^*(x_t, a_t) - \ell_t(a_t))^2 + 2(f^*(x_t, a_t) - \ell_t(a_t))(\hat{y}_t(x_t, a_t) - f^*(x_t, a_t)) + (\hat{y}_t(x_t, a_t) - f^*(x_t, a_t))^2.
\]

Summing this inequality across all rounds, we are guaranteed that for every sequence of outcomes,

\[
\sum_{t=1}^{T} (\hat{y}_t(x_t, a_t) - f^*(x_t, a_t))^2 \leq \sum_{t=1}^{T} (\hat{y}_t(x_t, a_t) - \ell_t(a_t))^2 - (f^*(x_t, a_t) - \ell_t(a_t))^2
\]

\[\quad - 2 \sum_{t=1}^{T} (f^*(x_t, a_t) - \ell_t(a_t))(\hat{y}_t(x_t, a_t) - f^*(x_t, a_t)) + \text{Reg}_{\text{Seq}}(T) - 2 \sum_{t=1}^{T} (f^*(x_t, a_t) - \ell_t(a_t))(\hat{y}_t(x_t, a_t) - f^*(x_t, a_t)), \tag{25}
\]

where we have used Assumption 2a. Now, observe that we have

\[-2 \sum_{t=1}^{T} \mathbb{E}\left[ (f^*(x_t, a_t) - \ell_t(a_t))(\hat{y}_t(x_t, a_t) - f^*(x_t, a_t)) \mid \mathcal{F}_{t-1} \right]
\]

\[= 2 \sum_{t=1}^{T} \mathbb{E}\left[ \varepsilon_t(x_t, a_t)(\hat{y}_t(x_t, a_t) - f^*(x_t, a_t)) \mid \mathcal{F}_{t-1} \right],
\]

where we have used that, since the adversary is oblivious, \( f^* \) does not depend on the outcomes \( \ell_1, \ldots, \ell_T \). By the AM-GM inequality (specifically, that \( ab \leq a^2 + \frac{1}{4} b^2 \) for all \( a, b \)), and Assumption 5 we have

\[2 \sum_{t=1}^{T} \mathbb{E}\left[ \varepsilon_t(x_t, a_t)(\hat{y}_t(x_t, a_t) - f^*(x_t, a_t)) \mid \mathcal{F}_{t-1} \right]
\]

\[\leq \sum_{t=1}^{T} \mathbb{E}\left[ (f^*(x_t, a_t) - \ell_t(a_t))^2 \mid \mathcal{F}_{t-1} \right] + \frac{1}{2} \sum_{t=1}^{T} \mathbb{E}\left[ (\hat{y}_t(x_t, a_t) - f^*(x_t, a_t))^2 \mid \mathcal{F}_{t-1} \right]
\]

\[\leq \varepsilon^2 T + \frac{1}{2} \sum_{t=1}^{T} \mathbb{E}\left[ (\hat{y}_t(x_t, a_t) - f^*(x_t, a_t))^2 \mid \mathcal{F}_{t-1} \right].
\]

Using the law of total expectation, we conclude that

\[-2 \mathbb{E}\left[ \sum_{t=1}^{T} (f^*(x_t, a_t) - \ell_t(a_t))(\hat{y}_t(x_t, a_t) - f^*(x_t, a_t)) \right] \leq \varepsilon^2 T + \frac{1}{2} \mathbb{E}\left[ \sum_{t=1}^{T} (\hat{y}_t(x_t, a_t) - f^*(x_t, a_t))^2 \right].
\]

33
Combining the inequality with (25) this implies,
\[
\mathbb{E}\left[\sum_{t=1}^{T}(\gamma f(x_t, a_t) - f^*(x_t, a_t))^2\right] \leq \text{Reg}_{\text{Sq}}(T) + \varepsilon^2 T + \frac{1}{2} \mathbb{E}\left[\sum_{t=1}^{T}(\gamma f(x_t, a_t) - f^*(x_t, a_t))^2\right].
\]
or, after rearranging,
\[
\mathbb{E}\left[\sum_{t=1}^{T}(\gamma f(x_t, a_t) - f^*(x_t, a_t))^2\right] \leq 2\text{Reg}_{\text{Sq}}(T) + 2\varepsilon^2 T.
\]
Using this bound with (24) gives
\[
\mathbb{E}\left[\sum_{t=1}^{T} \ell_t(a_t) - \ell_t(\pi(x_t))\right] \leq \frac{\gamma}{2}(\text{Reg}_{\text{Sq}}(T) + \varepsilon^2 T) + \frac{2KT}{\gamma} + 2\varepsilon T.
\]
The choice for \(\gamma\) in the theorem statement then makes the right-hand side equal to
\[
2\sqrt{KT(\text{Reg}_{\text{Sq}}(T) + \varepsilon^2 T)} + 2\varepsilon T \leq 2\sqrt{KT(\text{Reg}_{\text{Sq}}(T) + 4\varepsilon\sqrt{KT}}.
\]

**Proof of Theorem 6.** Let a policy \(\pi\) be fixed, and let the filtration \(\mathcal{F}_t\) be as in (17). Observe that we have
\[
\sum_{t=1}^{T} \mathbb{E}[\ell_t(a_t) - \ell_t(\pi(x_t)) \mid \mathcal{F}_{t-1}] = \sum_{t=1}^{T} \max_{a^* \in A} \mathbb{E}[\ell_t(a_t) - \ell_t(a^*) \mid \mathcal{F}_{t-1}] = \sum_{t=1}^{T} \max_{a^*} \sum_{a \in A} p_t, (\ell_t(a) - \ell_t(a^*)).
\]

Applying Lemma 3 at each round and summing, we can upper bound by
\[
\frac{\gamma}{4} \sum_{t=1}^{T} \sum_{a \in A} p_t, (\gamma f(x_t, a) - f_t(a))^2 + \frac{2KT}{\gamma} = \frac{\gamma}{4} \sum_{t=1}^{T} \mathbb{E}\left[\sum_{a \in A} (\gamma f(x_t, a_t) - f_t(a_t))^2 \mid \mathcal{F}_{t-1}\right] + \frac{2KT}{\gamma}.
\]
By the law of total expectation, this implies
\[
\mathbb{E}\left[\sum_{t=1}^{T} \ell_t(a_t) - \ell_t(\pi(x_t))\right] \leq \frac{\gamma}{4} \mathbb{E}\left[\sum_{t=1}^{T}(\gamma f(x_t, a_t) - f_t(a_t))^2\right] + \frac{2KT}{\gamma}.
\]

Next, we observe that by Assumption 2a, we are guaranteed that with probability 1,
\[
\sum_{t=1}^{T} (\gamma f(x_t, a_t) - f_t(a_t))^2 \leq \inf_{f \in \mathcal{F}} \sum_{t=1}^{T} (f(x_t, a_t) - f_t(a_t))^2 + \text{Reg}_{\text{Sq}}(T) \leq \varepsilon^2 T + \text{Reg}_{\text{Sq}}(T),
\]
where the second inequality follows from Assumption 5. Since this bound holds pointwise, it holds in expectation in particular, so we can combine with (26) to get

\[
\mathbb{E}\left[\sum_{t=1}^{T} \ell_t(a_t) - \ell_t(\pi(x_t))\right] \leq \frac{\gamma}{4} (\varepsilon^2 T + \text{Reg}_{\text{Sq}}(T)) + \frac{2KT}{\gamma}.
\]

The choice for \(\gamma\) in the theorem statement makes this at most

\[
\sqrt{2KT(\text{Reg}_{\text{Sq}}(T) + \varepsilon^2 T)} \leq \sqrt{2KT \cdot \text{Reg}_{\text{Sq}}(T) + \varepsilon \sqrt{2KT}}.
\]

\(\square\)

### E.2 Proofs from Section 5.2

**Proof of Theorem 7.** Let \(p_t\) denote the distribution over actions at time \(t\), conditioned on \(\mathcal{F}_{t-1}\) (where \(\mathcal{F}_{t-1}\) is defined as in Theorem 1). Using Lemma 2, we have that with probability at least \(1 - \delta\),

\[
\sum_{t=1}^{T} \mathbb{E}_{a_t \sim p_t}\left[\left(\overline{y}_t(x_t, a_t) - f^*(x_t, a_t)\right)^2\right] \leq 2\text{Reg}_{\text{Sq}}(T) + 16\log(2\delta^{-1}),
\]

and

\[
\text{Reg}_{\text{CB}}(T) \leq \sum_{t=1}^{T} \mathbb{E}_{a_t \sim p_t}\left[\left(f^*(x_t, a_t) - f^*(x_t, \pi^*(x_t))\right)\right] + \sqrt{2T \log(2\delta^{-1})}.
\]

Define \(f_t^* = f^*(x_t, \cdot) \in \mathbb{B}_{dA}\). We will show that for an appropriate choice of constants \(C_1\) and \(C_2\), for each timestep \(t\),

\[
\max_{a^* \in \mathbb{B}_{dA}} \mathbb{E}_{a_t \sim p_t}\left[\left(f_t^* - f_t^* - a^*\right)^2\right] \leq C_1 \cdot \mathbb{E}_{a_t \sim p_t}\left[\left(\overline{y}_t - f_t^* - a_t\right)^2\right] + C_2,
\]

from which it will follow that

\[
\text{Reg}_{\text{CB}}(T) \leq 2C_1 \text{Reg}_{\text{Sq}}(T) + 16C_1 \log(\delta^{-1}) + C_2 T + \sqrt{2T \log(\delta^{-1})}.
\]

(27)

**Basic properties of the action distribution.** We begin by calculating the first and second moment of the action distribution.

\[
\mu_t := \mathbb{E}_{a_t \sim p_t}[a_t] = (1 - \alpha_t) \cdot (-\overline{y}_t) + \alpha_t \cdot \mathbb{E}_{e_t}[e \cdot e_t] = -(1 - \alpha_t)\overline{y}_t,
\]

(28)

\[
\Sigma_t := \mathbb{E}_{a_t \sim p_t}[a_t a_t^\top] = (1 - \alpha_t) \cdot \overline{y}_t \overline{y}_t^\top + \alpha_t \cdot \mathbb{E}_{e_t}[e^2 \cdot e_t e_t^\top] = (1 - \alpha_t)\overline{y}_t \overline{y}_t^\top + \alpha_t \frac{1}{d_A} I \geq \frac{\alpha_t}{d_A} I.
\]

(29)

Note that with this notation, we have

\[
\mathbb{E}_{a_t \sim p_t}\left[\left(\overline{y}_t, a_t\right) - \left(f_t^*, a_t\right)\right)^2 = \|\overline{y}_t - f^*\|_{\Sigma_t}^2,
\]

(30)

where \(\|x\|_A = \sqrt{\langle x, A x \rangle}\) denotes the weighted euclidean norm.

From here, we break the analysis into two cases based on the value of \(\alpha_t\).
Case 1: $\alpha_t = \frac{1}{2}$. This constitutes a degenerate case in which $\bar{y}_t$ is very small. Indeed, we have $\frac{\beta}{\|y_t\|_2} \geq \frac{1}{2}$, so $\|\bar{y}_t\|_2 \leq 2\beta$. Moreover, by (29) we have $\Sigma_t \geq \frac{1}{d_A} I$. We upper bound the instantaneous regret by Cauchy-Schwarz and the AM-GM inequality as

$$\max_{a^* \in B_{d_A}} E_{a_t \sim p_t}(f_t^*, a_t) - \langle f_t^*, a^* \rangle \leq 2\|f_t^*\| \leq \frac{1}{\eta_1} + \eta_1\|f_t^*\|_2^2,$$

where $\eta_1 > 0$ is a free parameter. Using our bound on $\|\bar{y}_t\|_2$ and our lower bound on $\Sigma_t$, we have

$$\|f_t^*\|_2 \leq 2\|\bar{y}_t - f_t^*\|_2 + 2\|\bar{y}_t\|_2^2 \leq 2\|\bar{y}_t - f_t^*\|_2^2 + 8\beta^2 \leq 4d_A\|\bar{y}_t - f_t^*\|_2^2 + 8\beta^2.$$

Hence, we have

$$\max_{a^* \in B_{d_A}} E_{a_t \sim p_t}(f_t^*, a_t) - \langle f_t^*, a^* \rangle \leq \frac{1}{\eta_1} + 8\beta^2 \eta_1 + 4d_A \eta_1 \cdot \|\bar{y}_t - f_t^*\|_2^2.$$

We choose $\eta_1 = \frac{1}{\beta}$, which gives

$$\max_{a^* \in B_{d_A}} E_{a_t \sim p_t}(f_t^*, a_t) - \langle f_t^*, a^* \rangle \leq 9\beta + \frac{4d_A}{\beta} \cdot \|\bar{y}_t - f_t^*\|_2^2. \quad (31)$$

Case 2: $\alpha_t = \frac{\beta}{\|y_t\|_2}$. This case constitutes the interesting part of the proof. Define $\tilde{f}_t = f_t^*/\|f_t^*\|_2$. To begin we let the $a_t^*$ denote the optimal action and write.

$$\max_{a^* \in B_{d_A}} E_{a_t \sim p_t}(f_t^*, a_t) - \langle f_t^*, a^* \rangle = \langle \mu_t - a_t^*, \tilde{f}_t \rangle = \langle \mu_t - a_t^*, \tilde{y}_t \rangle + \langle \mu_t - a_t^*, \tilde{f}_t - \tilde{y}_t \rangle.$$

Noting that $a_t^* = -\tilde{f}_t$ and using (28), the first term is bounded as

$$\langle \mu_t - a_t^*, \tilde{y}_t \rangle = \langle \tilde{f}_t - (1 - \alpha_t)\bar{y}_t, \tilde{y}_t \rangle = \alpha_t\|\tilde{y}_t\| + \langle \tilde{y}_t, \tilde{f}_t \rangle - \|\tilde{y}_t\| = \beta - \mathcal{E}_t.$$

Since $\mathcal{E}_t = \|\tilde{y}_t\|_2 - \langle \tilde{y}_t, \tilde{f}_t \rangle \geq 0$, this term—up to a small additive error $\beta$—has a negative contribution to the regret, which we make use of in a moment.

Now, for the second term we begin by using Hölder’s inequality and AM-GM, which implies that for any $\eta_2 > 0$,

$$\langle \mu_t - a_t^*, \tilde{f}_t - \tilde{y}_t \rangle \leq \frac{1}{2\eta_2} \|\mu_t - a_t^*\|_{\Sigma_t^{-1}}^2 + \frac{\eta_2}{2} \|\tilde{y}_t - f_t^*\|_{\Sigma_t}^2.$$

The second term is precisely what we want, and we will show now that the first term is cancelled by $\mathcal{E}_1$ if $\eta_2$ is chosen appropriately. We use the lower bound on $\Sigma_t$ from (29), which implies that

$$\|\mu_t - a_t^*\|_{\Sigma_t^{-1}}^2 \leq \frac{d_A}{\alpha_t} \|\mu_t - a_t^*\|_2^2 = \frac{d_A}{\alpha_t} \left( \|a_t^*\|_2^2 + \|\mu_t\|_2^2 - 2\langle \mu_t, a_t^* \rangle \right).$$

Using the value of $\mu_t$ from (29), this is equal to

$$= \frac{d_A}{\alpha_t} \left( 1 + (1 - \alpha_t)^2 - 2(1 - \alpha_t)\langle \bar{y}_t, \tilde{f}_t \rangle \right)$$

$$= \frac{d_A(1 - \alpha_t)}{\alpha_t} \left( (1 - \alpha_t)^{-1} + (1 - \alpha_t) - 2\langle \bar{y}_t, \tilde{f}_t \rangle \right).$$

36
An elementary calculation reveals that since $\alpha_t \leq 1/2$, 

$$(1 - \alpha_t)^{-1} + (1 - \alpha_t) = \frac{1 + (1 - \alpha_t)^2}{1 - \alpha_t} = 2 + \frac{\alpha_t^2}{1 - \alpha_t} \leq 2 + 2\alpha_t^2.$$ 

Hence, we have

$$\frac{d_A(1 - \alpha_t)}{\alpha_t}((1 - \alpha_t)^{-1} + (1 - \alpha_t) - 2(\bar{y}_t, \bar{f}_t)) \leq \frac{d_A(1 - \alpha_t)}{\alpha_t}(2 - 2(\bar{y}_t, \bar{f} + 2\alpha_t^2)$$

$$= \frac{2d_A(1 - \alpha_t)}{\beta} (\|\bar{y}_t\| - (\bar{y}_t, \bar{f}_t)) + 2d_A\alpha_t$$

$$= \frac{2d_A(1 - \alpha_t)}{\beta} \varepsilon_t + 2d_A\alpha_t$$

$$\leq \frac{2d_A}{\beta} \varepsilon_t + 2d_A\alpha_t.$$ 

Combined with all of the calculations so far, this gives

$$\max_{a^* \in B_{d_A}} \mathbb{E}_{a_t \sim p_t} [(f_t^*, a_t) - (f_t^*, a^*)] \leq \beta - \varepsilon_t + \frac{1}{2\eta_2} \left( \frac{2d_A}{\beta} \varepsilon_t + 2d_A\alpha_t \right) + \frac{\eta_2}{2} \|\bar{y}_t - f_t^*\|_{\Sigma_t}.$$ 

By choosing $\eta_2 = \frac{d_A}{\beta}$, the $\varepsilon_t$ terms cancel, and we are left with

$$\max_{a^* \in B_{d_A}} \mathbb{E}_{a_t \sim p_t} [(f_t^*, a_t) - (f_t^*, a^*)] \leq \beta(1 + \alpha_t) + \frac{d_A}{2\beta} \|\bar{y}_t - f_t^*\|_{\Sigma_t} \leq \frac{3}{2} \beta + \frac{d_A}{2\beta} \|\bar{y}_t - f_t^*\|_{\Sigma_t}.$$ 

**Final bound.** Combining equations (31) and (32), we are guaranteed that in every round, regardless of which case holds,

$$\max_{a^* \in B_{d_A}} \mathbb{E}_{a_t \sim p_t} [(f_t^*, a_t) - (f_t^*, a^*)] \leq 9\beta + \frac{4d_A}{\beta} \|\bar{y}_t - f_t^*\|_{\Sigma_t}.$$ 

Using (27), this implies that

$$\text{Reg}_\text{CB}(T) \leq \frac{8d_A}{\beta} (\text{Reg}_\text{Sq}(T) + 8 \log(\delta^{-1})) + 9\beta T + \sqrt{2T \log(\delta^{-1})}.$$ 

Hence, by choosing $\beta = \sqrt{\frac{d_A(\text{Reg}_\text{Sq}(T)+8\log(\delta^{-1}))}{T}}$, we have

$$\text{Reg}_\text{CB}(T) \leq 18\sqrt{d_A T \text{Reg}_\text{Sq}(T) + 90d_A T \log(\delta^{-1})}.$$
