Abstract
In both criminal cases and civil cases, there is an increasing demand for the analysis of DNA mixtures involving relationships. The goal might be, for example, to identify the contributors to a DNA mixture where the donors may be related, or to infer the relationship between individuals based on a mixture. This paper introduces an approach to modelling and computation for DNA mixtures involving contributors with arbitrarily complex relationships. It builds on an extension of Jacquard’s condensed coefficients of identity, to specify and compute with joint relationships, not only pairwise ones, including the possibility of inbreeding. The methodology developed is applied to two casework examples involving a missing person, and simulation studies of performance, in which the ability of the methodology to recover complex relationship information from synthetic data with known ‘true’ family structure is examined. The methods used to analyse the examples are implemented in the new KinMix R package that extends the DNAmixtures package to allow for modelling DNA mixtures with related contributors.

1  |  INTRODUCTION

This article is concerned with probabilistic genotyping methods for DNA mixtures based on unlinked autosomal short tandem repeat (STR) markers, under hypotheses about biological relationships involving contributors to the mixture. For the first time, answers to important questions about complex relationships can be delivered by a fully probabilistic approach.

1.1  |  Genetic background

STR markers are the mainstay of DNA profiling systems used in forensic science laboratories worldwide. To create the data used in modelling and analysis, the DNA in a biological specimen is extracted, and through a process of polymerase chain reaction (PCR) amplified to create an electropherogram (EPG), a continuous trace that is digitised for analysis. Identifiable segments of this trace correspond to different known loci, called markers, on the genome. The markers used are chosen to lie far apart in the genome, usually on different chromosomes, so are unlinked, that is statistically independent. Each segment consists of peaks aligned to a known grid, one peak for each possible allele, or genetic variant, at that locus; for STR markers, these alleles take (generally, integer) values giving the repeat count of a short sequence in the genome. The heights of the peaks measure the abundance of that allele at that locus, and collectively carry a great deal of information about the genetic make-up of the original specimen, but are subject to degradation consisting of both random noise and artefacts introduced in the PCR process, for which a statistical model must be constructed.

The usual methodology uses only autosomal loci, that is, markers on the chromosomes that are not sex-linked, and so involve a contribution from each parent. The individual contributions we call genes, and the unordered pair of contributions the genotype. We call the collection of genotypes across all markers the genotype profile of the individual; note that in a statistical language, we regard genes and genotypes as random variables, while alleles are the possible values of a gene.

When a biological specimen is taken from one individual, and handled and processed under ideal conditions, an EPG represents a noisy version of the genotype profile of that one individual; in this case we can talk about genotyping or ‘typing’. In other situations, either through the circumstances in which the sample is obtained (e.g. in rape, or other violent assault) or through contamination, the DNA quantified by the EPG comes from two or more individuals; this is a DNA mixture. In both criminal and civil cases, even for simple tasks such as criminal identification or paternity testing, we need methodology for assessing hypotheses about the genetic origin of the DNA based on mixture data. The focus of this paper is to derive and demonstrate principled and practical methods for such tasks, in cases where there are biological relationships involving the contributors. We concentrate on so-called continuous methods using peak height information, as opposed to binary or semi-continuous methods.

More details of the genetic background to the use of STR markers and DNA mixtures can be found in Section 1 of Cowell et al. (2015), in this Journal, and also in the recent review article by Mortera (2020).

1.2  |  Modelling and inferential approach

Both the statistical model we use for EPG peak heights, and exact computationally-efficient methods for inference about the genotype profiles of contributors, can be found in Cowell et al. (2015). The present article extends the principles and practice of this work to allow for relationships among the
contributors and/or to make inferences about such relationships. We stress here that we are concerned with relationships, that is specific close familial associations such as between parent and child, or an individual and her maternal grandparents, not relatedness, that is an ambient genetic correlation induced among all members of a population or subgroup by virtue of shared ancestry, typically quantified by a coancestry coefficient.

There has been very little previous work on models, methodology and software for DNA mixtures that takes account of relationships with and among the contributors. The only examples we are aware of are our earlier work on paternity analysis in Green and Mortera (2017), the precursor to the present paper, and Hernandis et al. (2019). Our work models peak heights explicitly, while Hernandis et al. (2019) does not use peak height information; these two approaches underpin the KinMix and relMix software packages, respectively. There are several other packages dealing with mixtures in the presence of relatedness; some of these are listed in the Supplementary information, section 3, but we will not be concerned further with such models here; they are not capable of modelling close familial relationships accurately.

It is convenient and natural when modelling peak height data probabilistically to use a hierarchical formulation, with two main layers: the genotype profiles $n$ of the contributors, and the peak heights $z$ recorded in the electropherogram; the models typically then consist of two components:

1. $p(n)$—the joint distribution for $n$—parameterised by population allele frequencies, hypotheses about the contributors, etc., and
2. $p(z|n)$—the conditional distribution for $z$ given $n$—with parameters identifying the peak height model and the proportions of DNA from each of the contributors contained in the mixture.

Inference based on DNA mixtures usually focusses on the comparison between two hypotheses $H_p$ and $H_0$ concerning the constitution of the mixture, quantified by the likelihood ratio LR for $H_p$ versus $H_0$. In this article, these hypotheses will be about (arbitrarily complex) relationships between mixture contributors, and between contributors and other typed individuals. Simple examples of relationship tests we can construct are

- a paternity test given a child’s genotype, where $H_p$ and $H_0$, respectively, state that the putative father is a contributor to the mixture, or that no contributor to the mixture is related to the child, and
- a test for whether contributors to a mixture, perhaps found at a crime scene, are related in a particular way ($H_p$) or not at all ($H_0$).

Although above and throughout the paper, we use the words ‘test’ and ‘hypothesis’, etc., that are familiar from statistical hypothesis testing, we should make clear that this is not what we are doing. Rather, we are contrasting alternative explanations of the evidence, by means of $\log_{10}$ LR values. These ‘weights of evidence’ are to be interpreted in the applicable judicial context, where they will be combined with other evidence, not necessarily quantifiable numerically, rather than referred to a null distribution to yield for example p-values. The $\log_{10}$ LR scale for weights of evidence is standard in forensic statistics (Balding, 2005), but in general usage can be traced back to Turing; see Good (1979). The scale is natural and interpretable: for example a $\log_{10}$ LR of 6 means that the evidence is $10^6=1,000,000$ times more likely under one hypothesis than another.

Throughout we use the probabilistic and computational formulation for DNA mixtures of Cowell et al. (2015), and the software implementation of this in the DNAmixtures R package of Graversen (2013); the model emulates the PCR process described above, and recognises artefacts including stutter, drop-out, drop-in and silent alleles. Our new model extensions are largely aimed at modelling the
genotype profile distribution \( p(n) \) to express complex relationships; the methods are implemented in an R package KinMix (Green, 2020a) that supplements DNAmixtures. Early ideas in this direction can be found in Green and Mortera (2017). Although implementation is restricted to this model and this computational environment, the ideas are quite general and could be adapted to other probabilistic genotyping systems and to other peak height models.

1.3 Contribution of this paper, and its structure

The novel methodological contribution of this paper is to show both how recent unpublished work on extending coefficients of identity to more than two individuals provides a formalism for specifying complex family relationships, and how this can be used to automatically construct Bayesian network (BN) algorithms for computing inferences for models for DNA mixtures involving related individuals, including likelihood ratios for comparing hypotheses about relationships.

The paper is organised as follows. In Section 2, we present a formulation and notation for expressing quantitatively the simultaneous relationships among an arbitrary set of individuals, specified through their joint pedigree. This notation generalises long-standing coefficients of relationship applicable only to pairs of individuals, and is useful both for specifying relationships precisely and computing with them. The formulation is completely general, its applicability is not confined to STR markers and DNA mixtures, but encodes relationships for any quantitative genetic analysis. In Section 3, we use this encoding to characterise the joint distribution of genotypes in a family, and thereby develop efficient computational inference schemes for DNA mixtures, using BN methods. Section 4 is devoted to BN computations for mixtures where there is an ‘ambient’ level of relatedness across the whole population, rather than specific close relationships, or where allele frequencies are not exactly known. In section 5, we discuss the setting of parameters for likelihood calculations in our model, and in section 6, we introduce the R package KinMix implementing all of the methods in this paper. Sections 7 and 8 illustrate the methodology with some simulated scenarios, and several real case studies, including some comparative timings highlighting the fast computation times that are achieved. Finally, we discuss extensions such as allowing for mutation.

2 ENCODING RELATIONSHIPS VIA IBD PATTERN DISTRIBUTIONS

What are biological relationships, and how can they be encoded? An essential preliminary to modelling and analysis of DNA mixtures with related contributors is a compact and precise representation of joint relationships among a set of arbitrarily related individuals. Developing and illuminating such a representation is the focus of this section, which is of universal applicability, not confined to mixture analysis.

Under our simplified genetic model of unlinked autosomal STR markers, the sole source of relationship between individuals is identity by descent (IBD). This is the phenomenon that two genes may be identical because they are copies of the same ancestor gene, rather than being independent draws from the ‘gene pool’, so that the genotypes of two or more related actors will be positively associated.

It is important to distinguish IBD from identity by state (IBS), which includes the possibility that independent draws from the gene pool have the same value by chance. For example, consider a mother–daughter pair, and a single STR marker where the mother’s genotype is say \((a,b)\), and the
child's is \((c,d)\), where in both cases we have ordered the genes in the genotype as (maternal gene, paternal gene). Then by Mendel's first law, \(c\) is equal to \(a\) or \(b\) with equal probability, while \(d\) is contributed by the father. The gene \(c\) is identical by descent to either \(a\) or \(b\), respectively, but unless the mother's and father's genes are all distinct in value, this is not the only way that any of \((a, b, c, d)\) can be equal in value (identical by state). For example, \(a\) and \(b\) could by chance be equal (i.e. the mother is homozygous), or \(a\) and \(d\) could be equal, or indeed both.

For relationships other than parent–child, and for relationships among more than two individuals, we need a way to encode the implications of Mendel's first law for the joint distribution of all the individuals’ genotypes; that is the objective of this section.

A pedigree is a graphical or tabular depiction of the identities of all individuals under consideration, mapping to the identities of their parents, and is a useful compact and precise vehicle for specifying joint relationships. In all of the pedigrees we use and display, either both or neither of the parents is included; those with no parents in the pedigree are called founding individuals, or founders, and their genes are founding genes. Given a pedigree, IBD is determined by the meioses generating the genes of each child given those of its parents, and any inbreeding within or between founding individuals: the actual allelic values are not relevant to this. For two individuals, Table 1 of Thompson (2013) lays out all possible patterns; this table is adapted as our Table 1 below. An explanation of the IBD states is given in Section 2.2. Thompson credits this formulation to Nadot and Vaysseix (1973), although they do not use a tabular representation.

### 2.1 Coefficient of identity by descent

Two-person relationships are compactly summarised in numerical form using the coefficients of identity by descent \((\delta_i)\) and condensed coefficients of identity by descent \((\Delta_i)\) of Jacquard (1974) (chapter 6), which are probabilities of particular patterns of identity by descent. The \(\delta_i\) are the probabilities for the 15 individual rows of Table 1, the \(\Delta_i\) those of the 9 subsets of genotypically equivalent states, where we do not keep track of which parent donates which allele; in each case, the numbering of the coefficients follows that of the respective original authors, and conforms with the natural ordering in the Table. It is these condensed coefficients of identity that we use to characterise and quantify relationships among related individuals, including mixture contributors. Where inbreeding is ruled out, \(\Delta_i = 0\) for \(i = 1, 2, \ldots, 6\), and we need only the \(\kappa\) coefficients of Cotterman (1940), which have an explicit interpretation: \(\kappa_0 \equiv \Delta_9\), \(\kappa_1 \equiv \Delta_8\), \(\kappa_2 \equiv \Delta_7\) are the probabilities that the two individuals share 0, 1 or 2 alleles by descent. As examples,

1. a parent and child have a relationship summarised by \(\kappa_0 = 0, \kappa_1 = 1, \kappa_2 = 0\) (since a parent always contributes exactly one of its alleles to his or her child),
2. two half-siblings (with unrelated parents) have \(\kappa_0 = 0.5, \kappa_1 = 0.5, \kappa_2 = 0\) (since there is a 50–50 chance that the common parent contributes the same allele to each of its children), while
3. two children from an incestuous brother-sister mating are captured by \(\Delta = (0.06250, 0.03125, 0.12500, 0.03125, 0.12500, 0.03125, 0.21875, 0.31250, 0.06250)\), a more complicated example demonstrating the need to automate the calculation of these coefficients.

The \(\kappa\) and \(\Delta\) coefficients can be calculated from a pedigree by simple recursive calculations down the pedigree. In R, these are performed by the functions kappaIBD and condensedIdentity, respectively, in the package ribd (Vigeland, 2019b), part of the pedtools family of packages created by Vigeland (2019a).
The coefficients of identity, $\kappa$, $\delta$, or $\Delta$, should not be confused with a different measure of relatedness, the coefficient of coancestry or kinship coefficient, often represented by $\theta$. This is the probability that randomly chosen alleles from each of the two individuals are identical by descent. By elementary probability calculations, we find that $\theta = \frac{\Delta_1 + (\Delta_3 + \Delta_5 + \Delta_7)/2 + \Delta_8/4}{2}$, or simply $\kappa_2/2 + \kappa_1/4$ in the absence of inbreeding. This carries less information, for example, your coefficient of ancestry with your mother and sister are both $\theta = 1/4$, although you are differently related to these two, as shown by the $\kappa$s. Similarly, you have the same $\theta = 1/8$ with a double first cousin and an uncle.

For more than two individuals, Thompson (1974) seems to have been first to provide a general framework for gene identity given multiple relationships. She provides a rigorous algebraic formalism, with particular attention to enumerating the intrinsic symmetries in the problem, and counts the numbers of possible relationships, which increase very rapidly. For example, for as few as 4 individuals, there are already 712 possible (genotypically equivalent) IBD states, reducing to 139 if inbreeding is ruled out. She does not provide a notation for the probabilities of these states. We could extend the $\Delta$ notation to more than two individuals, using as subscript the IBD pattern, for example writing $\Delta_{1,2,1,2}$ in place of $\Delta_6$, but this seems cumbersome, especially for larger numbers of relatives. In typical pedigrees, only a very small fraction of these states have positive probability, so the vast
majority of condensed coefficients of identity are 0. Instead, we use what amounts to a sparse representation of such vectors of coefficients, namely a listing of which coefficients are non-zero, and their probability values; there are examples in Tables 2 and 3, where we use an arbitrary member of each equivalence class as a representative. We call this representative an IBD pattern and the whole table the IBD pattern distribution. In recent unpublished collaborative work, the present first author and Magnus Dehli Vigeland jointly devised an efficient algorithm for computing such tables, also known as ‘multi-person condensed coefficients of identity’, from the pedigree; this is implemented in the function pedigreeIBD in the R package KinMix and the function multiPersonIBD in the R package ribd.

We can display each IBD pattern in various ways, following the authors cited above. One is by a vector of integer labels, of length twice the number of individuals, \( n \), say, the pair in entries \((2i−1,2i)\) representing the genotype of the corresponding individual \( i = 1, 2, \ldots, n \), as in the first columns of Table 1. The numerical value of the labels is irrelevant, all that matters is whether two labels are the same or different, so the vector denotes a partition of the \( 2n \) genes according to which are identical by descent. Since we are only concerned with unordered pairs of genes, the interpretation of the pattern

TABLE 3  IBD pattern distributions for two scenarios of 3 pairwise cousins; (left) star, (right) cyclic arrangements
is unchanged if elements \((2i - 1, 2i)\) are exchanged, and also, of course, unchanged by any \(1 - 1\) relabelling. Diagrammatically, the pattern can be displayed as a graph with \(2n\) vertices laid out in a \(n \times 2\) rectangular array, and vertices connected by an arc if the corresponding genes are identical by descent. Both representations of IBD patterns were used (with \(n = 2\)) by Jacquard (1974) (chapter 6). Figure 2 and Table 3 show two examples of IBD pattern distributions displayed in each of these ways.

As a foretaste of what can be done with the \(\kappa\) and \(\Delta\) coefficients, or their generalisation the IBD pattern distribution, we remark that, together with the population alleles frequencies, they determine the joint distribution of the genotypes for any set of individuals; as a simple example, if \(a\), \(b\) and \(c\) are distinct alleles, with population frequencies \(q_a\), \(q_b\), \(q_c\), and in the absence of inbreeding, the probability that two individuals have genotypes \((a, b)\) and \((a, c)\), respectively, is simply \(\kappa_0(4q_a^2q_bq_c) + \kappa_1(q_aq_bq_c)\), when their relationship is summarised by \(\kappa = (\kappa_0, \kappa_1, \kappa_2)\). This can be verified directly algebraically with care, but in Section 3 we generalise this calculation and use it in modelling and analysing DNA mixtures.

### 2.2 IBD pattern distribution for a simple pedigree

As an illustration, consider a simple ‘triple’ of father F, mother M and child C, with the two parents unrelated. If we label the father’s genes by \((1, 2)\) and those of the mother by \((3, 4)\), then the child will have one gene that is either 1 or 2, and another gene that is 3 or 4; thus its genotype is \((1, 3)\), \((2, 3)\), \((1, 4)\) or \((2, 4)\) with equal probability. In tabular form, thus, we could write this family’s genetic structure at any single autosomal locus in a table as in panel (a) of Table 2, where we have labelled the columns with the individual identities, and the rows with the corresponding probabilities.

Note that without changing the meaning, we can arbitrarily permute the actual labels, separately in each row, so the first row of Table 2(a) could have been \((2, 4, 1, 3, 2, 1)\); the purpose of the labels is solely to indicate which genes are identical (by descent) and which different. Since a genotype is an unordered pair of genes, the interpretation of the table is also unchanged if any of the individual pairs are transposed, so the first row could equivalently be written \((2, 1, 4, 3, 1, 3)\), for example, and in many other ways. Combining these two rules, and aggregating the probabilities of identical rows, further economy of notation is possible: for example we could simply use the table in panel (b) of Table 2, to represent the same family, saving space and computer time. Effectively the labels 1 and 3 are then being used for the child’s paternal and maternal genes, respectively.

The example can be extended, by, for example, including also the Father’s father, GF. There are two equally likely possibilities: the gene inherited by Father from his father might be that labelled 1 or 2. So the relationships between the four individuals can now be represented by panel (c) of Table 2.

### 2.3 Pairwise relationships do not determine joint relationships

To demonstrate that pairwise relationships do not determine a full description of relatedness among more than two individuals, even in the absence of inbreeding, we present the simplest example. Consider two scenarios in which among three individuals, each pair are full cousins, that is have \((\kappa_0, \kappa_1, \kappa_2) = (0.75, 0.25, 0)\). This can arise in a ‘star’ arrangement, where the three have mothers who are full siblings, but unrelated fathers (or vice-versa, of course). In a ‘cyclic’ arrangement, each pair of cousins have between them parents of the opposite sex who are siblings, with the other parents unrelated. The two pedigrees are displayed in Figure 1.

The respective IBD pattern distributions are shown in Table 3 and visualised in Figure 2; the formats of each are described at the end of Section 2.1. It is very clear from these displays that these two families have
FIGURE 1 Pedigrees for the two 3-cousins scenarios: (left) star, (right) cyclic; one individual appears twice, to reduce line-crossing—the dotted curves link the replicate symbols

FIGURE 2 IBD pattern distributions for two scenarios of 3 pairwise cousins; (left) star, (right) cyclic arrangements, represented in the style introduced by Jacquard (1974) and described in the text. In each individual diagram, from top to bottom, the individuals are those labelled C1, C2 and C3, respectively, in Figure 1, and the corresponding probability is printed below the diagram. As an example, the final diagram in the right hand panel shows the case where each pair of C1, C2 and C3 have a gene identical by descent, which is represented by the IBD pattern (1, 2, 1, 3, 2, 3), which is how it is labelled in the final row of the right hand panel of Table 3, where it is assigned the same probability, 0.0156
different overall relatedness, for example in the star arrangement, there is probability 0.0625 that the three cousins have a common allele by IBD (as seen in the left-hand panels of Table 3 and Figure 2), while this is impossible in the cyclic arrangement. The fact that \((\kappa_0, \kappa_1, \kappa_2) = (0.75, 0.25, 0)\) for each pair of cousins, for both pedigrees, can be verified from the Table. Taking C1 and C2 for example, in none of the rows in either half of the table, are the labels for C1 and C1 both the same, so \(\kappa_2 = 0\). Meanwhile, the four labels are all distinct in rows 1, 3 and 4 in the left panel, and 1, 3, 4 and 7 in the right panel, so we can calculate \(\kappa_0\) as 0.3750 + 0.1875 + 0.1875 = 0.4219 + 0.1406 + 0.1406 + 0.0469 = 0.75.

We noted in Section 2.1 that pairwise relationships are not correctly quantified by coefficients of ancestry \(\theta\), so a fortiori neither are joint relationships between more than 2 individuals.

### 2.4 IBD pattern distribution in the Iulius–Claudius pedigree

As a demonstration that the IBD pattern distribution among a handful of individuals can be readily computed even when the pedigree describing their relationships consists of as many as 35 individuals, and inbreeding is present, we briefly consider the Iulius–Claudius dynasty. This was the first Roman imperial dynasty, consisting of the first five emperors—Augustus, Tiberius, Caligula, Claudius and Nero—and the family to which they belonged. They ruled the Roman Empire from its formation under Augustus in 27 BCE until 68 CE, when the last of the line, Nero, committed suicide. The name Iulius–Claudius dynasty refers to the two main branches of the imperial family: the gens Iulia and the gens Claudia. Figure 3 presents the Iulius–Claudius pedigree. Some of the names have been abbreviated.

As highlighted by the double horizontal bars in Figure 3, there are two inbred marriages within the pedigree, the first, between Germanicus and Agrippina Maior, leading to the other. The two emperors Caligula and Nero are descendants of this couple. We therefore look at the IBD pattern distribution among Germanicus, Agrippina Maior, Caligula and Nero, and also that between the three emperors Claudius, Caligula and Nero. Figure 4 shows excerpts (the most probable 9 patterns) of the IBD pattern distribution for these two subsets of individuals, respectively. As one can see from the figure, both Caligula and Nero share many alleles IBD. As an example of summarising a pairwise relationship, Germanicus and Agrippina Maior, parents of Caligula and of Nero’s mother, have probabilities of sharing none and one of their genes IBD equal to \(\kappa_0 = 0.9375\) and \(\kappa_1 = 0.0625\). The IBD pattern distribution, and coefficients like these extracted from it, very compactly yet exactly capture the very complex multi-generational story told by the pedigree.

**FIGURE 3** Iulius–Claudius family tree
Under our universal assumption that we are using unlinked autosomal markers, and all individuals are drawn from a population in Hardy–Weinberg equilibrium, it is clear that genotypes $n$ and peak heights $z$ are independent across markers. Then the distributions $p(n)$ and $p(z|n)$ are products over markers—and therefore so are likelihood ratios computed from them. We therefore consider each marker separately, and assume a single marker for the rest of this section. The likelihood for observed peak heights $z$ is of course regarded as a function of the parameters in the two model component distributions.

For the peak height model introduced and investigated by Cowell et al. (2015), $p(z|n)$ is defined as follows. As in Cowell et al. (2015), it is convenient both algebraically and computationally to represent genotypes $n$ by allele count arrays: $n_{ia} = 0, 1, 2$ being the number of allele $a$ in the genotype for individual $i$.

The peak heights $Z_a$ at allele $a$ are gamma distributed, conditional on $n$,

$$p(z_a|n) = g(z_a;\rho D_a(\phi, \xi, n), \eta),$$

independently for each $a$, where $g$ denotes the gamma density function, $\rho$ quantifies the total amount of DNA in the mixture before amplification, $\xi$ denotes the mean stutter proportion, $\eta$ the scale (not rate), $D_a(\phi, \xi, n) = (1 - \xi) \sum_i \phi_i n_{ia} + \xi \sum_i \phi_i n_{i,a+1}$ the effective allele counts taking into account the stutter artefact and $\phi = (\phi_i)_{i=1}^I$ denotes the proportion of DNA from individual $i$ in the mixture.
For given genotypes \( n \), given parameters \( \psi = (\rho, \xi, \eta, \phi) \), the conditional distribution for the peak heights \( z = (z_a)_{a=1}^A \) factorizes over alleles \( a \)

\[
p(z | n) = p(z | n; \psi) = \prod_a L_a(z_a) \tag{3}
\]

where

\[
L_a(z_a) = \begin{cases} 
g(z_a; \rho D_a(\phi, \xi, n), \eta) & \text{if } z_a > C \\
G(C; \rho D_a(\phi, \xi, n), \eta) & \text{otherwise,}
\end{cases}
\]

with \( G \) denoting the gamma distribution function and \( C \) the detection threshold.

For a given hypothesis \( H \) about the joint distribution \( p(n) \) of the genotypes of the \( I \) individuals, the full likelihood is obtained by summing over all possible combinations of genotypes to give

\[
p(z) = p(z; \psi) \text{ as in (1)}.
\]

Unless both the number of mixture contributors and the number of alleles are very small, computing the sum in (1) is a formidable task, often an intractable one. The key observation in Graversen and Lauritzen (2015), exploited in the DNAmixtures package, is that if genotypes \( n \) are encoded as allele count arrays \((n_{ia})\) giving the number of alleles of type \( a \) for individual \( i \), and the joint distribution \( p(n) \) factorised into conditional distributions sequentially over \( a \) for each \( i \), then \( p(n) \) has the structure of a BN with considerable sparsity.

Computation of \( \sum_n p(n)p(z | n) \), which is the expectation over the BN distribution for \( n \) of the function \( p(z | n) \), is then exactly the kind of task performed by a BN probability propagation algorithm (Lauritzen & Spiegelhalter, 1988). We follow the DNAmixtures formulation, including the allele count array representation of genotypes; for more computational detail see Graversen and Lauritzen (2015).

The IBD pattern distribution formulation helps to create methodology that considerably extends that described in Green and Mortera (2017). That paper introduced four approaches to adapting the BN computation in DNAmixtures to deal with paternity testing (where the putative father is a contributor to the mixture, and with or without the mother’s genotype profile being available in addition to the child’s). Three of these, additional likelihood node (ALN), replace probability tables (RPT) and meiosis Bayesian network (MBN) involve modifying the BN and are fast and essentially exact, the other, weighted likelihood ratio (WLR) is slow and approximate but easy to code.

It turns out that the RPT method is easiest to adapt to the case of relationships that are more complex or involve more contributors. This entails replacing the default genotype conditional probability tables (CPTs), representing independent multinomial draws from the gene pool, by tables that encode assumed relationships and condition on any observed genotypes. All genotypes are determined by the values of the draws from the gene pool and the meiosis pattern, so by including the gene pool draws and the meiosis pattern as nodes in the BN, the CPTs for the individual genotype arrays consist only of 0s and 1s; they are then easy to construct, and can be stored compactly and processed efficiently in some BN engines, including Hugin.

Rather than define this process formally in the cumbersome and unilluminating algebra needed for generality, here we work through an example in detail. We begin by giving a constructive definition of the joint distribution of a family’s genotypes, using the IBD pattern distribution describing the family; this is useful in its own right, but it could also be used explicitly in simulating cases for testing purposes, and it also helps to motivate how we can construct CPTs for allele count arrays.
The joint distribution of genotype profiles when contributors are related

Here we show how the IBD pattern distribution, together with the allele frequencies for each marker, determines the joint distribution of genotype profiles. For expository purposes only, we will give a constructive specification, as if it was intended to simulate profiles from the correct distribution. STR markers are at unlinked loci, so profiles at different markers are independent.

Consider first the four-individual family in Table 2(c), which shows two IBD patterns, with probabilities 1/2 each. For each marker, independently, we proceed in three stages:

1. Choose a pattern (row of the table) at random, with the indicated probability.
2. Draw alleles from the gene pool, according to the allele frequencies, independently for each distinct label in the pattern—in this case, there are five distinct labels, 1, 2, ..., 5 in each pattern, so we draw alleles $a_1, a_2, ..., a_5$.
3. Assign gene pool draws to form genotypes for the individuals using the labels—so here we set $F_{gt} = (a_1, a_2), M_{gt} = (a_3, a_4), C_{gt} = (a_1, a_3)$ and $GF_{gt} = (a_1, a_5)$ or $(a_2, a_5)$ for rows 1 and 2, respectively.

The general formulation should be clear from this example. Given the IBD pattern distribution, an allele will be drawn from the gene pool for each distinct label among the patterns, using the population allele frequencies for the marker in question. A pattern is drawn from the IBD pattern distribution, and the genes and hence genotypes for all individuals obtained by selecting the corresponding gene pool draws. The IBD pattern distribution applies equally for all markers, but the drawing of the alleles from the gene pool and of the IBD pattern will be independent for each marker. It is important to note that this procedure generates the genotypes for all the individuals of interest simultaneously, rather than sequentially from parents to child.

Pseudo-codes for this algorithm, viewed as a method for simulating genotypes for members of a family, and those of the next two sections are given in Supplementary information, Section 1, and all are implemented in open-source code in the KinMix package.

Computing CPTs for related contributors

The case where no individuals are genotyped, so we are simply modelling family relationships among some or all of the mixture contributors is very straightforward. As in the previous section, we use the IBD pattern distribution directly. Continuing the Table 2(c) example, with the four individuals labelled $i = 1, 2, 3, 4$, the nodes of the required BN represent $\{n_{ia}, i = 1, 2, 3, 4; a = 1, 2, ..., A\}, \{m_{ja}, j = 1, 2, 3, 4, 5; a = 1, 2, ..., A\}, \{T_{ja}, j = 1, 2, 3, 4, 5; a = 2, ..., A−1\}$, and $s$. Here $n_{ia} = 0, 1, 2$ is the number of alleles $a$ for individual $i$, $m_{ja} = 0, 1$ the numbers of $a$ for the $j$th draw from the gene pool, and the $T$ are cumulative sums of the $m$ (cumulative over $a$). Again, pseudo-code for this algorithm is given in Section 1 of the Supplementary information, following the same pattern as that of the previous section, but at each node, instead of generating an allele count, we compute its conditional distribution given its parents in the graph in the form of a table.

The typical structure of the BN representing this model when the gene pool draws and individual’s genotypes are represented by allele count arrays is shown for a small example in Figure 5; this corresponds to the situation in Table 2(c), but including just three of the four individuals in this family, the Grandfather, Mother and Child, here numbered 1, 2 and 3, respectively, and assuming just four
allelic values. Note that there are directed edges from $m_{ja}$ to $n_{ia}$ if and only if the pattern label $j$ appears among the IBD patterns for individual $i$. In general, the graph depends on the number of individuals in the family, the number of alleles and the IBD pattern distribution.

3.4 Conditioning on typed relatives

The case where some individuals in the family have been typed is a little more complicated; again similar reasoning applies to both simulation of genotypes, and computations of their CPTs.

Consider the four-individual family again, and suppose that the Father and Mother are mixture contributors, and the Child and Grandfather are typed, with genotypes $(a, b)$ and $(b, c)$, respectively, where $a$, $b$ and $c$ are distinct alleles.
Our construction is shown schematically in Table 4. Recalling that genotypes are unordered pairs of genes, we first expand the IBD pattern distribution table by explicitly laying out all possible permutations of the allele labels for the two typed individuals, giving equal probability to each; this is to expedite checking for matches for each label. Matching these four allele labels onto their observed values \(a, b, b, c\), respectively, allows us to map allele labels onto actual allele values, for each of the permuted patterns. It also reveals that some permuted patterns cannot generate the observed alleles. For example the first row is impossible, given the observed genotypes, since the allele label 1 cannot simultaneously map onto the distinct alleles \(a\) and \(b\), while the second row is possible, with the mapping 1\(\mapsto b\), 3\(\mapsto a\) and 5\(\mapsto c\). These mappings already determine some of the alleles of the Father and Mother, the mixture contributors. Those that are still not fixed are distinguished by underlining in bold in Table 4. A column, headed \(p(Cgt,GFgt)\), has been added to the table giving for each permuted pattern the probability of the typed individuals having the observed values. The final columns for the table summarise what is now known about the Father’s and Mothers’ genotypes for each permuted pattern, with \(?\) denoting a draw from the gene pool. (In this example, all such draws are independent, since there is no duplication in allele labels for the Father and Mother.)

We now have all the information needed either to simulate Father and Mother genotypes, or to construct a BN for the genotype allele count arrays of the Father and Mother, in each case conditional on the genotypes of the Child and Grandfather. The BN ‘parents’ for each count node consist of one node indexing the permuted pattern, together with nodes indicating the values of the draws from the gene pool required. The probability distribution over the permuted pattern node is modified from the ‘prior’ (uniform) distribution by being conditioned on the typed genotypes, that is, it consists of the values of \(p(Cgt,GFgt)\) (see Table 4 in the case of our worked example), renormalised to sum to 1.

It might be useful to point out that the approach we take to computing conditional genotype probabilities (as a crucial step on the way to delivering likelihood ratios) avoids any manual algebra, which is straightforward in simple cases but can be tedious and error-prone otherwise. Of course, it obtains the same answer. To see this, consider the familiar example of paternity testing given both mother's and child's genotypes. For the case where these two genotypes are \((a, b)\) and \((b, c)\), respectively, where again \(a, b, c\) are all different, see Table 5, which is in exactly the same format as Table 4. Simple algebra tells us that the Father must donate the \(c\) allele to his child, and that his other allele is drawn from the gene pool, and this is exactly the answer that Table 5 provides.
4 | COANCESTRY AND UNCERTAIN ALLELE FREQUENCIES

We have so far focused on the role in modelling DNA mixtures of close relationships, specified through family structures. In this section, we will briefly touch on the different situation of coancestry, or what we could call ambient relatedness, where purportedly unrelated actors in fact have dependent genotypes because the population from which they are drawn exhibits high relatedness, for example through inbreeding. Just as with close relationships, these dependencies are driven by identity by descent, but the impact is somewhat different, because it applies generally to the whole population, and the dependence is usually substantially lower in magnitude.

In model-based inference from DNA profiles of STR markers, it has become routine to apply the ‘θ correction’ of Balding and Nichols (1994). The scalar parameter θ, the kinship coefficient or coefficient of ancestry, can be identified with Wright’s measure of interpopulation variation $F_{ST}$ (Wright, 1940, 1951; ), and informally interpreted as the ‘proportion of alleles that share a common ancestor in the same subpopulation’. As discussed by Balding and Nichols (1994), the parameter θ arises in various models for dependent populations, for example the ‘island model’ of partially separated subpopulations. That θ does not determine coefficients of identity was noted in Section 2.1.

Green and Mortera (2009) observed that exactly the same probabilistic model for the joint distribution of multiple genes arises in a simple model for uncertainty in allele frequencies (UAF), in which the true allele frequencies are treated as unknowns with a Dirichlet distribution and the database used for calculation regarded as a multinomial sample from these true frequencies. The parameter $\alpha = (1-\theta)/\theta$ is then the effective size of the database. Green and Mortera (2009) also observed that this model is amenable to implementation as a BN, as an alternative to algebraic specification; this BN actually encodes a Pólya urn scheme.

4.1 | Ambient relatedness for allele count arrays

In discussion of Cowell et al. (2015), both Tvedebrink (modelling kinship) and Green (modelling uncertainty in allele frequencies) observe that when genotypes are represented by allele counts arrays $n_{ia}$, the number of alleles $a$ of individual $i$, this Pólya urn scheme can be expressed through the recursion

$$n_i \sim \text{DM}(2, (\alpha_{a_{\text{ave}1}})^A)$$

$$n_i | (n_j)_{j=1}^{i-1} \sim \text{DM}(2, (\alpha_a + n_{<,ia})_{a=1}^A)$$

where $n_{<,ia} = \sum_{j=1}^{i-1} n_{ja}$ (etc.), and DM denotes the Dirichlet–Multinomial distribution. See Green (2015); Tvedebrink (2010). The Dirichlet-multinomial distribution is the straightforward generalisation...
of the Beta-binomial to more than two categories. It is a Dirichlet mixture of multinomial distributions. 

\[ X \sim DM(n, (\alpha_a)_{a=1}^A) \]

means

\[ P(X = x) = \left\{ \frac{n!}{\prod_a x_a!} \right\} \times \left\{ \prod_a \frac{\Gamma(\alpha_a + x_a)}{\Gamma(\alpha_a)} \right\} \times \frac{\Gamma(\sum_a \alpha_a)}{\Gamma(\sum_a \alpha_a + n)}, \]

so long as \( \sum_a x_a = n \).

Factorising the conditional distributions in (4) over alleles, we find that individual allele counts have Beta-binomial conditional distributions:

\[ n_{ia} \mid (n_{ja})_{j=1}^{j-1}, \{n_{ib}, b < a\} \sim BB((2 - n_{i,a}), (\alpha_a + n_{<i,a}), (\alpha_a + n_{<i,a})). \]

The Beta-binomial distribution: \( X \sim BB(n, \alpha, \beta) \) means

\[ p(X = x) = \binom{n}{x} \frac{\Gamma(\alpha + x)\Gamma(\beta + n - x)\Gamma(\alpha + \beta)}{\Gamma(\alpha)\Gamma(\beta)\Gamma(\alpha + \beta + n)}. \]

Note that BB(1, \( \alpha \), \( \beta \)) is just Bernoulli (\( \alpha/(\alpha+\beta) \)).

The KinMix package includes functions for modifying genotype CPTs to model UAF and ambient IBD.

Tvedebrink et al. (2015) give a fuller analysis, including a quantitative study of the implications. They show that relatedness/uncertainty in allele frequencies can increase or decrease LR’s in identification tasks. Section 3 of the Supplementary information provides a list of software that handles DNA mixtures in the presence of coancestry.

### 4.2 Coancestry and relationships together

Particular casework may involve both close relationships and ambient relatedness (or uncertainty in allele frequencies). Modelling such a situation combines elements from Sections 3.3 and 4.1. Full details are omitted, but the key algebraic manipulations are given in Supplementary information, Section 2. The algorithmic implications are that binomial distributions in algorithms would be replaced by Beta-binomials, with the meiosis pattern as an additional parent at each instance of the Pólya urn. See also Cowell (2016) for a different analysis of this combined model.

At present, simultaneous modelling of close relationships and coancestry/uncertainty in allele frequencies is not implemented in the KinMix package. Previous work with allele-presence data only (Green & Mortera, 2009) and the work of Tvedebrink et al. (2015) show that the numerical difference in log likelihood ratios due to coancestry is rarely important in scientific terms.

### 5 Setting parameters

The methodology of this article is based on the joint probability model \( p(n,z) = p(n)p(z|n) \) for the genotype profiles and peak heights, and this distribution has a number of parameters, notably the population allele frequencies, the relative proportions of the contributions of the different contributors.
to the mixture, and the parameters describing the PCR process and the artefacts of measurement embedded in the Cowell et al. (2015) peak height model. We do not prescribe any particular approach to setting these parameters when evaluating the likelihood, as this choice must be strongly influenced by regulation and practice in the judicial regime in which the analysis of the mixture is to be used, and the particular question that is being addressed.

Although Bayesian networks are a key concept in the computations we use, this does not mean that a Bayesian formalism is intended. In fact the Cowell et al. (2015) model is presented as entirely frequentist, with the BN computations simply a device to compute an otherwise intractable likelihood function. The DNAmixtures package includes a function for maximising the likelihood as a function of the model parameters (the relative proportions of the contributions of the different contributors to the mixture, and the parameters describing the PCR process and the artefacts of measurement), and that function applies equally to a model modified using KinMix.

In principle a Bayesian analysis could be conducted, and the fast calculations of the likelihood that the packages provide would be an asset in implementing a Markov chain Monte Carlo (MCMC) sampler for posterior simulation, but we have not attempted this.

Considering now only maximum likelihood estimation (MLE), when we are comparing alternative models for mixtures, the question arises under which model(s) should the likelihood be maximised? The answer depends on context and perspective. In a likelihood ratio test of $H_p$ against $H_0$, the respective likelihoods would each be maximised separately, and the ratio of the maximised values used as the test statistic. However, here the $\log_{10}$ LR measures the weight of the evidence, and we are not appealing to statistical testing theory. In a criminal trial, depending on jurisdiction, custom might suggest or dictate choosing parameter values for both numerator and denominator that minimise the ratio, or perhaps maximise the denominator, in line with the presumption of innocence of the defendant (in dubio pro reo). In a civil case, say a paternity suit, the notion of defendant hardly applies.

Our experience has been that in many contexts, choice between these approaches makes little difference to the values of likelihood ratios, or their interpretations; we give a numerical example of this below. However, this cannot be a general conclusion; we anticipate, for example, that in comparing alternative hypotheses about the relatedness of mixture contributors to each other, parameter choice could have more impact.

Our numerical illustration revisits the Italian singer case, used for motivation in Green and Mortera (2017) (sections 4 and 5). This is a case of paternity testing, where the putative father is represented in the evidence only as a contributor to a mixture, assumed to be of 2 contributors, denoted $U_1$ and $U_2$; this is because the claim of paternity only arose some years after the putative father’s death and the remains available had been corrupted. The child’s genotype Cgt is available, and we presented weights of evidence for paternity, with and without using also the mother’s genotype Mgt. The hypotheses are $H_p$ that the major contributor to the mixture is the father, against $H_0$, that neither contributor to the mixture is related to the child (or mother).

Table 6 illustrates that under either $H_0$ or $H_p$ the MLEs ($\hat{\psi}_0$, $\hat{\psi}_p$, respectively) of the parameters $\psi = (\rho, \eta, \xi, \phi_{U1}, \phi_{U2})$ do not vary substantially, as mentioned above. Table 7 gives the likelihood ratios in favour of paternity without and with information on Cgt’s mother’s genotype Mgt: (a) when using the MLEs computed under $H_0$ in both numerator and denominator of the LR (columns 2 and 3) and (b) when using the MLEs computed separately under $H_p$ and $H_0$ (columns 4 and 5). Adopting (a) or (b) makes only immaterial differences to the LRs (less than 2%), in the context where the LR in favour of paternity is already more than 250,000, and including also the information about the mother’s genotype increases this at least 500-fold.
The modelling and methods introduced in this paper form the basis for an R package KinMix (Green, 2020a) that extends the package DNAmixtures (Graversen, 2013). As with DNAmixtures, therefore, the package relies on the Hugin system for probabilistic expert systems, accessed via the R package. The model for peak heights given genotypes $p(z|n)$, together with the treatment of artefacts such as drop-out and stutter, are exactly as in Cowell et al. (2015). The KinMix package provides functions for constructing IBD pattern distributions from pedigree information, and using these pattern distributions to modify the default DNAmixtures genotype profile distribution $p(n)$ (in which untyped individuals are assumed unrelated draws from a specified gene pool), to allow for related contributors. KinMix also provides facilities from simulating genotype profiles from groups of individuals with specified joint relationships, making graphical displays of joint relationships, and many other utilities. In addition to the package manual pages in standard R format, a tutorial user guide is available as Green (2020b).

KinMix inherits from DNAmixtures the representation of genotypes via allele count arrays, which is important in saving both computation time and computer memory, and allows the modelling of mixtures with as many as five or six untyped individuals, depending on the details of the case, especially the numbers of alleles, and on the memory available. Although building in relationships between individuals does increase both time and space requirements, examples in this paper demonstrate that quite complex problems can be considered. Under standard assumptions, once parameters are fixed, likelihoods and likelihood ratios in our mixture models factorise over markers. Furthermore, in the case of related contributors, logarithms of likelihoods and likelihood ratios are weighted averages of those obtained from the individual IBD patterns. The weights are the probabilities of the patterns, the posterior probabilities in the case where some of the relatives have been typed. An option in KinMix allows exploiting these facts, with the effect of considerably reducing the storage requirements when many markers are involved, since separate BNs are used for each marker/IBD pattern combination.

**TABLE 6** Maximum likelihood estimates in the Italian singer paternity case; the parameters are those in the Cowell et al. (2015) peak height model

| MLEs                  | $\rho$ | $\eta$ | $\xi$     | $\phi_{U1}$ | $\phi_{U2}$ |
|-----------------------|--------|--------|-----------|--------------|-------------|
| $H_0$ — baseline      | 0.718  | 1124   | 0.006643  | 0.9783       | 0.02166     |
| $H_p$ with Cgt known  | 0.745  | 1083   | 0.006527  | 0.9797       | 0.02034     |
| $H_p$ with Cgt & Mgt known | 0.745  | 1083   | 0.006526  | 0.9797       | 0.02035     |

**TABLE 7** Likelihood ratios and their logarithms, in the Italian singer paternity case

| Likelihood ratios | $\psi_p = \psi_{\theta} = \psi_{\theta}(z)$ | $\psi_p = \psi_{\theta}$, $\psi_{\theta} = \psi_{\theta}$ |
|-------------------|----------------------------------|----------------------------------|

| With Cgt          | 266,100 | 5.425 | 270,100 | 5.432 |
| With Cgt & Mgt known | $143.5 \times 10^6$ | 8.157 | $145.7 \times 10^6$ | 8.163 |

6  | SOFTWARE: THE KINMIX PACKAGE
7 | SIMULATIONS

In this section, we examine the performance of log_{10}-likelihoods, based on the Cowell et al. (2015) model, at discriminating between different joint relationships, in a study using simulated electropherogram (EPG) and genotype data. Each simulated data set consists of genotype profiles generated from a prescribed ‘True’ model, using the generative model in Section 3.2; from each we generate artificial EPG data using the pcrsim (Hansson, 2017) package, which simulates the DNA amplification process. These PCR simulations were based on using the AmpFℓ STR™ SGM Plus™ PCR Amplification Kit, with the Norwegian SGM database, on 10 STR markers, together with Amelogenin, all available in pcrsim. The numbers of cells amplified varied from 200 to 251.

The resulting data are analysed using KinMix (Green, 2020a), under a variety of assumed models. In each case, we compute the log likelihood ratio against a baseline model that assumes the same number of unrelated contributors. In all examples, the focus of interest is on the log_{10} LR from the peak height data given the stated available genotypes, that is, on the additional information about the question of interest attributable to the mixture data. These ratios are tabulated or graphed for a small number of replicates of the PCR process, for each of a small number of independently generated genotype profiles, thus giving an idea of the variation attributable to these two sources. Parameters for the DNAmixtures peak height model are estimated by maximum likelihood using that package, assuming the appropriate number of unrelated contributors, estimated separately on each simulated EPG.

Each analysis in the following experiments involves specifying the true joint relationship between the actors involved, the hypothesised relationship(s), which of the actors contribute to the mixture, and which if any of the actors are genotyped.

7.1 | Study 1: Two-way relationships

In this experiment, we study DNA mixtures with two contributors, and no other typed actors. We consider five possible familial relationships between the two contributors; for each relationship, we simulate EPG data and fit mixture models hypothesising each of the five relationships in turn. In Table 8, we report the median log_{10} LR for each of the hypothesised models, over four replicated EPGs for each of four replicated genotypes. In each case, the EPG data are simulated with 150 cells from the major contributor and 50 from the minor one.

The variation in these log_{10} LRs across replicate genotype profiles and EPGs is depicted in Figure 6. The rows of the figure correspond to the true relationships, and the columns to the four replicate genotype profiles. Within each panel we see a colour-coded diagram showing the variation in log_{10} LR over the four EPG replicates. The log_{10} LRs when parent–child is hypothesised are suppressed from the Figure as they take extreme values, as can be seen in the parent–child column of Table 8.

The highest median log_{10} LRs are all found down the diagonal, so that if we select a model on the basis of the largest, then on average, we correctly identify the true model in all five cases. This is most pronounced when the true model is parent–child, a pattern that is perhaps to be expected given the κ coefficients, also tabulated in Table 8. Some of the other relationships are harder to distinguish. Also, recall that many relationships, like half-sibs, aunt/uncle, grandparent, etc., have identical IBD pattern.

---

1Other PCR parameters were as defined by the pcrsim command simPCR(data=res, pcr.prob=1, pcr.cyc=28, vol.aliq=20, vol.pcr=50, sd.vol.pcr=1).

2These are independent identically distributed repeats of the PCR simulation, not replicates in the sense of DNA replication.
distributions and $\kappa$ coefficients. Perhaps a more meaningful interpretation is that on an individual-replicate basis, for the five true relationships, in 11, 11, 9, 4 and 12 out of the 16 = 4 × 4 replicates, respectively, the correct model was identified.

When there is additional information, such as the genotypes of individuals potentially related to mixture contributors the evidence becomes much stronger, as we will see in some of the following examples.

### 7.2 Study 2: Three-way relationships

This experiment is exactly similar to the previous one, except now we consider relationships between three related contributors. The five considered relationships are, respectively, trio (mother, father and child); a mother and two children; three sibs; three-cousins-cyclic, three-cousins-star; the last two are defined and illustrated in Section 2.3. Again, there are no typed actors. In each case the EPG data are simulated with 100, 50 and 25 cells from the three contributors.

Table 9 gives the median $\log_{10}$ LR relative to the baseline (three unrelated contributors) for comparing each combination of true and hypothesised relationship model, over four replicated genotypes by four replicated EPGs. The highest median $\log_{10}$ LRs are again all found down the diagonal, implying that each of the five relationships are correctly identified on average. This effect is strongest when the relationships are mother and two children, or three sibs. In these two scenarios, the three contributors all have a close pairwise relationship, whereas in the trio, the mother and father are unrelated. Also, the three cousins scenarios have more distant relationships among each other, and of course have identical pairwise relationships, so are harder to distinguish. These factors explain the asymmetry in the table. On a per-replicate basis, for the five true relationships, in, respectively, 12, 7, 12, 14 and 11 out of the 16 = 4 × 4 replicates, the correct model was identified.

Figure 7 shows the variation in $\log_{10}$ LRs within the genotypes and across the four replicated EPGs in each row panel for five different three-way relationships. As in the previous section, each row corresponds to a true relationship, and the four panels to the genotype profile replicates.

### 7.3 Study 3: Three-way relationships, with a relation genotyped

Here we consider four brothers, and DNA mixtures simulated from a true model in which three of the brothers are contributors. We consider testing $H_p$: three brothers contributed to the mixture versus $H_0$: the three contributors are unrelated, and drawn from the gene pool. We perform this test with
and without the assumption that the fourth brother is genotyped, yielding genotype Bgt, and as usual we generate four replicate joint genotype profiles, and four replicate EPGs for each. In each case the EPG data are simulated with 200, 100 and 50 cells from the three brothers contributing to the mixture; the same EPGs are used for the analyses without and with the fourth brother’s genotype.

This kind of case can arise when brothers are engaged in a joint criminal activity and DNA might be found on, for example a get-away car, balaklava, banknote, crowbar, or gun.

The $\log_{10}$ LR results when parent–child is hypothesised are suppressed from the Figure as they take extreme values, as can be seen in the parent–child column of Table 8.

**FIGURE 6** Study 1: Variation in the $\log_{10}$ LRs across replicate genotype profiles and EPGs for the two-way example. The rows of the figure correspond to the true relationships, and the columns to the four replicate genotype profiles. Within each panel $\log_{10}$ LR is plotted against hypothesised relationship (from left to right: sibs (S), half-sibs (HS), cousins (C) and half-cousins (HC), respectively). Lines join values corresponding to the same EPG replicate. The $\log_{10}$ LRs when parent–child is hypothesised are suppressed from the Figure as they take extreme values, as can be seen in the parent–child column of Table 8.
TABLE 9  Study 2: Median log$_{10}$ LR over four replicated genotypes by four replicated EPGs in simulations of a DNA mixture for each three-way relationship

| True                  | Hypothesised                  | Trio     | Mother, 2 kids | 3 sibs   | 3-cousins-cyclic | 3-cousins-star |
|-----------------------|-------------------------------|----------|----------------|----------|------------------|----------------|

| 3-cousins-star        |                               | −20.741  | −20.325        | −5.740   | 0.502            | 0.540          |

FIGURE 7  Study 2: Variation in the log$_{10}$ LRs across replicate genotype profiles and EPGs for the three-way example. The rows of the figure correspond to the true relationships, and the columns to the four replicate genotype profiles. Within each panel log$_{10}$ LR is plotted against hypothesised relationship (from left to right: trio, mother and two children (M2C), 3 sibs (3S), 3-cousins-cyclic (3Cc), 3-cousins-star (3Cs), respectively). Lines join values corresponding to the same EPG replicate. All values are truncated below at −40 before plotting.
Study 4: Incestuous sibs

Our remaining examples consider incestuous relationships in two person DNA mixtures of unknown or partly known contributors, in cases of possibly incestuous relationships. This section concerns incest between sibs.

The setup we consider is of a father/mother/child trio, and a mixture where the contributors are the mother and child. Cases like this occur when a mother-foetus mixture is found and we wish to test the paternity. The hypotheses entertained are $H_p$: the father and mother are siblings, as in the pedigree in Figure 9(a) and $H_0$: the father and mother are unrelated. The EPG data are simulated under $H_p$ in this experiment, and with 200 cells from the mother and 100 from the child.

Table 11 shows the IBD pattern distribution of the three genotypes under $H_p$.

The results for testing whether there was incest or not are shown in Table 12 and Figure 10, the table giving medians over the replicates, the figure showing the variation across 4×4 replicates. In this example, there is very little variation across EPGs with genotype profiles.

Some of the dependency visible here on which actors are genotyped may seem counter-intuitive. For example, why does typing both Father and Child give apparently less clear evidence of incest than typing either one of Father and Child or neither separately, and indeed in some replicates give evidence against incest? Recall from the beginning of Section 7 that in all of our simulation studies, the focus of interest is on the $\log_{10}$ LR from the peak height data given the stated available genotypes. Taking the peak height data and genotype data together (not shown here), as expected, removes the apparent paradox.
FIGURE 9  Studies 4 and 5: Pedigrees for ((a), left) incestuous sibs; ((b), right) father–child incest

TABLE 11  Study 4: IBD pattern distribution for the incestuous case where the father F of the child C is the brother of the mother M

| \(p_r\) | F | M | C |
|---|---|---|---|
| 0.125 | 1 | 2 | 1 |
| 0.125 | 1 | 2 | 2 |
| 0.125 | 1 | 2 | 1 |
| 0.125 | 1 | 2 | 3 |
| 0.125 | 1 | 2 | 3 |
| 0.25 | 2 | 3 | 1 |

TABLE 12  Study 4: \(\log_{10}\) LR for testing whether there was incest or not, medians over 4 × 4 replicate data sets

| Typed actors | F & C | F | M | C | none |
|---|---|---|---|---|---|
| Median \(\log_{10}\) LR | 1.030 | 2.718 | 1.233 | 0.076 | 1.318 |

FIGURE 10  Study 4: \(\log_{10}\) LRs for the incestuous sibs example. The panels represent the replicated genotype profiles. In each panel, variation in \(\log_{10}\) LRs is shown across replicated EPGs, colour-coded by which actors are genotyped: dark red, red, green, orange and purple for F and C, F, M, C and none, respectively
A more careful study of the conditional dependencies in this example reveals that the peak heights convey no information about incest if the Mother and one or other or both of the Father and Child are typed.

7.5 | Study 5: Incest and rape

Here we consider the horrendous scenario where a child has been raped, and we have a mixed trace from her vagina. The suspected culprit is her maternal grandfather, and additionally, there is some suspicion that the grandfather is also her father, that is, that she is the offspring of an incestuous relationship between her mother and maternal grandfather. We assume the child is the major contributor to the mixture, and that there is one other contributor. The pedigree for the case of incest is shown in Figure 9(b), and this pedigree is assumed in simulating our EPG data for this study. The EPG data are simulated with 200 cells from the child and 100 from the rapist. In all cases we do not question that M is the mother of C, and that GF is the father of M. Table 13 shows the IBD pattern distribution of the three genotypes for an incestuous family where the maternal grandfather GF of a child C is the father of the mother M.

We consider various possibilities for which actors are separately genotyped: either both M and C, M only, C only, none. As before, our experiments for the above scenarios are based on four replicated genotypes by four replicated EPGs.

For brevity, in describing this study, we will use the term rape to mean that the GF is the second contributor to the mixture, and incest to mean that GF is father of C. We wish to examine whether it is possible from the DNA mixture and any typed genotypes to distinguish the possibilities of incest and/or rape. Table 14 reports the log10 LRs for each of (i) rape assuming incest, (ii) incest assuming

| Table 13 | Study 5: IBD pattern distribution for the incestuous case where the grandfather GF of a child C is the father of the mother M |
|---|---|---|---|---|

| 0.25 | 1 | 2 | 1 | 3 | 1 | 1 |
| 0.25 | 1 | 2 | 1 | 3 | 1 | 2 |
| 0.25 | 1 | 2 | 1 | 3 | 1 | 3 |
| 0.25 | 1 | 2 | 1 | 3 | 2 | 3 |

| Table 14 | Study 5: log10 LRs for the tests (i)-(iv) over four replicated genotypes by four replicated EPGs with the set of typed actors given in (b) |
|---|---|---|---|---|---|---|---|
| Scenarios | | Both M and C | M | C | None |
| Rape assuming incest | | 25.145 | 7.713 | 20.403 | 3.679 |
| Incest assuming rape | | 2.916 | 4.608 | 1.721 | 2.506 |
| Rape assuming no incest | | 21.404 | 3.111 | 18.682 | 2.002 |
| Incest assuming no rape | | 0 | 0.574 | 0 | 0.787 |
Figura 11 Study 5: Variation in the log_{10} LR across replicate genotype profiles and EPGs for the incest and rape example. The rows of the figure correspond to the various tests, and the columns to the four replicate genotype profiles. Within each panel log_{10} LR is plotted against which actors are genotyped (colour-coded: red, red, green, and orange for mother and child, mother alone, child alone, or no one, respectively). Lines join values corresponding to the same EPG replicate.

rape, (iii) rape assuming no incest and (iv) incest assuming no rape. Figure 11 shows the variation in the log_{10} LRs by replicate.

Note that for the test of incest assuming no rape, when the child’s genotype is known, a conditional independence argument confirms that the log_{10} LR is identically 0.

We can see that there tends to be a stronger signal for rape than for incest, and also that when we have the additional information on the child’s genotype the log_{10} LR becomes much larger. Having only the mother’s genotype does not make a substantial difference.
8  |  REAL CASE APPLICATIONS

8.1  |  Case 1: Identification of a missing person

Here we analyse a real case related to a missing male, provided by the DNA Laboratory, Comisaría General de Policía Científica of Madrid. We refer to Green et al. (2021) for details of the case analysis. Here we will revisit some of the results, and also compare them with an analysis made with different software. The full anonymised data together with the R scripts to compute the results are given in the webpage\(^3\). The data are anonymised to avoid serious privacy and confidentiality concerns.

In this case, only a daughter of the missing male was available to donate a DNA sample. A biological sample was collected from a toothbrush, presumably used by the missing person. DNA was recovered and analysed on 21 STR markers, plus three sex-related markers, included in GlobalFiler\(^{\text{TM}}\) PCR amplification kit (ThermoFisher). The reference sample from the daughter of the missing male was also genotyped with the same kit. A two-person DNA mixture was detected on the toothbrush. We denote the two distinct unknown contributors by \(U_1\) for the major contributor and \(U_2\) for the minor. An excerpt of the data is shown in Table 15, showing the alleles and peak heights in the DNA mixture found on the toothbrush \(T\). The DNA profile of the daughter, denoted by \(D\), is also shown. The sex-related markers (not shown) indicated that the mixture was most probably from a male and a female donor.

Here we analyse the DNA mixture found on the toothbrush \(T\) presumably used by the missing person. We assume known allele frequencies and adopt a threshold of 50 rfu (relative fluorescent units).

In the preliminary analysis of the data, we found that the estimated proportion of DNA for the major contributor \(U_1\), \(\phi_{U_1} = 0.93\) is large. We also computed the \(\log_{10} LR\) for testing \(H_p\): \(D\) is the child of \(U_1\) (and similarly for \(U_2\)) versus \(H_0\): \(U_1\) and \(U_2\) are assumed drawn at random from the gene pool. The \(\log_{10} LR = 10.97\) is large, pointing to \(U_1\) being a parent of \(D\) but it is also substantial, \(\log_{10} LR = 4.53\), for the hypothesis that the minor contributor \(U_2\) is a parent of \(D\). We then questioned whether \(U_1\) and \(U_2\) were possibly related. The negative \(\log_{10} LRs\) for comparing \(H_p\): \(U_1\) has the relationship to \(U_2\), versus \(H_0\): \(U_1\) and \(U_2\) are unrelated, given in Table 16, show that they are most likely to be unrelated and thus are likely to be the parents of \(D\) or close relatives thereof. Furthermore, the likelihood that \(D\) was one of the contributors is practically zero.

\begin{table}[h]
\centering
\caption{Case 1: An excerpt of the anonymised data from the toothbrush \(T\), showing the markers, alleles and relative peak heights together with the daughter's genotype \(D\)}

\end{tabular}
\end{table}

\(^3\)https://petergreenweb.wordpress.com/example-1-data-code-and-output/
We now examine the joint relationships between the mixture contributors and the typed daughter D, which clarifies the role of D in validating the mixture profile. Table 17 shows the $\log_{10} LR$ for item $T$ for several hypotheses $H_p$ concerning different relationships among $U_1$, $U_2$ and D, versus the null hypothesis that these individuals are all unrelated. The values of the $\log_{10} LR$ show that there is strong evidence that the two contributors to item $T$ are the missing father of D and D’s mother, or at least very close relatives of them. Comparing the first 4 rows of Table 17 confirms that the most likely single possibility is that they are indeed the mother and father. All values in the Table remain unchanged if the sexes of all contributors are reversed; we choose to identify them in the way shown because inference (not shown) also including the Amelogenin locus indicates that is is most likely that the major contributor $U_1$ is female.

If there is interest in comparing two of the models displayed in Table 17, the appropriate $\log_{10} LR$ is simply obtained by calculating the difference between the values shown. For example, comparing the first row and the fifth, $17.935-10.974=6.961$ gives the weight of evidence that $U_2$ is the father of D, given that it is already assumed that $U_1$ is the mother of D. There are too many different such comparisons that can be made to list them all here.

Some of the specific relationships examined in Table 17 are speculative, but might be of interest in cases where a home is shared by an extended family.

**Table 16**  
Case 1: The $\log_{10} LR$ for $H_p$: the two contributors to the mixture are related as specified versus $H_0$: the two contributors are unrelated

| Relationship between $U_1$ and $U_2$ under $H_p$ | $\log_{10} LR$ |
|-------------------------------------------------|---------------|
| Monozygotic twins                                | $-\infty$     |
| Parent-child                                     | $-\infty$     |
| Sibs                                            | $-2.14$       |
| Double first cousins                             | $-0.51$       |
| Half-sibs                                        | $-0.37$       |
| First cousins                                    | $-0.10$       |
| Half-cousins                                     | $-0.034$      |

**Table 17**  
Case 1: For item $T$, $\log_{10} LR$ for several hypotheses $H_p$ concerning different relationships among $U_1$, $U_2$ and D, versus $H_0$: $U_1$, $U_2$ and D are all unrelated. The results in the lower half of the table can be used as baselines for comparison for those in the upper half. All $\log_{10} LR$ remain unchanged if the sexes of $U_1$ and $U_2$ are switched

| $H_p$                                      | $\log_{10} LR$ |
|--------------------------------------------|---------------|
| $U_1$ mother of D and $U_2$ father of D    | 17.935        |
| $U_1$ maternal aunt of D and $U_2$ father of D | 14.028        |
| $U_1$ mother of D and $U_2$ paternal uncle of D | 15.579        |
| $U_1$ maternal aunt of D and $U_2$ paternal uncle of D | 11.763       |
| $U_1$ mother of D and $U_2$ unrelated      | 10.974        |
| $U_1$ maternal aunt of D and $U_2$ unrelated | 7.452         |
| $U_1$ unrelated and $U_2$ father of D      | 4.530         |
| $U_1$ unrelated and $U_2$ paternal uncle of D | 2.796        |
8.1.1 | Case 1, comparison with relMix

The R package relMix (Hernandis et al., 2019) also analyses DNA mixtures involving relatives, but is based only on allele presence, not considering the peak heights when modelling the DNA mixture as does KinMix. Based on the toothbrush sample, here we draw a comparison between results when using KinMix with and without the peak height data, and using relMix.

Table 18 presents a marker-wise comparison between the likelihood LR and the overall $\log_{10}$ LR, for comparing $H_p; U_1$ is the father of D versus $H_0; U_1$ and $U_2$ are assumed drawn at random from the gene pool. Note that on comparing columns 2 and 3 to column 4 in Table 18, for only 2 markers out of 20 does using the peak heights yield a smaller $\log_{10}$ LR than using allele-presence data alone. The results obtained with relMix and KinMix when not including the peak height information are quite similar, although based on quite different models.

| Marker | relMix | KinMix w/o peak heights | KinMix with peak heights |
|--------|--------|--------------------------|--------------------------|
| 1      | 3.02   | 3.11                     | 4.84                     |
| 2      | 7.18   | 7.77                     | 10.92                    |
| 3      | 9.23   | 9.81                     | 12.89                    |
| 4      | 3.54   | 3.61                     | 3.72                     |
| 5      | 4.75   | 4.93                     | 5.16                     |
| 6      | 2.55   | 2.58                     | 3.34                     |
| 7      | 1.08   | 1.07                     | 1.59                     |
| 8      | NaN    | 5.53                     | 5.07                     |
| 9      | 1.26   | 1.18                     | 1.62                     |
| 10     | NaN    | 2.34                     | 2.15                     |
| 11     | 6.30   | 6.35                     | 10.92                    |
| 12     | 1.71   | 1.71                     | 1.99                     |
| 13     | 2.25   | 2.26                     | 2.27                     |
| 14     | 2.09   | 2.12                     | 1.51                     |
| 15     | 2.39   | 2.46                     | 2.54                     |
| 16     | 5.02   | 5.24                     | 6.17                     |
| 17     | 1.89   | 1.74                     | 2.39                     |
| 18     | 3.48   | 3.52                     | 6.77                     |
| 19     | 3.01   | 3.11                     | 3.30                     |
| 20     | 1.60   | 1.49                     | 1.23                     |
| Partial $\log_{10}$ LR | 8.35 | 8.42 | 9.94 |
| Computation times (s) | 1314 | 2.30 | 2.32 |
| Overall $\log_{10}$ LR | 9.53 | 10.97 |
| Computation times (s) | 3.02 | 3.09 |
We found that relMix was not able to compute the LR for markers 8 and 10; these are the markers for which there are more than 16 different alleles in the allele frequency database. We indicate this in Table 18 by NaN. When using only those markers that relMix is able to compute, the partial $\log_{10}$ LR obtained with KinMix with peak height information, is 9.94, is substantially bigger than that obtained without peak height information (8.35 with relMix, 8.42 with KinMix).

Using KinMix on all the markers, the overall $\log_{10}$ LR is 10.97 with peak heights, compared with the result 9.53 when not using the peak height information, a LR 27.5 times smaller.

The time to do the computations with relMix is considerably longer; it takes 1,314 s (22 min) compared to 2.30 s for KinMix without peak height information, and the 2.32 s using peak heights. (These times were obtained with an i7-7600U processor clocked at 2.80 GHz.) This discrepancy between computational times is likely to be due to differences in the data structures used to represent relationships in DNA mixtures.

8.2 | Case 2: Rape case

Here we analyse another real case from the DNA Laboratory, Comisaría General de Policía Científica of Madrid, concerning a sexual assault. The victim stated that two individuals raped her, both using condoms. The two condoms were found and two DNA mixtures, EPG1 and EPG2, were detected and analysed on 22 markers including Amelogenin (for gender identification). The two DNA mixtures were each compatible with the victim's profile and with that of an unknown male. An excerpt of the data on two DNA mixtures EPG1, EPG2 showing the markers, alleles, peak heights and victim's genotype is shown in Table 19.

The police wished to know if the unknown male in EPG1 and that in EPG2 could belong to two brothers. We also tested whether the two unknown males have a relationship $R = \{\text{father–son, brothers, half-brothers, cousins or are identical (the same individual or a hypothetical monozygotic twin)}\}$.

| Marker   | CSF1PO | D10S1248 | D12S391 | D18S51 |
|----------|--------|----------|---------|--------|
| Allele   | 10     | 13       | 19      | 12     |
|          | 11     | 14       | 20      | 14     |
|          |        | 13       | 21      |        |
| Height   | 1449   | 6380     | 172     | 88     |
| Height   | 173    | 1527     | 152     |        |
| Height   | 13     | 139      | 73      |        |
| Height   |        |          |         |        |
| Victim   | 10     | 13       | 20      | 15     |
|          |        |          |         |        |

TABLE 19 Case 2: An excerpt of the data on two DNA mixtures EPG1, EPG2 showing the markers, alleles, peak heights and victim's genotype
In order to deal with problems like this we consider having the victim, \( v \), and two unknown contributors \( U_1 \) and \( U_2 \). We assume that the proportion contributed to EPG1 by \( U_2 \) is zero, \( \phi_{U_2} = 0 \), and the proportion contributed to EPG2 by \( U_1 \) is zero, \( \phi_{U_1} = 0 \). The estimated mixture parameters for EPG1 and EPG2, under the above assumption, are given in Table 20.

Table 21 gives the \( \log_{10} \) LR for testing \( H_p \): \( U_1 \) in EPG1 and \( U_2 \) in EPG2 have the specified relationship versus \( H_0 \): \( U_1 \) in EPG1 and \( U_2 \) in EPG2 are unrelated. In both \( H_p \) and \( H_0 \) we assume that the victim is a contributor to both EPG1 and EPG2.

In subsequent developments of the case two brothers were arrested and DNA reference samples were collected from them. We compared the prosecution hypothesis \( H_p \): \( v \) and brother 1 contributed to EPG1 versus \( H_0 \): \( v \) and an unknown, selected at random from the database, contributed to EPG1. The resulting \( \log_{10} \) LR = 22.28 for \( H_p \) versus \( H_0 \) is highly incriminating for brother 1. Similarly, when testing the prosecution hypothesis \( H_p \): \( v \) and brother 2 contributed to EPG2 versus \( H_0 \): \( v \) and an unknown, selected at random from the database, contributed to EPG2, the \( \log_{10} \) LR = 24.14 for \( H_p \) versus \( H_0 \) is highly incriminating also for brother 2.

9 | DISCUSSION

We have shown that the IBD pattern distribution for a collection of related individuals, which extends Jacquard’s concept of coefficient of identity by descent beyond pairwise relationships, is an invaluable approach both to encoding relationships and to BN computations for DNA mixture analysis involving family relationships. Implementation of these ideas in the package KinMix, extending DNAmixtures, provides a convenient, powerful and flexible means for delivering the computations needed for DNA mixture analysis, using peak heights, involving arbitrarily complex relationships.

In this paper, we have not paid attention to the possibility of mutation, which can be important, for example in paternity cases, where a putative father can be excluded because his genotype profile is incompatible, even though a single mutation could make it compatible. We have experimental additions to KinMix, that compute likelihood ratios allowing for mutation, in various scenarios involving very close relationships. We aim to provide a comprehensive treatment of mutation in subsequent work.
ACKNOWLEDGEMENTS

We thank Amke Caliebe, Thore Egeland and Michael Nothnagel for organising an excellent workshop on Advanced Statistical and Stochastic Methods in Forensic Genetics, in Cologne in August 2018, and acknowledge fruitful conversations with Marjan Sjerps, Nuala Sheehan, Torben Tvedebrink, and Magnus Dehli Vigeland at and after the meeting, and also helpful correspondence with Elizabeth Thompson, and comments from Phil Dawid. Oskar Hansson was very helpful in discussion about using his package pcrsim. We also thank Lourdes Prieto, Comisaría General de Policía Científica, DNA Laboratory, Madrid, Spain for providing the data for the real case applications.

Finally, we are indebted to the referees for their careful reviews, which have led to a much improved presentation of these ideas.
