We report resistivity measurements from 0.03 K to 10 K in a dilute high mobility 2D electron system. Using an undoped GaAs/AlGaAs heterojunction in a gated field-effect transistor geometry, a wide range of densities, 0.16 $\times$ 10$^{10}$ cm$^{-2}$ to 7.5 $\times$ 10$^{10}$ cm$^{-2}$, are explored. For high densities, the results are quantitatively shown to be due to scattering by acoustic phonons and impurities. In an intermediate range of densities, a peak in the resistivity is observed for temperatures below 1 K. This non-monotonic resistivity can be understood by considering the known scattering mechanisms of phonons, bulk and interface ionized impurities. Still lower densities appear insulating to the lowest temperature measured.

The resistivity of 2D electrons at zero magnetic field has been used to probe scattering and quantum processes for many years. Interest in the conducting behavior of 2D electrons and holes was further heightened in 1994 when Kravchenko and coworkers discovered an apparent metallic transition of 2D electrons in Si MOSFETs. While 2D systems are expected to exhibit insulating behavior (weak or strong localization) at sufficiently low temperatures and/or densities, the metallic side of the metal-insulator transition is more puzzling. A true metal conducts at temperatures and/or densities, the metallic side of the behavior (weak or strong localization) at sufficiently low

For intermediate densities a low temperature peak in the resistivity is typically observed when the dimensionless parameter $r_s$ (ratio of Coulomb to kinetic energy, $\sim n^{-1/2}$) is much larger than 1, suggesting that electron-electron interactions may be important. The issue here is understanding the physical mechanisms underlying the metallic behavior and elucidating the roles of disorder and interaction.

In this Letter, we present the temperature dependence of the resistivity of a dilute 2D electron gas (2DEG) in GaAs. Electron-electron interactions can be extremely important in this system at low temperatures due to the low amount of disorder present in GaAs heterostructures. In the sample discussed here, the density can be continuously tuned from $0.16 \times 10^{10}$ cm$^{-2}$ ($r_s = 13.7$) to $7.5 \times 10^{10}$ cm$^{-2}$ ($r_s = 2.0$). With the ability to achieve very high $r_s$ in low disorder samples, these resistivity measurements provide a test of the importance of Coulomb interactions in the metallic regime. In particular, the $r_s$ ($\gtrsim 10$) values of our 2DEGs are very comparable to those in the best Si MOSFETs whereas the effective disorder in our sample (as measured by $k_F\ell$, $k_F$ is the Fermi wavevector and $\ell$ the mean free path) is more than two orders of magnitude lower. Earlier experimental studies of the metallic behavior in 2D electrons in GaAs systems were restricted to higher densities and lower mobilities, and the drop in resistivity was much weaker than the 20% drop observed here. Finally, the wide range of $n$ and $T$ reported here allow several scattering regimes to be identified.

We find that our measured temperature dependence of the resistivity can be qualitatively well understood solely within the framework of Fermi liquid theory. At high density, the resistivity is linear with temperature, and the slope agrees both with previous measurements and established theory for acoustic phonon scattering. For intermediate densities a low temperature peak in the resistance is observed. The non-monotonic resistivity agrees qualitatively with the predicted temperature dependence of ionized impurity scattering (screening at low

The interface (see Fig. 1 inset) is separated from remote delta-doping. The interface roughness scattering is not relevant for data presented here. The temperature dependence of the resistivity at high density is better shown in the inset of Fig. 2, where $\rho$ is initially constant (see Fig. 2), then increases and decreases to form a local maximum below $T = 1$ K. The third regime occurs at the lowest densities, with the resistivity decreasing as the temperature increases in the experimentally accessible temperature range.

The phonon contribution to the resistivity at high density is better shown in the inset of Fig. 2, where $\rho$ is plotted for $n > 1.0 \times 10^{10}$ cm$^{-2}$. The inverse mobility for $T \approx 2$ K is linear, and each density has roughly the same slope of $\sim 3.2 \times 10^{-8}$ Vs/Kcm$^2$.

Acoustic phonon scattering with both piezoelectric and deformation potential coupling leads to a linear dependence of $\mu$ above the Bloch-Grüneisen temperature ($kT_{BG} = 2k_F c$, $c$ is the phonon speed of sound). Previously reported experimental [8] and theoretical [9] studies of higher density 2DEGs in conventional GaAs heterostructures quantitatively agree with slope found here. This demonstrates that the resistivity of the high density 2DEG is accurately captured using well known scattering mechanisms. Note that the high temperature resistivity of the low density data in the inset of Fig. 2 remains consistent with phonon scattering even as the non-monotonic features begin to appear at low temperatures.

As the density is lowered below $n = 1 \times 10^{10}$ cm$^{-2}$,
the resistivity becomes non-monotonic. A peak in $\rho$ appears for $T < T_F$, and the position of the peak shifts to lower temperature for lower densities. The resistivity at the maximum can be up to 23% larger than the low temperature ($T = 30$ mK) value of the resistivity. The non-monotonic peak occurs for $T < T_{BG}$, where phonon scattering is strongly suppressed. In this regime of $n$ and $T$ the temperature dependence of ionized impurity scattering must be considered. Screening leads to $\rho(T) \sim T$ for $T \ll T_F$, and the crossover from a degenerate Fermi gas to a classical system leads to $\rho(T) \sim 1/T$ for $T > T_F$. Competition between these effects will lead to a low $T$ resistivity peak. Detailed calculations including both ionized impurity and acoustic phonon scattering are presented below (Fig. 3).

For the lowest density that can be attained in our samples $\rho$ decreases monotonically as $T$ increases. While it appears that the 2D electron system is insulating for these densities, comparison to the non-monotonic resistivities indicates a different interpretation is possible. Clearly, if the data were only taken to 0.2 K, some of the non-monotonic curves at higher density would also appear insulating. Similarly, it is possible that the low $n$ insulating behavior could become non-monotonic if the electron temperature were lowered further. From the results in Fig. 3, it is clear that a separatrix cannot be identified in this system. The functional form of the “insulating” temperature dependence for $n \leq 0.23 \times 10^{10} \text{cm}^{-2}$ is more consistent with a power law dependence than an activated or Mott variable range hopping behavior.

In performing $\rho$ measurements at low $n$ great care must be taken to insure that features do not arise as a result of inhomogeneities in the current flow. The temperature dependence of the resistances is shown in Fig. 3. Two resistances, $R_A$ and $R_B$, are measured for current flowing, on average, in orthogonal directions. A constant current of 0.3 nA (for the lowest density) to 20 nA (for the highest density) is used in a standard lock-in amplifier measurement at a frequency of 7 Hz. The resistivity is determined from the resistances using a procedure prescribed by Van der Pauw. At high density ($n = 1.57 \times 10^{10} \text{cm}^{-2}$, Fig. 3a), the curves $R_A(T)$ and $R_B(T)$ almost lie on top of each other and the temperature dependence is due to phonon scattering. At lower density (Fig. 3b,c), non-monotonic features appear in both $R_A$ and $R_B$, but the resistances are no longer identical. Here we observe $R_A/R_B$ can be as large as 1.6. Earlier designs of undoped samples exhibited a severe ratio: $R_A/R_B$ approached 30. This effect originates in the sample fabrication, with the higher resistance always related to the location of the metallic gate contact. We speculate that the gate contact created a locally strained region above the square 2DEG causing inhomogeneous current flow. After redesigning the sample geometry to make the gate contact far from the square measurement region, $R_A/R_B$ was reduced by more than a factor of 10.

While this effect is still visible in Fig. 3b and c, the remaining ratio has a very small ($< 10\%$) impact on the resistivity. Both $R_A$ and $R_B$ are non-monotonic, with resistance peaks located at nearly the same temperature. The qualitative nature of the non-monotonic resistivity is due to the underlying physics of ionized impurity scattering and not inhomogeneous current flow.

To understand the low temperature ($T < 1$ K) data, where the phonons contribute little to the resistivity as the system enters the Bloch-Grüneisen regime, we have carried out a microscopic transport calculation using the Boltzmann theory, where we include effects of charged impurity scattering on the electronic resistivity. Our calculation includes the following effects: (1) scattering by ionized charged impurities in the bulk GaAs layer and at the GaAs/AlGaAs interface; (2) temperature dependent screening, where the electron-charged impurity scattering is taken to be the temperature dependent statically screened Coulomb interaction with the screening calculated within the finite wavevector random phase approximation; (3) acoustic phonon scattering including both deformation potential and piezoelectric coupling; (4) the quasi-2D nature of the system through subband form factors calculated in the Fang-Howard-Stern variational scheme. This approach is valid for $k_F \ell > 1$.

We show our calculated results in Fig. 3 for several experimental intermediate and high densities. Reasonable values are chosen for bulk and interface impurities to allow a comparison of the calculated results to the ex-
FIG. 4: Result from scattering calculations are remarkably similar to the data in Fig. 3. The density (from the top) is 0.42, 0.55, 0.68, 0.80, 1.06 and 1.57 x 10^10 cm^-2. Calculations include acoustic phonons, bulk and interface impurities. Experimental data shown in Fig. 2. Note that the overall resistivity scale depends on the unknown impurity densities, but the qualitative trends in $\rho(T, n)$ are real and arise from very basic aspects of the underlying scattering mechanisms. The rise in $\rho$ with increasing $T$ at low temperatures is a direct effect of the thermal weakening of screening. The non-monotonicity of $\rho(T)$ at the intermediate temperatures arises from the competition among temperature dependent screening, quantum-classical crossover and phonon scattering. The rise at higher $T$ is a phonon effect.

Quantitative understanding requires a more sophisticated theory which includes higher order electron-electron interactions and disorder induced localization corrections. Recently, electron-electron interaction corrections have been considered by Zala and coworkers[14]. They find that for a range of temperature, $\hbar/\tau \ll T \ll T_F$ where $\tau$ is the transport relaxation time, $\rho(T)$ is expected to be linear. From the slope, the Fermi liquid parameter $F_0$ can be determined. In the data presented here there is no significant range over which linear $\rho$ is observed for $T \ll T_F$ (except for the phonon effect at higher $T$), and therefore we do not attempt to determine $F_0$.

In conclusion, we have made resistivity measurements on low disorder gatable 2DEGs over a wide range of densities and temperatures. The resistivity data of high density 2DEGs agree quantitatively with both experimental and theoretical accounts of acoustic phonon scattering in GaAs. For the lowest densities, insulating behavior is observed. At intermediate densities, the resistivity becomes non-monotonic, with a peak appearing for $T < T_F$. At low temperature the competition between screening ($\sim T$) and a crossover from a degenerate Fermi system to a classical 2D gas ($\rho \sim T^{-1}$) leads to the formation of a peak. Theoretical scattering calculations including both ionized impurities and acoustic phonons in GaAs show excellent qualitative agreement with the data. This agreement between experiment and theory suggests that the underlying physics involved is conventional Fermi liquid physics.
