Abstract

We propose a method—a quantum time mirror (QTM)—for simulating a partial time-reversal of the free-space motion of a non-relativistic quantum wave packet. The method is based on a short-time spatially homogeneous perturbation to the wave packet dynamics, achieved by adding a nonlinear time-dependent term to the underlying Schrödinger equation. Numerical calculations, supporting our analytical considerations, demonstrate the effectiveness of the proposed QTM for generating a time-reversed echo image of initially localized matter-wave packets in one and two spatial dimensions. We also discuss possible experimental realizations of the proposed QTM.

1. Introduction

The question of how to invert the time evolution of a wave, classical or quantum, in an efficient and controllable way has both fundamental and practical importance. The fundamental aspect of the question is evident from its connection with the problem of unidirectionality of the arrow of time, conceived in a seminal 19th century debate between Loschmidt and Boltzmann [1, 2]. The practical importance is apparent from numerous applications in medicine, telecommunication, material analysis, and, more generally, wave control [3–7].

One fruitful approach to the time inversion of classical wave motion is based on the concept of a time-reversal mirror: an array of receiver-emitter antennas is used to first record an incident wavefront, originating say from a localized source, and then to rebroadcast a time-inverted copy of the recording, thus generating a wave that effectively propagates backward in time and refocuses at the source point. To date, time reversal mirrors have been successfully implemented with acoustic [8, 9], elastic [3], electromagnetic [10], and water waves [11, 12].

The classical procedure at the heart of such time-reversal mirrors, i.e. a continuous measurement and a subsequent reinjection of the signal, cannot be directly applied to quantum systems. The fundamental obstacle here is that any measurement performed on a quantum system is bound to perturb the quantum state and consequently affects its time evolution. (A theoretical scenario in which a time-dependent wave function is measured, recorded and then ‘played back’ by a perfect non-invasive detector-emitter has been analyzed in [13, 14].) An alternative approach to manipulate the propagation of waves relies on non-adiabatic perturbations to the system dynamics, such as an instantaneous change of its boundary conditions [15–22]. Protocols of this kind were considered for time- and space-modulated one-dimensional photonic [23–25] and magnonic crystals [26, 27]. More recently, Bacot et al put forward and experimentally realized an instantaneous time mirror for gravity-capillary waves, requiring a sudden but homogeneous modulation of water wave celerity [7]. Such approaches bypass the recording procedure, and are thus very appealing for quantum systems. A specific time-reversal protocol, albeit valid in a very narrow momentum range, was indeed devised for a one-dimensional periodically kicked optical lattice [28] and realized in a ⁸⁷Rb Bose–Einstein condensate (BEC) [29]. On the other hand, an instantaneous quantum time mirror (QTM) for Dirac-like systems (exploiting their spinor structure) was recently proposed in [30].
In this paper, we propose and investigate an experimentally realizable method for simulating the time-reversal of the free-space motion, thus mimicking a nonlinear QTM, for a spatially extended (orbital) quantum-mechanical wave function, such as a BEC cloud. The approach relies on generating a short-time spatially uniform perturbation to the wave packet dynamics that corresponds to an additional nonlinear term added in the Schrödinger equation; in a BEC cloud system, such a perturbation can be realized using established experimental techniques allowing to tune the strength of the interaction among the cloud atoms [31, 32]. More precisely, our QTM protocol comprises three stages: (i) a matter-wave packet propagates freely in space for a time $0 < t < t_0$; (ii) at $t = t_0$, a strong nonlinear perturbation is switched on globally for a short period $\delta t$, leading to a near-instantaneous modification of the position-dependent phase of the wave function; (iii) the perturbation is switched off, the wave function evolves freely again, and at a time $t_{\text{echo}} > t_0 + \delta t$ an ‘echo’ signal of the original wave packet is observed. From the conceptual viewpoint, the nonlinear QTM proposed in this paper can be viewed as a quantum-mechanical counterpart of the instantaneous time mirror for gravity-capillary waves by Bacot et al [7].

The paper is organized as follows. In section 2, we describe the physical principle underlying the proposed QTM. Two concrete scenarios for generating a time-reversed motion of matter waves in one and two spatial dimensions are analyzed in section 3. A summary, concluding remarks, and a discussion of the feasibility of an experimental realization of the proposed QTM are presented in section 4. Technical calculations are deferred to an appendix.

2. Physical principle of a nonlinear QTM

We address the time evolution of a matter-wave packet $\Psi(r, t)$, subject to the initial condition $\Psi(r, 0) = \Psi_0(r)$, in accordance with the $(D + 1)$-dimensional nonlinear Schrödinger equation

$$i\hbar \frac{\partial \Psi}{\partial t} = -\frac{\hbar^2}{2m} \nabla^2 \Psi + i f(t - t_0) |\Psi|^2 \Psi.$$  

(1)

Here, $m$ is the atomic mass, $\lambda$ quantifies the nonlinearity strength, and $t_0$ denotes the time around which the nonlinear term representing interaction effects is switched on. The function $f(\zeta)$ is sharply peaked around $\zeta = 0$ and is chosen to satisfy the normalization condition $\int_{-\infty}^{\infty} \text{d}n(t) = 1$. We take $f$ to be a $\delta$-function in our analytical calculations and a Gaussian peak $f(\zeta) = \frac{\sqrt{4\pi D\Delta t}}{\sqrt{2\pi\delta^2}} e^{-\zeta^2/\delta^2}$ in all numerical simulations. The pulse length $\Delta t \ll t_0$ will be taken as 0.001$t_0$ and 0.0025$t_0$ in one and two-dimensions, respectively.

Wave packet dynamics in the presence of an infinitesimally short nonlinear kick, $f(\zeta) = \delta(\zeta)$, can be described as follows. Rescaling $t \rightarrow t_0 t$, $r \rightarrow \sqrt{\frac{m}{\lambda}} r$, $\Psi \rightarrow \left(\frac{m}{\lambda t_0}\right)^{D/4} \Psi$, and $\lambda \rightarrow \hbar \left(\frac{\lambda t_0}{\hbar}\right)^{D/2} \lambda$, we write the nonlinear Schrödinger equation in a dimensionless form as

$$i\frac{\partial \Psi}{\partial t} = -\frac{1}{2} \nabla^2 \Psi + \lambda \delta(t - 1) |\Psi|^2 \Psi.$$  

(2)

The evolution of the wave function from $\Psi_0(r)$ at $t = 0$ to its value $\Psi_1(r) = \Psi(r, t = 1^+)$ right before the kick is given by

$$\Psi_1(r) = \int d^D r' K(r - r', t) \Psi_0(r')$$  

(3)

where the integration runs over the infinite $D$-dimensional space, and $K(q, t) = (2\pi it)^{-D/2} \exp[i|q|^2/(2t)]$ is the free-particle propagator. The nonlinear kick results in an instantaneous change of the wave function from $\Psi_1(r)$ at $t = 1^+$ to

$$\Psi_2(r) = \Psi_1(r) e^{-i\lambda|\Psi_1(r)|^2}$$  

(4)

at $t = 1^+$. Indeed, during the time interval $1^- < t < 1^+$, the wave function transformation is dominated by the second term in the right-hand side of equation (2), and effectively governed by the differential equation

$$\frac{\partial \ln \Psi_2(r, t)}{\partial t} = -i\lambda |\Psi_1(r)|^2 \delta(t - 1),$$

the solution of which is given by equation (4). After the kick, the wave function evolves freely, so that $\Psi(t, t) = \int d^D r' K(r - r', t) \Psi_2(r')$ for all times $t > 1$.

As evident from equation (4), the instantaneous nonlinear kick alters the phase of the wave function without producing any probability density redistribution, so that $\rho(r) \equiv |\Psi_2(r)|^2 = |\Psi_1(r)|^2$. The phase change however affects the probability current, whose dimensionless expression reads

$$j(r, t) = \text{Im} \left[ \Psi_2^* (r, t) \nabla \Psi_2(r, t) \right].$$

(5)

A straightforward evaluation of the current right after the kick, $j_+ = \text{Im} \left[ \nabla \Psi_2 \right]$, yields

$$j_+ = j_0 + \Delta j$$

where $j_0 = \text{Im} \left[ \nabla \Psi_0 \right]$ is the probability current immediately preceding the kick. This in turn means that, by properly tuning the kicking strength $\lambda$, the wave propagation direction can be reversed for those parts of the
matter wave for which the vector $\nabla \rho$ is aligned (or anti-aligned) with $\mathbf{j}$). Below we show that in geometries accessible in atom-optics experiments this reversal effect is robust and well-pronounced.

3. The QTM at work

As our first example, we consider the case of the initial state given by a 1D Gaussian wave packet,

$$\Psi_0(x) = (\pi \sigma^2)^{-1/4} \exp \left( -\frac{x^2}{2\sigma^2} + ikx \right).$$

characterized by the dimensionless real spatial dispersion $\sigma$ and average momentum $k$. The corresponding wave function at time $t = 1$ is obtained from equation (3) and reads (up to a position-independent phase factor)

$$\Psi(x) = [\pi (\sigma^2 + x^2)]^{-1/4} \exp[-\xi^2/2(\sigma^2 + i)] + ikx] \psi = x - k$$ denoting the distance from the wave packet center. Thus, the probability density at $t = 1$ is $\rho = \exp(-\xi^2/\sigma^2) / \sqrt{\pi} \sigma_1$, where $\sigma_1 = \sqrt{\sigma^2 + x^2}$ is the dispersion of the wave packet at the time of the kick. The probability currents before and after the kick are, respectively, $j_\downarrow = (k + \xi/\sigma_1) \rho$ and $j_\uparrow = j_\downarrow + \Delta j$, with $\Delta j = \frac{2\pi}{\sigma_1^2} \rho^2$. The minimal kick strength $\lambda_{\text{min}}$ necessary for reversing the direction of motion of (and effectively reflecting) a part of the wave packet can be estimated by requiring $j_\uparrow = 0$ at $\xi = -\sigma_1$. In the case of a fast moving wave packet, such that $k \gg 1/\sigma^2 \sigma_1$, this estimation yields

$$\lambda_{\text{min}} \approx C k \left( \sigma^2 + \frac{1}{\sigma^2} \right)$$

with $C = \sqrt{\pi}/2 \approx 2.4$. Then, given a kicking strength $\lambda > \lambda_{\text{min}}$, the time $t_{\text{echo}}$ at which the reflected part of the wave packet reaches its initial position, leading to a partial echo of the original wave packet, can be evaluated as follows. The velocity of the reflected wave is $k_{\text{rev}} \approx j_\downarrow k_{\downarrow} \approx k - \frac{\lambda}{\sigma_1^2} = \left(1 - \frac{\lambda}{\lambda_{\text{min}}} \right) k$, and the revival occurs when $|k_{\text{rev}}(t_{\text{echo}} - 1)| = k$ or, correspondingly, at

$$t_{\text{echo}} = \frac{\lambda}{\lambda - \lambda_{\text{min}}}.$$ 

The numerical simulations are based on the wave packet propagation algorithm, Time-dependent Quantum Transport [33]. The state is discretized on a square grid and the time evolution is calculated for sufficiently small time steps such that the Hamilton operator can be assumed time independent for each step. We calculate the action of $\hat{H}$ on $\psi$ in a mixed position and momentum-space representation by the application of Fourier Transforms. With this a Krylov Space is spanned, which can be used to calculate the time evolution using a Lanczos method [34].

The echo strength is quantified by the norm correlation between the initial and the time propagated wave packet defined as [35]

$$\mathcal{N}(t) = \frac{\int d^3 r \, |\Psi_0(r)|^2 |\Psi(r, t)|^2}{\sqrt{\int d^3 r \, |\Psi_0(r)|^4 \int d^3 r \, |\Psi(r, t)|^4}}.$$ 

In contrast to other possible measures of the echo strength, such as fidelity, the norm correlation is easily accessible in experiments on quantum systems with continuous degrees of freedom, e.g., atom optics experiments. Figure 1(a) presents $\mathcal{N}(t)$ for various pulse strengths $\lambda$ at constant $\sigma$ and $k$, demonstrating echo strengths up to 60%. The occurring lower peaks at higher $\lambda$ for larger times are due secondary peaks of the distorted wave packet, which can be seen in figure 1(b): this panel shows the spatial probability density $\rho = |\psi|^2$ at times $t = 0$ (black dashed curve) and $t = 0.99$ (immediately before pulse, black dashed–dotted curve), as well as the reflected wave packets for different $\lambda$’s (color code as in panel (a)), each shown at its peak echo time. In the lower plot, the current density $j$ is shown directly after the pulse $t = 1.01$. Parts of the wave packet with negative current density move backwards leading to the echo. For the parameters used, the estimated value for the minimal pulse strength in (7) is $\lambda_{\text{min}} \approx 20$ corresponding to the red curve, whose current density exhibits only a vanishing negative part that is insufficient for echo generation, thus verifying the prediction (7).

To explore the parameter space for the possibility of achieving echoes, the peak of the norm correlation (in time) is plotted as a function of $\lambda$ and $\sigma$ in figure 1(c) and as a function of $\lambda$ and $k$ in figure 1(d). The black curve shows the analytic approximation (7) of the minimal pulse strength $\lambda_{\text{min}}$. Although it does not fit perfectly, the analytic approximation is in good agreement and still well-suited to approximate the minimal pulse strength required for a time-reversal.

In order to better understand the quality, underlying principles and limitations of the proposed QTM, it is instructive to compare the state $\Psi_\downarrow$, rendered by the nonlinear kick (see equation (4)), against the desired (perfectly time-reversed) state $\mathcal{C} \Psi_\downarrow$, obtained by applying the (anti-unitary) complex conjugation operator $\mathcal{C}$ to...
and the pre-kick state $\Psi_0$. In the case of the initial state given by equation (6), we have

$$\Psi_0 = \Psi_0 e^{-i\phi}, \quad \phi = \frac{\lambda}{\sqrt{\pi} \sigma_1} e^{-\xi^2/\sigma_1}$$

and

$$\lbar{\Psi}_0 = \Psi_0 e^{-(\phi + \phi_\lambda)}, \quad \phi_\lambda = \frac{(x-k)^2}{\sigma_2 \sigma} + 2k\xi,$$

where $\sigma_1 = \sqrt{\sigma^2 + \sigma^{-2}}$ is the width of wave packet at time $t = 1$ when the kick occurs, $\xi = x - k$ is the distance measured from the center of the wave packet, and $\phi_\lambda$ is a constant (position-independent) phase related to the global phase of $\Psi_0$. While, in general, the two phases, $\phi$ and $\phi_\lambda$, have different functional forms, $\phi(\xi)$ may serve as a reasonable approximation to $\phi(\xi)$, modulo a physically irrelevant constant shift, over a finite position interval. It is the probability density supported by this position interval that makes the main contribution to the time-reversed wave generated by the nonlinear QTM. Figure 2 presents a comparison between the ideal target phase $\phi(\xi)$ and the phase $\phi(\xi)$ imprinted by the proposed QTM. The system parameters are taken to be the same as in figure 1(a), i.e. $\sigma = 1$ and $k = 4$, and the three values of the kicking strength considered are $\lambda = 30, 40, \text{ and } 50$.

We further investigate the dynamics of a 2D wave packet, initially given by

$$\Psi_0(r) = \frac{1}{2\pi^{1/2}R\sigma} \exp \left[ \frac{-(r-R)^2}{2\sigma^2} + ikr \right]$$

with $r = |r|$ and $k > 0$. For $R \gg \sigma$, the wave function is normalized to one and describes a Gaussian ring of radius $R$ and width $\sigma$ that spreads radially with the average velocity $k$. A straightforward, although tedious, calculation shows that, in the parametric regime defined by $1 \ll \sigma \ll R$ and $kR \gg 1$, the wave packet at $t = 1$...
In summary, we have proposed a protocol for simulating the time-reversed motion of a localized matter-wave packet evolving in free space. Our method is based on making a near-instantaneous spatially homogeneous perturbation to the wave packet dynamics by externally switching on a nonlinear perturbation for a short time interval. The analytical and numerical considerations presented in our paper demonstrate the efficiency of the proposed QTM in one and two spatial dimensions.

We note that the time reversal protocol proposed in this paper could in principle be employed in different physical systems, such as ultracold atomic clouds, optical pulses, or shallow water waves, as long as the system’s time evolution is governed by the nonlinear Schrödinger equation. Here, we further explore the possible connection between the numerical simulations reported in this paper and relevant atom-optics experiments. To this end, we provide an estimate for values of the dimensionless parameters $\sigma$ and $k$, defined in equations (6) and (12), for the case of ultracold lithium atoms. The mass of a $^7$Li atom is $m = 7.016 \, \text{u} = 1.165 \times 10^{-26} \, \text{kg}$.

Taking the wave packet propagation time until the nonlinear kick to be $t_0 = 10 \, \text{ms}$, we see that the wave packet

\[
\lambda_{\text{min}} \approx 2\pi C(R + k)k\sigma^2.
\]

Finally, just as in the 1D case, the echo time is determined by equation (8).

The numerical calculations (figure 3) attest the possibility of pronounced echoes up to 90% also in the 2D setup. Although the parameter range is not in the regime of the analytical approximation, the value of $\lambda_{\text{min}}$ in equation (14) is still well-suited to estimate the minimal pulse strength $\lambda$ required (see black curves).

The color plots in figures 1 and 3 seem to imply $\lambda > \lambda_{\text{min}}$ (marked as black lines) to be the only echo requirement for echo generation. However for large $\lambda$ the wave packet splits into many peaks, as shown in figure 1(b), blue curve for $\lambda = 200$. In such a scenario the norm correlation is still fairly high, but the wave packet might not longer have the desired shape. The effect of many peaks, i.e. very large $\lambda$, on the norm correlation can be seen in figure 3(c), where the echo strength moderately declines for $\sigma \approx 1$ and $\lambda > 3000$.

\[\text{Figure 2. Comparison between the QTM-imprinted phase } \phi(Q) \text{ (shifted by a physically irrelevant constant) and ideal-time-reversal phase } \varphi(Q), \text{ as given by equations (10) and (11), respectively. The system parameters are the same as in figure 1(a): } \sigma = 1 \text{ and } k = 4. \text{ Three different values of the kicking strength are considered: } \lambda = 30 \text{ (orange curve), } \lambda = 40 \text{ (green curve) and } \lambda = 50 \text{ (cyan curve). (The color code coincides with the one adopted in figure 1(a).)}\]
width range of 10–50 μm corresponds to 1.05 < σ < 5.26, and the mean velocity range of 2–10 mm s⁻¹ corresponds to 2.1 < k < 10.5. These parameter ranges coincide with the ones considered in this paper, which strongly suggests that the matter wave reversal effects predicted here can be realized in experiments with lithium BECs.

In order to further facilitate experimental realization of the proposed QTM, we make a rough estimate of the scattering length of condensed lithium atoms required to generate a reflected wave. In the one-dimensional case, the (dimensional) kicking strength \( \lambda \mathcal{D}_{\text{tm}} t_0 \) (see the discussion preceding equation (2)) is approximately equal to \( 2N\hbar^2 a_s/\sqrt{\hbar m/\Delta t} \), where \( N \) is the number of condensed atoms, \( a_s \) is the scattering length, \( \Delta t \) is the kick duration (taken to be \( \Delta t = 0.001t_0 = 10 \mu s \) in our numerical simulations), and \( a_s \) is the linear length scale of the potential confining the atomic motion in the transverse direction [36]. This yields the estimate \( a_s = \lambda \hbar^2 \sqrt{\hbar \mu /\Delta t} / (2N \Delta t) \). Taking \( N = 10^5 \), \( a_s = 10 \mu m \), and \( \lambda \) in the range 10–200 (see, e.g., figure 1), we find the required scattering length to lie in the range 5 nm ≤ \( a_s \) ≤ 105 nm. While challenging, the suggested parameter values are not impossible to achieve in modern atom-optics experiments, using, for instance, such novel techniques as optical control of Feshbach resonances [37].

Appendix. Free spreading of a Gaussian ring wave packet in 2D: Derivation of equation (13)

Let us consider a two-dimensional wave packet, initially \( \Psi(\mathbf{r}) = C \exp \left( -\frac{(r - R)^2}{2\sigma^2} + i k_0 (r - R) \right) \)

with \( r = |\mathbf{r}| = \sqrt{x^2 + y^2} \), \( \sigma \ll R \), \( k_0 > 0 \) and \( C \approx 1/\sqrt{2\pi^{1/2} R} \), so that the probability density is normalized to unity. Let \( \Psi(\mathbf{r}, t) \) be the wave packet evolved from \( \Psi(\mathbf{r}) \) in the course of a free-particle evolution through time \( t \). Here, we would like to show that in the parametric regime given by \( \sqrt{\hbar/m} \ll \sigma \ll R \) and \( k_0 R \gg 1 \) the wave packet \( \Psi \) has the same functional dependence on \( \mathbf{r} \) as \( \Psi(\mathbf{r}) \).

The free-particle propagator in 2D reads

\[
\mathcal{K}(r, r', t) = \frac{m}{2\pi \hbar} \exp \left( -\frac{m(r - r')^2}{2\hbar} \right).
\]

Hence,

\[
\Psi(\mathbf{r}, t) = \frac{mC}{2\pi \hbar} \int d^2 r' \exp \left( -\frac{(r' - R)^2}{2\sigma^2} + i k_0 (r' - R) + i \frac{m(r - r')^2}{2\hbar} \right) \mathcal{K}(r, r', t),
\]

where

\[
G(r, t) = \int_0^\infty dr' \int d^2 r' \frac{mrr'}{\hbar} \exp \left[ -\frac{1}{2} \left( \frac{1}{\sigma^2} - i \frac{m}{\hbar} \right) r'^2 + \left( \frac{R}{\sigma^2} + i k_0 \right) r' \right].
\]

Let us investigate the behavior of \( G(r, t) \) around the spatial point \( R + \frac{\hbar k_0}{m} t \). Taking into account the fact that the main contribution to the integral comes from the region \( |r' - R| \ll \sigma \), we have

\[
\frac{mrr'}{\hbar} \sim \frac{mR}{\hbar} \sim \frac{mR^2}{\hbar} + \frac{\hbar k_0 R}{m} + k_0 R \gg k_0 R.
\]

Assuming \( k_0 R \gg 1 \), we see that the argument of the Bessel function is always large compared to one, i.e. \( \frac{mrr'}{\hbar} \gg 1 \). This allows us to use the large argument asymptotics,

\[
J_0 \left( \frac{mrr'}{\hbar} \right) \approx \sqrt{\frac{\hbar}{2\pi mrr'}} \left[ e^{i \left( \frac{mrr'}{\hbar} - \frac{\hbar}{2m} \right)} + e^{-i \left( \frac{mrr'}{\hbar} - \frac{\hbar}{2m} \right)} \right],
\]

in order to write

\[
\Psi(\mathbf{r}, t) \approx \frac{C}{i} \sqrt{\frac{mR}{2\pi \hbar \sigma^2}} \exp \left( -\frac{R^2}{2\sigma^2} - i k_0 R + i \frac{mrr'}{2\hbar} \right) \left[ \Phi_+(r, t) + \Phi_-(r, t) \right].
\]

Here,

\[
\Phi_{\pm}(r, t) = e^{\mp i\frac{\pi}{4}} \int_{-\infty}^{+\infty} dt' \sqrt{\frac{R}{\hbar}} \exp \left\{ -\frac{1}{2} \left( \frac{1}{\sigma^2} - i \frac{m}{\hbar} \right) r'^2 + \frac{\hbar k_0 R}{m} r' \right\} \left[ \Phi_+(r, t) + \Phi_-(r, t) \right]
\]

\[
\approx e^{\mp i\frac{\pi}{4}} \sqrt{\frac{2\pi}{\sigma^2 \left( \frac{1}{\sigma^2} - i \frac{m}{\hbar} \right)}} \exp \left[ \frac{R}{\sigma^2} + i \left( k_0 \pm \frac{mR}{\hbar} \right) \right].
\]

Introducing

\[
\epsilon = \frac{\hbar}{m\sigma^2} \quad \text{and} \quad \nu_0 = \frac{\hbar k_0}{m},
\]

we rewrite the previous expression as

\[
\Phi_{\pm}(r, t) = e^{\pm i\frac{\pi}{4}} \sqrt{\frac{2\pi i\hbar}{m(1 + i\epsilon)}} \exp \left( i \frac{m}{2\hbar} \left[ \epsilon R + i(\nu_0 t \pm r) \right]^2 \right).
\]
This leads to
\[
\Psi(r, t) = C \frac{mR}{i} \sqrt{\frac{2\pi}{itr}} \exp \left( \frac{m}{2it} \left[ -\epsilon R^2 - 2iR\nu_0 t + i\epsilon^2 \right] \right) [\Psi_\gamma(r, t) + \Phi(r, t)]
\]
\[
= C \frac{R}{i(1 + i\epsilon) r} \sum_{\gamma = \pm 1} e^{-i\gamma^2} \times \exp \left( -\frac{m}{2it} \epsilon (R + \nu_0 t + \gamma\tau)^2 + i2(R + \nu_0 t + \gamma\tau)\nu_0 t - i[(\nu_0 t)^2 + \epsilon^2(R + \gamma\tau)^2] \right).
\]

Assuming further that \( \epsilon \ll 1 \), we have
\[
\Psi(r, t) \approx C \frac{R}{ir} \sum_{\gamma = \pm 1} e^{-i\gamma^2} \exp \left\{ -\frac{m}{2it} [\epsilon (R + \nu_0 t + \gamma\tau)^2 + i2(R + \nu_0 t + \gamma\tau)\nu_0 t - i(\nu_0 t)^2] \right\}
\]
\[
= C \frac{R}{ir} \sum_{\gamma = \pm 1} e^{-i\gamma^2} \times \exp \left( \frac{-(R + \nu_0 t + \gamma\tau)^2}{2\sigma^2} - i\frac{m}{h^2} t \frac{\nu_0}{m} + \frac{m}{h^2} t \frac{\nu_0}{m} \right).
\]

Taking into account that the last expression for \( \Psi \) is only valid for \( r \) close to \( r_\gamma \), where
\[
r_\gamma = R + \nu_0 t = R + \frac{h\nu_0}{m},
\]
we see that a contribution of the term with \( \gamma = +1 \) is negligibly small. Thus we arrive at the sought approximation for the freely propagated wave function:
\[
\Psi(r, t) \approx \frac{1}{\sqrt{2\pi^{3/2}\sigma_r}} \exp \left( \frac{(r - \eta_r)^2}{2\sigma^2} + i\frac{m}{h^2} t \frac{\nu_0}{m} + i\frac{m}{h^2} t \frac{\nu_0}{m} \right).
\]

This expression is only valid in the parametric regime defined by
\[
\sqrt{\frac{hr}{m}} \ll \sigma \ll R \quad \text{and} \quad \frac{k_0}{R} \gg 1.
\]
