SUMMARY
The estimation of potential fields such as the gravitational or magnetic potential at the surface of a spherical planet from noisy observations taken at an altitude over an incomplete portion of the globe is a classic example of an ill-posed inverse problem. Here we show that the geodetic estimation problem has deep-seated connections to Slepian’s spatiospectral localization problem on the sphere, which amounts to finding bandlimited spherical functions whose energy is optimally concentrated in some closed portion of the unit sphere. This allows us to formulate an alternative solution to the traditional damped least-squares spherical harmonic approach in geodesy, whereby the source field is now expanded in a truncated Slepian function basis set. We discuss the relative performance of both methods with regard to standard statistical measures as bias, variance and mean-square error, and pay special attention to the algorithmic efficiency of computing the Slepian functions on the region complementary to the axisymmetric polar gap characteristic of satellite surveys. The ease, speed, and accuracy of this new method makes the use of spherical Slepian functions in earth and planetary geodesy practical.

1 I N T R O D U C T I O N
Satellites mapping out the spatial variations of the gravitational or magnetic fields of the Earth or other planets ideally fly on polar orbits, uniformly covering the entire globe. Thus potential fields on the sphere are usually expressed in spherical harmonics, basis functions with global support. For various, especially engineering, reasons, however, inclined orbits are favorable. These leave a “polar gap”: an antipodal pair of axisymmetric polar caps, typically less than 10° in diameter, without any data coverage. Estimation of spherical harmonic field coefficients from an incompletely sampled sphere is prone to error, since the spherical harmonics are not orthogonal over the partial domain of the cut sphere.

The historically somewhat neglected geodetic polar gap problem has been revived by, among others, Sneeuw & van Gelderen (1997), and recently, Albertella et al. (1999), who constructed a new basis of so-called Slepian functions (after Slepian 1983) on the sphere. These bandlimited functions are designed to have the majority of their energy optimally concentrated inside the latitudinal belt composed of the entire globe minus the polar gap, i.e. the region covered by satellites. Slepian functions are orthogonal on both the entire as well as the cut sphere, a property that can be exploited to our advantage. Here, we study the inverse problem of retrieving a potential field on the unit sphere from noisy and incomplete observations made at an altitude above their source. We derive exact expressions for the estimation error due to the traditional method of damped least-squares spherical harmonic analysis as well as that arising from a new approach using a truncated set of Slepian basis functions.

We cast the geodetic estimation problem in the much wider context of spatiospectral localization, whereby bandlimited functions are spatially concentrated to regions of arbitrary shape on the sphere [Wieczorek & Simons 2005; Simons et al. 2006], and derive a new semi-analytical numerical method to calculate the spherical Slepian functions on the latitudinal belt or its complement, the double polar cap. Our approach requires no numerical integration, and avoids the construction of matrices other than a tridiagonal matrix whose elements are prescribed analytically. Finding spherical harmonic expressions for bandlimited functions concentrated to polar caps or latitudinal belts, as in Figure II thus becomes so effortless as to be achievable by a handful of lines of computer code, and the problems with
2 STATEMENT OF THE PROBLEM

We are concerned with estimating source-level potential fields from noise-contaminated satellite observations at an altitude over an incomplete portion of the unit sphere. The geometry of this problem is illustrated in Figure 1. The unit sphere Ω on which the unknown signal is defined is parameterized as usual in terms of spherical coordinates, colatitude θ and longitude φ. The angular distance between two position coordinates \( \hat{r} = (\theta, \phi) \) and \( \hat{r}' = (\theta', \phi') \) is denoted by \( \Delta \). In the lower right, the domain over which satellite observations are available is left unshaded, whereas the area in which measurements are missing is shaded grey. We denote the white region covered by satellite tracks by \( R \), and the shaded, uncovered region by \( \bar{R} \). Although our treatment will start out quite general, without restrictions on the shape of \( R \) or \( \bar{R} \), as long as they are complementary closed regions on the surface of the unit sphere, the lower right panel of Figure 1 illustrates the case in which the region \( \bar{R} \) is a double polar cap symmetric about the polar axis \( \hat{z} \). The angular radius of the polar caps is denoted by \( \Theta \). The double polar cap is representative of the geodetic case in which \( \bar{R} \) is the so-called polar gap of missing observations; its complement \( R \) is a latitudinal belt of angular width \( \pi - 2\Theta \) around the equator, as shown. In the following, for brevity, we will shorten all double summations to a notation requiring only a single sum:

\[
\sum_{l=0}^{\infty} \sum_{m=-l}^{l} \rightarrow \sum_{lm},
\]

\[
\sum_{l=0}^{L} \sum_{m=-l}^{l} \rightarrow \sum_{lm} \quad \text{and} \quad \sum_{l>L} \sum_{m=-l}^{l} \rightarrow \sum_{lm>L}.
\]

2.1 Preliminary considerations on the source signal

We model the geophysical signal as a broadband, square-integrable, real-valued function \( s(\hat{r}) \) on the surface of the unit sphere \( \Omega = (\theta, \phi) \), defined by the transform pair

\[
s(\hat{r}) = \sum_{lm} s_{lm} Y_{lm}(\hat{r}), \quad s_{lm} = \int_{\Omega} s(\hat{r}) Y_{lm}(\hat{r}) \, d\Omega. \quad (1)
\]

The integers \( l \) and \( m \) are the degree and order of the real spherical harmonics \( Y_{lm}(\hat{r}) \). These are defined by

\[
Y_{lm}(\theta, \phi) = \begin{cases} 
\sqrt{\frac{2}{\pi}} X_{lm} \cos m\phi & \text{if } -l \leq m < 0 \\
X_{l0}(\theta) & \text{if } m = 0 \\
\sqrt{\frac{2}{\pi}} X_{lm} \sin m\phi & \text{if } 0 < m \leq l,
\end{cases}
\]

Figure 1. Geometry of the geodetic estimation problem, and some symbols used in this paper. In the lower left, an axisymmetric polar cap, shaded, of colatitudinal radius \( \Theta \). In the lower right, an antipodal pair of polar caps, shaded, representing the geodetic polar gap.
where the upward continued signal coefficients are given in terms of the source-level terms by (Stacey 1992; Blakely 1995)

\[ s_{\uparrow lm} = (1 + a)^{-l-1} s_{lm}. \]  

The data over the region of coverage \( R \) would be given by eq. (15) were it not that they are contaminated by noise. In the uncovered areas \( \bar{R} \), no measurements are available. A satellite thus observes

\[ d(\tilde{\mathbf{r}}) = \begin{cases} s_{\uparrow}(\tilde{\mathbf{r}}) + n(\tilde{\mathbf{r}}) & \text{if } \tilde{\mathbf{r}} \in R \\ \text{unknown} & \text{if } \tilde{\mathbf{r}} \in \bar{R}. \end{cases} \]

We will restrict attention to the case in which the measurement noise \( n(\tilde{\mathbf{r}}) \) is additive and given by a zero-mean stochastic process, which we assume to be white:

\[ \langle n(\tilde{\mathbf{r}}) \rangle = 0, \quad \langle n(\tilde{\mathbf{r}}) n(\tilde{\mathbf{r}}') \rangle = N \delta(\tilde{\mathbf{r}}, \tilde{\mathbf{r}}'). \]

Thus, the power of the noise is denoted by \( N \), and we use angular brackets to denote the ensemble averaging over all possible realizations required to define the process mean and its spatial (co)variance.

Combining eqs. (13)–(14) and (11) with the definition (10), we can write the signal observed at orbital level as a convolution of the surface-level signal in the form

\[ s_{\uparrow}(\tilde{\mathbf{r}}) = \int_\Omega \Gamma(\tilde{\mathbf{r}}, \tilde{\mathbf{r}}') s(\tilde{\mathbf{r}}') \, d\Omega', \]

where we have defined a “point spread function”

\[ \Gamma(\tilde{\mathbf{r}}, \tilde{\mathbf{r}}') = \sum_{l=0}^{\infty} (1 + a)^{-l-1} \left( \frac{2l+1}{4\pi} \right) P_l(\hat{\mathbf{r}} \cdot \hat{\mathbf{r}}'). \]

Thus, the value of the potential field that is observed at a point \( \tilde{\mathbf{r}} \) outside the unit sphere is a weighted mixture of the function values at \( \tilde{\mathbf{r}} \) and distant other points \( \tilde{\mathbf{r}}' \) on the unit sphere. Measurements taken by a satellite at \( a > 0 \) are affected by regions it does not fly over directly. A satellite thus does probe into the uncovered regions; conversely, in regions of coverage, it may be affected by uncovered areas. As the fractional altitude \( a \) increases, the convolution kernel \( \Gamma(\tilde{\mathbf{r}}, \tilde{\mathbf{r}}') \) is increasingly supported globally. On the other hand, when \( a = 0 \), eq. (15) returns the delta function, eq. (9), and eq. (18) merely illustrates its sifting property (10).

## 2.3 A new basis for bandlimited field estimators

We seek an estimate \( \hat{s}(\tilde{\mathbf{r}}) \) of the signal in eq. (11) at the level of the source, from the data \( d(\tilde{\mathbf{r}}) \), given by eq. (15), at altitude \( a \). It is crucial to realize that, although any real physical signal \( s(\tilde{\mathbf{r}}) \) will in general be infinite-band, our estimate \( \hat{s}(\tilde{\mathbf{r}}) \) must always be bandlimited. We are thus at liberty to define a new, bandlimited set of basis functions, to replace the spherical harmonics. In this manner, the broadband source field can be expressed as

\[ \hat{s}(\tilde{\mathbf{r}}) = \sum_{\alpha=1}^{(L+1)^2} s_{\alpha}(\tilde{\mathbf{r}}') + \sum_{l=0}^{\infty} s_{lm}(\tilde{\mathbf{r}}'), \]

where

\[ s_{\alpha}(\tilde{\mathbf{r}}') = \sum_{l=0}^{L} s_{\alpha lm}(\tilde{\mathbf{r}}'). \]
whereas the bandlimited estimated field is given by

\[ \hat{s}(\hat{r}) = \sum_{l=0}^{L} \hat{s}_{lm} Y_{lm}(\hat{r}) = \sum_{\alpha=1}^{(L+1)^2} \hat{s}_\alpha g_\alpha(\hat{r}). \]  

(21)

These new bandlimited basis functions \( g_\alpha(\hat{r}) \) indexed by \( \alpha = 1, \ldots, (L + 1)^2 \) will themselves be combinations of spherical harmonics, inasmuch as they are defined by the transform pair

\[ g_\alpha(\hat{r}) = \sum_{l=0}^{L} g_{\alpha,lm} Y_{lm}(\hat{r}), \]  

(22a)

\[ Y_{lm}(\hat{r}) = \sum_{\alpha=1}^{(L+1)^2} g_{\alpha,lm} g_\alpha(\hat{r}), \]  

(22b)

\[ g_{\alpha,lm} = \int_{\Omega} g_\alpha(\hat{r}) Y_{lm}(\hat{r}) \, d\Omega. \]  

(22c)

The new basis will be rendered orthonormal by requiring

\[ \int_{\Omega} g_\alpha(\hat{r}) g_\beta(\hat{r}) \, d\Omega = \delta_{\alpha\beta}, \]

(23a)

\[ \sum_{l,m} g_{\alpha,lm} g_{\beta,lm} = \delta_{\alpha\beta}, \]

(23b)

\[ \sum_{\alpha=1}^{(L+1)^2} g_{\alpha,lm} g_{\alpha,l'm'} = \delta_{\alpha l \lambda \mu \nu} \delta_{m m'}. \]  

(23c)

The transformation of the spherical harmonic basis coefficients \( \hat{s}_{lm} \) of the estimate to the expansion coefficients \( \hat{s}_\alpha \) in the new basis is achieved by

\[ \hat{s}_{lm} = \sum_{\alpha=1}^{(L+1)^2} g_{\alpha,lm} \hat{s}_\alpha \quad \text{and} \quad \hat{s}_\alpha = \sum_{l,m} g_{\alpha,lm} \hat{s}_{lm}, \]

(24)

as can be easily deduced by combining eq. (21) with the orthonormality conditions, eqs (6) and (23), and using eq. (22).

Upward continued to the satellite altitude \( a \), the estimate in either basis is

\[ \hat{s}_{lm}(a) = a^{l+1} \hat{s}_{lm}, \]

and the upward continued expansion coefficients of the new basis by

\[ \hat{s}_\alpha(a) = \frac{a^l}{\alpha} \hat{s}_\alpha \]

(25)

where the spherical harmonic coefficients are naturally given by

\[ \hat{s}_{lm}(a) = (1 + a)^{-l-1} \hat{s}_{lm}, \]

(26)

and the upward continued expansion coefficients of the new basis by

\[ \hat{s}_\alpha(a) = \frac{a^l}{\alpha} \hat{s}_\alpha \]

(27a)

\[ = \sum_{l,m} g_{\alpha,lm} (1 + a)^{-l-1} \hat{s}_{lm} \]

(27b)

as is verified by combining eqs (25) and (26). As expected, eq. (27) reduces to a trivial identity at the surface of the unit sphere, i.e. when \( a = 0 \), by virtue of eqs (22) or (24).

Given that the measurements made by the satellite are restricted to the domain \( R \) on the unit sphere \( \Omega \), we consider it natural to require of the new basis functions that they be optimally concentrated on this domain. We will seek a basis of functions \( g(\hat{r}) \) whose energy is maximally concentrated inside of the domain \( R \) by maximizing the spatial energy ratio,

\[ \lambda = \frac{\int_{R} g^2 \, d\Omega}{\int_{\Omega} g^2 \, d\Omega} = \text{maximum.} \]

(28)

Eq. (28) is a statement of Slepian’s problem, a classic in one-dimensional time-series analysis [Slepian 1983, Percival & Walden 1993], on the two-dimensional sphere, which we have recently studied in detail (Simons et al. 2000). In the next section, we review the main properties of the general solution of eq. (28) for concentration domains of arbitrary geometry, which we subsequently specialize to the geodetic context by imposing the circular symmetry of the double-cap polar gap.

3 SLEPIAN’S SPHERICAL PROBLEM

In Slepian’s problem, the concentration of a bandlimited function \( g \) given by

\[ g = \sum_{l,m} g_{lm} Y_{lm}, \quad g_{lm} = \int_{\Omega} g Y_{lm} \, d\Omega, \]

(29)

to a region \( R \) of area \( A \) on the unit sphere \( \Omega \) is expressed as the norm ratio, eq. (28). Maximization of this concentration criterion can be achieved in the spectral domain by solving the algebraic eigenvalue problem

\[ Dg = \lambda g, \]

(30)

where \( g \) is the \((L + 1)^2\)-dimensional spherical harmonic coefficient column vector

\[ g = (g_{00} \cdots g_{lm} \cdots g_{LL})^T \]

(31)

and \( D \) is the \((L + 1)^2 \times (L + 1)^2\)-dimensional matrix

\[ D = \begin{pmatrix} D_{00,00} & \cdots & D_{00,LL} \\ \vdots & \ddots & \vdots \\ D_{LL,00} & \cdots & D_{LL,LL} \end{pmatrix}, \]

(32)

whose elements \( D_{lm,l'm'} \), \( 0 \leq l \leq L \) and \( -l \leq m \leq l \), are

\[ D_{lm,l'm'} = \int_{R} Y_{lm} Y_{l'm'} \, d\Omega. \]

(33)

The obvious symmetry \( D^T = D \) guarantees that the eigenvectors \( g_1, g_2, \ldots, g_{(L+1)^2} \) are mutually orthogonal. We choose them to be orthonormal:

\[ g_\beta^T g_\beta = \delta_{\alpha\beta} \quad \text{and} \quad g_\beta^T D g_\beta = \lambda_\beta \delta_{\alpha\beta}. \]

(34)

The resulting Slepian functions \( g \) are orthonormal over the whole sphere \( \Omega \) and orthogonal over the region \( R \):

\[ \int_{\Omega} g_\alpha g_\beta \, d\Omega = \delta_{\alpha\beta} \quad \text{and} \quad \int_{R} g_\alpha g_\beta \, d\Omega = \lambda_\alpha \delta_{\alpha\beta}. \]

(35)
The leftmost equations in eqs (54–55) correspond to the conditions of eq. (23) and guarantee that the solution indeed forms a valid orthonormal basis. The rightmost equations illustrate the so-called double orthogonality of the Slepian basis [Gilbert & Slepian 1977], which, as we will see in a later section, is a central feature of their utility for the geodetic estimation problem.

An approach equivalent to the maximization of eq. (28) is to find broadband functions \( h(\hat{r}) \) that are spacelimited to the domain \( R \), but spectrally concentrated in a bandwidth interval \( 0 \leq l \leq L \). The concentration measure in this case, \[
\lambda = \frac{\sum_{lm} h_{lm}^2}{\sum_{lm} h_{lm}^2} = \text{maximum},
\]
is satisfied by the eigenfunctions of a Fredholm integral eigenvalue equation in the spatial domain:
\[
\int_R D(\hat{r}, \hat{r}') h(\hat{r}') \, d\Omega' = \lambda h(\hat{r}), \quad \hat{r} \in R.
\]
The symmetric kernel of eq. (37) depends only on the geodesic angular distance, \( \Delta \), between \( \hat{r} \) and \( \hat{r}' \):
\[
D(\hat{r}, \hat{r}') = \int_0^\infty \left( \frac{2l+1}{4\pi} \right) P_l(\hat{r} \cdot \hat{r}') \, \frac{d\Omega'}{\sin \theta}.
\]

The problems of finding bandlimited functions \( g(\hat{r}) \) concentrated to a spatial interval or spacelimited functions \( h \) concentrated in a spectral interval are completely equivalent. The domain of eq. (37) can be extended to the entire sphere in which case it applies to the bandlimited functions \( g \):
\[
\int_R D(\hat{r}, \hat{r}') g(\hat{r}') \, d\Omega' = \lambda g(\hat{r}), \quad \hat{r} \in \Omega,
\]
We normalize such that the eigenfunctions \( g \) that maximize the spatial energy ratio (37) are identical, within the region \( R \), to the eigenfunctions \( h \) maximizing the spectral ratio (36).
\[
h(\hat{r}) = \begin{cases} 
  g(\hat{r}) & \text{if } \hat{r} \in R \\
  0 & \text{otherwise.}
\end{cases}
\]
The relation
\[
h_{lm} = \sum_{l'm'} D_{lm,l'm'} g_{l'm'}
\]
expresses the coefficients \( h_{lm} \), where \( 0 \leq l \leq \infty \), in terms of the coefficients \( g_{lm} \), with \( 0 \leq l \leq L \). This is a straightforward consequence of the definitions in eqs (29), (33) and (40), and, by eq. (36), it amounts to \( h_{lm} = \lambda g_{lm} \) when \( 0 \leq l \leq L \). The eigenvalues of eqs (39) or (40),
\[
1 > \lambda_1 \geq \lambda_2 \cdots \geq \lambda_{(L+1)^2} > 0,
\]
measure the quality of the spatiospectral concentration: the bandlimited function that is most concentrated inside \( R \) is \( g_1 \), with \( \lambda_1 \) being the largest associated eigenvalue, and so on. The sum of the eigenvalues, or Shannon number, equal to the trace of \( D \), defines a diagnostic area-bandwidth product
\[
K = \sum_{\alpha=1}^{(L+1)^2} \lambda_\alpha = \int_R D(\hat{r}, \hat{r}) \, d\Omega = (L + 1)^2 \frac{A}{4\pi}.
\]

Spherical Slepian functions of equal Shannon number are scaled versions of each other in the asymptotic limit \( L \to \infty \) and \( R \to \infty \) with \( K \) held fixed (Simons et al. 2006). Whenever the area \( A \) of the region \( R \) is a small fraction of the area of the sphere, \( A \ll 4\pi \), i.e., when \( K \ll (L + 1)^2 \), there will be many more well excluded eigenfunctions with insignificant eigenvalues \( (\lambda \approx 0) \) than well concentrated eigenfunctions with significant eigenvalues \( (\lambda \approx 1) \). If on the other hand, \( R \) covers most of the sphere so that \( A \approx 4\pi \) and \( K \approx (L + 1)^2 \), there will be many more well concentrated eigenfunctions than well excluded ones.

The sum of the squares of the \((L+1)^2\) bandlimited eigenfunctions \( g(\hat{r}) \) is independent of position on the sphere:
\[
\sum_{\alpha=1}^{(L+1)^2} g^2_\alpha(\hat{r}) = \frac{(L+1)^2}{4\pi} = \frac{K}{A}.
\]
Since the first \( K \) eigenfunctions \( g_1, g_2, \ldots, g_K \) have eigenvalues near unity and lie mostly within \( R \), and the remainder \( g_{K+1}, g_{K+2}, \ldots, g_{(L+1)^2} \) have eigenvalues near zero and lie mostly in the complementary region \( \bar{R} = \Omega - R \), the eigenvalue-weighted sum of squares is well approximated by
\[
\sum_{\alpha=1}^{(L+1)^2} \lambda_\alpha g^2_\alpha(\hat{r}) \approx \begin{cases} 
  K/A & \text{if } \hat{r} \in R \\
  0 & \text{otherwise.}
\end{cases}
\]
The terms with \( K < \alpha \leq (L + 1)^2 \) should be negligible, so it is immaterial whether they are included in the sum or not. Taken together, the first \( K \) orthogonal eigenfunctions \( g_1, g_2, \ldots, g_K \), with significant eigenvalues \( \lambda_\alpha \approx 1 \), provide an essentially uniform coverage of the region \( R \). Rather than requiring \((L+1)^2\) basis functions to represent an arbitrary spatially concentrated bandlimited function, the first \( K = (L + 1)^2 A/(4\pi) \) members of the Slepian basis provide a very reasonable approximation.

We shall denote the operator localizing to the complementary region \( \bar{R} \) by \( \mathcal{D} \), its eigenfunctions by \( \hat{g} \) and its eigenvalues by \( \hat{\lambda} \). It follows from the orthogonality relation (40) that the elements of \( \mathcal{D} \) are
\[
\hat{D}_{lm,l'm'} = \int_R Y_{lm} Y_{l'm'} \, d\Omega = \delta_{ll'} \delta_{mm'} - D_{lm,l'm'}.
\]
The eigenfunctions of \( \mathcal{D} \) are identical to those of \( \mathcal{D} \), but their ordering indices are reversed. The bandlimited function that is most concentrated within \( R \) is most excluded from \( \bar{R} \), i.e., \( \hat{g}_1 = g_{(L+1)^2} \), with an associated eigenvalue \( \hat{\lambda}_1 = 1 - \lambda_{(L+1)^2} \), and so on.

The localization operator \( \mathcal{D} \) has an inverse satisfying
\[
\sum_{l''m''} D^{-1}_{lm,l''m''} D_{l''m'',l'm'} = \delta_{ll'} \delta_{mm'},
\]
and for which $D^{-1}g = \lambda^{-1}g$. For future reference, the inverse of a weighted sum of the localization matrix and its complement obeys

$$(D + \eta \hat{D})^{-1}g = [\lambda + \eta/(1 - \lambda)]^{-1}g,$$  

(48a)

$g^{T}(D + \eta \hat{D})^{-1}g_{\beta} = [\lambda_{\alpha} + \eta/(1 - \lambda_{\alpha})]^{-1} \delta_{\alpha \beta},$  

(48b)

for any weighting parameter $\eta$. Finally, we may extend the validity of the definition [53] to include all degrees $l \leq \infty$ and use eqs (48a–48b) to prove that

$$\sum_{l' m''} D_{lm, l'm''} D_{l'm', l'm'} = D_{lm, l'm'}. \quad (49)$$

4 AXISEMTRIC DOMAINS

In the previous section we showed that the optimally concentrated bandlimited basis functions that are the solutions to the Slepian problem are found by numerical diagonalization of the operator in eq. (33). That this is in general possible for arbitrary geometries was shown by Simons et al. (2006). However, the particular geometry of data acquisition on the sphere in the geostationary estimation problem (Figure 1) allows for substantial simplifications of this general result. We discuss the special case of finding concentrated basis functions on the latitudinal belt, the domain over which satellite measurements are made, via the concentration within the single and the double polar cap. As we have seen, the eigenfunctions on a domain $R$ are identical to those on a complementary spherical domain $R'$, but with their ordering indices reversed. Identifying $R$ with the polar caps, rather than their complement, the belt, as we do – in this section and the one that follows only – greatly simplifies the equations.

4.1 Concentration within an axisymmetric polar cap

When the region of concentration is a circularly symmetric cap of colatitudinal radius $\Theta$, centered on the north pole, i.e.

$$R = \{ \theta : 0 \leq \theta \leq \Theta \},$$  

(50)

of area $A = 2\pi (1 - \cos \Theta)$, the matrix elements of eq. (33) reduce to

$$D_{lm, l'm'} = 2\pi \delta_{mm'} \int_{0}^{\Theta} X_{lm} X_{l'm'} \sin \theta d\theta. \quad (51)$$

The Kronecker delta $\delta_{mm'}$ renders the matrix $D$ of eq. (33) block-diagonal,

$$D = \text{diag} \left( D^{0}, D^{1}, D^{1}, \ldots, D^{L}, D^{L} \right), \quad (52)$$

where every submatrix $D^{m} \neq D^{0}$ occurs twice due to the double degeneracy of $\pm m$. Rather than solving the complete $(L + 1)^{2} \times (L + 1)^{2}$ eigenvalue equation (33), we may solve a series of $(L - m + 1) \times (L - m + 1)$ spectral-domain eigenvalue problems, one for each non-negative order $m$, where we have dropped the superscript identifying the order.

$$D_{l' ml} = \lambda_{l'} g_{l'}, \quad (53)$$

and the fixed-order matrix $D$ is of the form

$$D = \begin{pmatrix} D_{mm} & \cdots & D_{mL} \\ \vdots & \ddots & \vdots \\ D_{Lm} & \cdots & D_{LL} \end{pmatrix}, \quad (55)$$

where, for a particular order $0 \leq m \leq L$,

$$D_{l'l} = 2\pi \int_{0}^{\Theta} X_{lm} X_{l''m} \sin \theta d\theta. \quad (56)$$

Various methods exist to evaluate the elements of eq. (56). Wieczorek & Simons (2005) Simons et al. (2006). The important point is that, while symmetric, and banded, the matrix $D$ is never sparse. Its construction thus requires on the order of $(L - m + 1)^{2}/2$ integrals each.

We rank the $L - m + 1$ eigenvalues $\lambda_{1}, \lambda_{2}, \ldots, \lambda_{L-m+1}$ obtained by solving the fixed-order problem (53) so that

$$1 > \lambda_{1} \geq \lambda_{2} \geq \cdots \geq \lambda_{L-m+1} > 0,$$  

(57)

and orthonormalize the eigenvectors $g_{1}, g_{2}, \ldots, g_{L-m+1}$ as in eq. (34). The associated bandlimited eigenfunctions $g_{1}(\theta), g_{2}(\theta), \ldots, g_{L-m+1}(\theta)$, are given by

$$g = \sum_{l=m}^{L} g_{l} X_{lm}, \quad g_{l} = 2\pi \int_{0}^{\Theta} g X_{lm} \sin \theta d\theta, \quad (58)$$

and satisfy the colatitudinal orthogonality relations

$$2\pi \int_{0}^{\Theta} g_{\alpha} g_{\beta} \sin \theta d\theta = \delta_{\alpha \beta}, \quad (59a)$$

$$2\pi \int_{0}^{\Theta} g_{\alpha} g_{\beta} \sin \theta d\theta = \lambda_{\alpha} \delta_{\alpha \beta}. \quad (59b)$$

The optimally concentrated spatial eigenfunctions $g(\hat{r})$ for a given order $-L \leq m \leq L$ are expressed in terms of the fixed-order colatitudinal eigenfunctions (53) by

$$g(\hat{r}, \phi) = \begin{cases} \sqrt{2} g(\theta) \cos m\phi & \text{if } -L \leq m < 0 \\ g(\theta) & \text{if } m = 0 \\ \sqrt{2} g(\theta) \sin m\phi & \text{if } 0 < m \leq L. \end{cases} \quad (60)$$

The fixed-order Shannon number

$$K_{m} = \sum_{\alpha=1}^{L-m+1} \lambda_{\alpha}, \quad (61)$$

again is simply the trace of the fixed-order matrix $D$.

We further note that the complementary fixed-order matrices are given by

$$\bar{D}_{l'l'} = \delta_{l'l} - D_{l'l}. \quad (62)$$

The eigenfunctions of the fixed-order matrix $D$ are identical
to those of \( D \) but appear in reverse order, and their eigenvalues sum to one. The axisymmetric inversion formula analogous to eq. (42) is

\[
\sum_{l''=0}^{L} D_{ll''}^{-1} D_{l''l} = \delta_{ll'},
\]

and the axisymmetric analog to eq. (49) is

\[
\sum_{l''=m}^{\infty} D_{ll''}^{m} D_{l''l}^{m} = D_{ll}^{m}.
\]

### 4.2 Concentration within a double polar cap

When the region of concentration is a pair of axisymmetric antipodal caps of colatitudinal radius \( \Theta \), i.e., when

\[
R = \{ \theta : 0 \leq \theta \leq \Theta \} \cup \{ \theta : \pi - \Theta \leq \theta \leq \pi \},
\]

of area \( A = 4\pi (1 - \cos \Theta) \), the reflection symmetry

\[
X_{lm}(\pi - \theta) = (-1)^{l+m} X_{lm}(\theta)
\]

checks the fixed-order matrices \( D \) with zeroes, following

\[
D_{ll'} = 2\pi \left[ 1 + (-1)^{l+l'} \right] \int_0^\pi X_{lm} X_{l'm} \sin \theta d\theta.
\]

Comparison of eqs (56) and (67) reveals that the eigenfunctions of the double-cap problem can be trivially obtained from the kernels belonging to the single polar cap.

The spherical Slepian functions resulting from the diagonalization of the double-cap kernel in eq. (67) are either even or odd across the equator. Indexing their parity by \( p \), even \((p = e)\) or odd \((p = o)\), we modify eq. (58) to explicitly skip every other degree by using a primed summation symbol,

\[
g_p = \sum_{l=m_p}^{L_p} g_{l}^' X_{lm},
\]

where the lower limit \( m_p \) is given by

\[
m_e = m \quad \text{and} \quad m_o = m + 1,
\]

and the upper limit \( L_p \) is

\[
L_e = \begin{cases} L & \text{if } m \text{ and } L \text{ have the same parity} \\ L-1 & \text{opposite} \end{cases}
\]

\[
L_o = \begin{cases} L-1 & \text{if } m \text{ and } L \text{ have the same parity} \\ L & \text{opposite} \end{cases}
\]

In this formalism, the coefficients that are required for \( g_e \) are \( g_{m}, g_{m+2}, \ldots, g_{L} \) if \( m \) and \( L \) are both even or both odd, and \( g_{m}, g_{m+2}, \ldots, g_{L-1} \) if \( m \) and \( L \) are of opposite parity. Likewise, the coefficients of \( g_o \) are \( g_{m+1}, g_{m+3}, \ldots, g_L \) if \( m \) and \( L \) are both even or both odd, and \( g_{m+1}, g_{m+3}, \ldots, g_{L-1} \) if \( m \) and \( L \) have opposite parity. Eqs (66) and (68) then confirm that

\[
g_e(\theta) = g_e(\pi - \theta) \quad \text{and} \quad g_o(\theta) = -g_o(\pi - \theta).
\]

While an equation of the form (53) returns an alternation of even and odd functions with decreasing eigenvalues \( \lambda \), the indices of the matrix \( D \) may be permuted to form a block-diagonal form

\[
D = \text{diag}(D_e, D_o),
\]

for which the half-size separate eigenvalue equations

\[
D_e g_e = \lambda_e g_e \quad \text{and} \quad D_o g_o = \lambda_o g_o
\]

return exclusively even or odd solutions. This avoids round-off problems and speeds up the diagonalization.

The slight perversity of our notation is that, in an all-even or all-odd approach as in eq. (73), writing the fixed-order coefficient \( g_l \) or indeed any expression involving the spherical harmonic degree \( l \), always has to be accompanied by the set of allowable degrees \( l \), since \( l = m_p, m_p + 2, \ldots, L_p \), depending on the parity.

### 5.1 A commuting operator for the single polar cap

In the case of the single symmetric polar cap, eq. (47) can be rewritten as a series of fixed-order integral equations

\[
\int_0^\Theta D(\theta, \theta') h(\theta') \sin \theta' d\theta' = \lambda h(\theta), \quad 0 \leq \theta \leq \Theta.
\]

each with an \( m \)-dependent, separable, symmetric kernel

\[
D(\theta, \theta') = 2\pi \sum_{l=m}^{L} X_{lm}(\theta) X_{lm}(\theta').
\]

Building on the results derived by Gilbert & Slepian (1977), Grünbaum et al. (1982) found a second-order differential operator that commutes with the convolutional integral operator of eq. (74). For any \( 0 \leq m \leq L \), it is of the form

\[
T = (\cos \Theta - \cos \theta) \nabla^2_m + \sin \theta \frac{d}{d\theta} - L(L + 2) \cos \theta,
\]

where \( \nabla^2_m = d^2/d\theta^2 + \cot \theta (d/d\theta) - m^2(\sin \theta)^{-2} \) is the fixed-order Laplace-Beltrami operator. The proof of the commutation relation is sketched in Simons et al. (2006).
Since commuting operators have identical eigenfunctions, the \( \text{spacelimited, fixed-order eigenfunctions } h(\theta) \) can be found by solving the differential eigenvalue equation
\[
T h(\theta) = \chi h(\theta), \quad 0 \leq \theta \leq \Theta,
\]
where \( \chi \neq \lambda \) is the associated Grünbaum eigenvalue.

Grünbaum’s operator is a Sturm-Liouville operator (Simons et al. 2006). Thus, eq. (77) has a simple and easily sorted spectrum, with an infinite number of distinct eigenvalues \( \chi_1, \chi_2, \ldots \) having an accumulation point at infinity. The rank orderings of the eigenvalues \( \chi_1, \chi_2, \ldots \) and the spatio-spectral concentration factors \( \lambda_1, \lambda_2, \ldots, \lambda_{L-m+1} \) are reversed, so that the eigenfunction \( h_1(\theta) \) associated with the numerically smallest eigenvalue \( \chi_1 \), which has no nodes in the polar cap \( 0 \leq \theta \leq \Theta \), is the best concentrated fixed-order eigenfunction; \( h_2(\theta) \), which has exactly one node, is the next best concentrated, and so on.

Extending the domain of eq. (77) to the entire domain \( 0 \leq \theta \leq \pi \) transforms the unknown functions from the spacialimited functions \( h \) again into the bandlimited functions \( g \). Eq. (78) is then equivalent to the algebraic eigenvalue equation
\[
T g = \chi g,
\]
where \( T \) is the \( (L - m + 1) \times (L - m + 1) \) matrix with coefficients
\[
T_{ll'} = 2\pi \int_0^\pi X_{lm}(\theta) X_{l'm}(\theta) \sin \theta d\theta.
\]
Eqs (78)–(79) are completely equivalent to eqs (53) and (56). Both matrices \( D \) and \( T \) are symmetric, \( D = D^T \) and \( T = T^T \). In addition, they commute, \( DT = TD \), so they have identical eigenvectors. In index notation,
\[
\sum_{n=1}^{L} D_{ln} T_{nl'} = \sum_{n=1}^{L} T_{ln} D_{nl'},
\]
which can be used as a numerical check.

There are a number of ways to evaluate the elements of the Grünbaum matrix in eq. (79), but the important result is that \( T \) is tridiagonal (Simons et al. 2006):
\[
T_{ll} = -l(l+1) \cos \Theta,
\]
\[
T_{l(l+1)} = \frac{[l(l+2)-L(L+2)]}{\sqrt{(l+1)^2-m^2}} \frac{2l+3}{2l+5} [l(l+1)^2-m^2]
\]
\[
\times \left[ 3 - \frac{2}{3} \frac{3m^2 - l(l+1)}{(2l+3)(2l-1)} \right],
\]
\[
T_{ll'} = 0 \quad \text{otherwise}.
\]

Eq. (78) can be used to find the \( (L - m + 1) \)-dimensional eigenvectors \( g \) and thus the optimally concentrated polar cap eigenfunctions \( g(\theta) \) by numerical diagonalization of a tridiagonal matrix \( T \) with analytically prescribed elements and a spectrum of eigenvalues \( \chi \) that is guaranteed to be regular. Unlike the diagonalization of the original matrix \( D \) in eq. (53), this procedure enables the stable computation of bandlimited functions that are optimally concentrated in a large rather than a small region of the unit sphere, as may be the case in geodesy.

### 5.2 A commuting operator for the double polar cap

Knowing that the solutions to the concentration problem for the double polar cap are either even or odd across the equator, we may write the integral equation (74), by analogy with eq. (78), as follows. Indicating the parity of the solutions by the subscript \( e \) or \( o \), which takes the values \( p = e \) for the even solutions and \( p = o \) for the odd solutions, it can be seen that
\[
\int_0^\Theta D_p(\theta, \theta') h_p(\theta') \sin \theta' d\theta' = \lambda h_p(\theta),
\]
which is valid inside the double antipodal polar cap \( \{ \theta : 0 \leq \theta \leq \Theta \} \cup \{ \theta : \pi - \Theta \leq \theta \leq \pi \} \), and where the \( m \)-dependent kernel, analogous to eq. (78), is
\[
D_p(\theta, \theta') = 4\pi \sum_{l=m}^L X_{lm}(\theta) X_{l'm}(\theta').
\]
As in eq. (68), the primed summation skips every second entry, and the lower and upper limits are as in eqs (69)–(70).

Again basing ourselves on the results of Gilbert & Slepian (1977) and Grünbaum et al. (1983), we show in Appendix A that a Sturm-Liouville second-order differential operator that commutes with the convolutional integral operators of eq. (82) is of the form
\[
T_p = (\cos^2 \Theta - \cos^2 \theta) \nabla_m^2 + 2 \cos \theta \sin \theta \frac{d}{d\theta}
\]
\[- L_p (L_p + 3) \cos^2 \theta.
\]
The individual matrix operators \( T_p \) are once again tridiagonal and symmetric and commute with the even or odd \( D_p \) of eq. (78). The bandwidth \( L_p \) is the same as in (70). The elements of the double-cap Grünbaum matrices are
\[
T_{ll}^p = -l(l+1) \cos^2 \Theta + \frac{2}{2l+3} \left[ (l+1)^2 - m^2 \right]
\]
\[- [l(l-2)(l+1) - L_p(L_p+3)]
\]
\times \left[ 1 - \frac{2}{3} \frac{3m^2 - l(l+1)}{(2l+3)(2l-1)} \right],
\]
\[
T_{ll+2}^p = \frac{[l(l+3) - L_p(L_p+3)]}{2l+3} \frac{2l+3}{2l+5} [l(l+1)^2-m^2]
\]
\times \left[ 3 - \frac{2}{3} \frac{3m^2 - l(l+1)}{(2l+3)(2l-1)} \right],
\]
\[
T_{ll'}^p = 0 \quad \text{otherwise}.
\]

We again emphasize that, since we focus our attention separately on the kernels returning even or odd eigenfunctions \( g_e \) or \( g_o \), the degrees involved are restricted to \( l, l' = m_p + 1, 2, \ldots, L_p \). Since every other degree in the matrix described by eq. (54) is skipped, both \( T_e \) and \( T_o \) are tridiagonal as in the single-cap case. As in eq. (74), we compute the even and odd eigenfunctions by separately solving
\[
T_e g_e = \chi_e g_e \quad \text{and} \quad T_o g_o = \chi_o g_o.
\]
(87)

Subsequently, we establish a single rank order of decreasing spatio-spectral concentration: either per order, as in eq. (74), or across all orders, as in eq. (68).
Slepian functions and the polar gap

Figure 2. Colatitudinal dependence of the first six fixed-order, \( m = 0 \rightarrow 4 \), eigenfunctions \( g_\alpha(\theta) \), \( \alpha = 1 \rightarrow 6 \), bandlimited to \( L = 18 \), that are well concentrated in the latitudinal belt extending \( \pm 60^\circ \) on either side of the equator. The quality of the spatial concentration is expressed by the labeled eigenvalues \( \lambda_\alpha \). None of the plotted functions show appreciable energy inside the complementary pair of antipodal polar caps of radius \( \Theta = 30^\circ \).

Figure 3. Colatitudinal dependence of the last six fixed-order, \( m = 0 \rightarrow 4 \), eigenfunctions \( g_\alpha(\theta) \), \( \alpha = L - m + 1 \rightarrow L - m - 4 \), bandlimited to \( L = 18 \). These are generally poorly concentrated in the latitudinal belt \( \pm 60^\circ \) about the equator, except where the rank \( \alpha \) exceeds the fixed-order Shannon number \( K_m \) (examples in lower right). The functions that have the least energy inside of the equatorial belt, as shown by their low eigenvalues \( \lambda_\alpha \), are best concentrated inside the complementary polar caps of colatitudinal radius \( \Theta = 30^\circ \).
Figure 4. Three-dimensional spatial dependence of the first four fixed-order, $m = 0 \rightarrow 2$, eigenfunctions $g_\alpha(\theta)$, $\alpha = 1 \rightarrow 4$, bandlimited to $L = 18$, well concentrated in the latitudinal belt extending $\pm 60^\circ$ on either side of the equator, as expressed by their eigenvalues $\lambda_\alpha$. Plot arrangement is as in Figure 2.

Figure 5. Three-dimensional spatial dependence of the last four fixed-order, $m = 0 \rightarrow 2$, eigenfunctions $g_\alpha(\theta)$, $\alpha = L - m + 1 \rightarrow L - m - 2$, bandlimited to $L = 18$, poorly concentrated in the belt $\pm 60^\circ$ about the equator, as expressed by their eigenvalues $\lambda_\alpha$. Plot arrangement is as in Figure 2.
6 A SLEPIAN BASIS ON THE BELT

Concentration within a single polar cap was treated extensively by [Wieczorek & Simons, 2003] and [Simons et al., 2006]. We refer to their figures for illustrations. In this section we illustrate the solutions to the concentration problem when the concentration region contains all but an antipodal pair of polar caps of radius $\Theta$. Reverting to our notational convention in Section 2, we again use $R$ to denote an equatorial strip or latitudinal belt extending $\pi/2 - \Theta$ north and south of the equator. Consequently, the antipodal pair of polar caps themselves is again defined to be the excluded region $R$, in line with their role as the geodetic polar gap in which no satellite observations are available.

6.1 Spatial-domain solutions

The six eigenfunctions $g_{\alpha}(\theta)$, $\alpha = 1 \rightarrow 6$ of fixed order $0 \leq m \leq 4$ that are most optimally concentrated in the latitudinal belt complementing a $\Theta = 30^\circ$ double polar cap are plotted in Figure 2. Their associated eigenvalues $\lambda_{\alpha}$ are listed to six-figure accuracy. The latitudinal belt ranges from $60^\circ$ north to $60^\circ$ south symmetrically about the equator. With the chosen bandwidth $L = 18$, the Shannon number defined in eq. (43) is $K = (L + 1)^2 \cos \Theta \approx 313$, which approximates the number of well concentrated eigenfunctions with $\lambda \approx 1$. The best concentrated eigensolution of every order is a bell-shaped even function with no nodes in the belt. In keeping with the Sturm-Liouville character of the Grünbaum operator, every subsequent solution acquires one more node, so that the second best of every order is an odd function, the third is even, and so on. All of the eigenvalues shown in Figure 2, calculated by numerically integrating eq. (28), are equal to one within six-figure accuracy, indicating that the concentration to the belt is nearly perfect, while both poles are almost completely excluded. Since the concentration region is very large, the calculation of these functions by any means other than the Grünbaum procedure described above will fail.

With the parameters unchanged from Figure 2, Figure 3 shows the six worst concentrated eigenfunctions on the belt, $g_{\alpha}(\theta)$, $\alpha = L - m + 1 \rightarrow L - m - 4$. These now naturally have almost all of their energy inside of the antipodal pair of polar caps of radius $\Theta = 30^\circ$. For the zonal functions of order $m = 0$, the even-odd alternation starting at $\alpha = 1$ with an even function in Figure 2 ends at $\alpha = L + 1$ with an even function, since $L$ itself is even. At $m = 1$, the sequence starts with an even function but ends at $\alpha = L$ with an odd function, at $m = 2$ with an even function at $\alpha = L - 1$, and so on. Thus, the worst concentrated $m = 0$ eigenfunction is even about the equator, the worst $m = 1$ eigenfunction is odd, and so on, in a pattern that alternates with increasing order. Had $L$ itself been odd, the worst concentrated zonal function would have been odd, the worst $m = 1$ function even, and so on, reversing the pattern.

Three-dimensional perspective views of the first four of the fixed-order $m = 0 \rightarrow 2$ functions whose colatitudinal dependence we plotted in Figure 2 are shown in Figure 4. In accordance with eq. (40) the zonal $m = 0$ eigenfunctions do not display any longitudinal zero crossings, since the number of longitudinal nodes follows the order $m$. Similarly, in Figure 5 we plot a three-dimensional rendering of twelve of the worst concentrated eigenfunctions of Figure 3.

In Figure 6 we show the eigenvalue-weighted pointwise sums of squares $\sum_{\alpha} \lambda_{\alpha} g_{\alpha}^2(\theta, \phi)$ for latitudinal belts complementing double polar caps of radii $\Theta = 5^\circ, 10^\circ, 15^\circ, 20^\circ$. The Shannon numbers are $K = 360, 356, 349$ and 339. The sums of squares $g_1^2(\theta, \phi) + g_2^2(\theta, \phi) + \cdots$ and $\lambda_1 g_1^2(\theta, \phi) + \lambda_2 g_2^2(\theta, \phi) + \cdots$ are plotted versus colatitude $\theta$, along a fixed arbitrary meridian $\phi$. Dashed lines show the full unweighted sums of $(L + 1)^2$ terms, which attain the constant value $K/A$ over the entire sphere $0^\circ \leq \theta \leq 180^\circ$. Solid lines show the eigenvalue-weighted partial sums of $K$ terms and the full sums of $(L + 1)^2$ terms, which are nearly equal, and concentrated uniformly inside of the belt $\Theta \leq \theta \leq 180^\circ - \Theta$.

In Figure 7 we show the eigenvalue-weighted pointwise sums of squares $\sum_{\alpha} \lambda_{\alpha} g_{\alpha}^2(\theta, \phi)$ for latitudinal belts complementing double polar caps of radii $\Theta = 5^\circ, 10^\circ, 15^\circ, 20^\circ$, with a bandwidth $L = 18$. The cumulative sums are con-
Figure 8. Eigenvalue spectra of the mixed-order $L = 18$ bandlimited operators concentrating within the equatorial belts that complement antipodal pairs of axisymmetric caps of radius $\Theta = 5^\circ, 10^\circ, 15^\circ$ and $20^\circ$. The total number of eigenvalues is $(L + 1)^2 = 361$; only $\lambda_1 \to \lambda_{10}$ and $\lambda_{12} \to \lambda_{361}$ are shown. Different symbols are used for the various orders $-18 \leq m \leq 18$; juxtaposed identical symbols are $\pm m$ doubles. Top labels specify the rounded Shannon numbers $K = 360, 356, 349$ and 339.

6.2 Eigenvalue spectra

In Figure 8 we show the reordered, mixed-order eigenvalue spectra for the concentration problem within the latitudinal belt between polar caps of colatitudeal radii $\Theta = 5^\circ, 10^\circ, 15^\circ, 20^\circ$. Once again the maximal spherical harmonic degree is $L = 18$. The rounded Shannon numbers $K = 360, 356, 349, 339$ lie in the middle of the steep, transitional part of the spectra, roughly the cap eigenfunctions, shown in Figure 7 are concentrated within the double polar cap. The full unweighted sums $\sum_{\omega} g_m^k(\theta, \phi)$ of all $(L + 1)^2$ terms (dashed black lines) are exactly $K/A = (L + 1)^2/(4\pi)$ over the entire sphere in accordance with eq. (44), and the expectation in eq. (45) is confirmed: inside of the concentration domain, the weighted sums approach $K/A$.

6.3 Analytic continuation

The Slepian functions $g_1(\hat{r}), \ldots, g_{(L+1)^2}(\hat{r})$ are defined on the surface of the unit sphere $\Omega$. Together, they form a natural basis set for the expansion of potential fields and, in particular, estimates of these fields, on a sphere of radius $||\hat{r}|| = 1$, as in eqs. (20)–(21). This new basis is localized: the support of the first Shannon number $K$ basis functions lies mostly in the concentration region $R$, whereas the remainder are concentrated outside of this area of interest, in $\bar{R}$. With satellite observations we are of course mostly interested in the signal at some height above the surface of the unit sphere. We have previously derived an expression for the expansion of a field estimate at satellite altitude $\alpha$, in eq. (27). It is immediately obvious from this equation that, even if we were only interested in the first $K$ upward continued Slepian expansion coefficients of the estimate, we would still need to know and calculate the full set of $(L + 1)^2$ coefficients at zero altitude.
The full impact of this statement will not become clear until later in this paper, but to anticipate it we derive here a set of Slepian basis functions that are designed specifically to represent signals at an altitude. We can do this by interpreting the Slepian functions we have just constructed as potential functions themselves. In that case their upward harmonic continuation onto a sphere larger radius \( r > a \) yields new functions \( g_\uparrow \) for which

\[
\begin{align*}
g_\uparrow &= \sum_{lm} g_{\uparrow lm} Y_{lm}, \\
g_{\uparrow lm} &= (1 + a)^{-l-1} g_{lm}.
\end{align*}
\]

Had we instead defined the Slepian functions on the larger sphere to begin with, their analogues downward continued onto the unit sphere would be obtained as

\[
\begin{align*}
g_\downarrow &= \sum_{lm} g_{\downarrow lm} Y_{lm}, \\
g_{\downarrow lm} &= (1 + a)^l g_{lm}.
\end{align*}
\]

It is thus useful to define a symmetric, \((L+1)^2 \times (L+1)^2\), upward continuation matrix \( A \), whose elements

\[
A_{lm,l'm'} = (1 + a)^{l'-l} \delta_{l,l'} \delta_{m,m'},
\]

which allows us to restate the equations relating the upward and downward continued coefficients to each other concisely as:

\[
\begin{align*}
g_\uparrow &= A^{-1} g, \\
g_\downarrow &= A g.
\end{align*}
\]

The orthogonality relations of eqs \(23\) and \(34\) can be rewritten in terms of \( g_\downarrow \) and \( g_\uparrow \) in the form

\[
\begin{align*}
g_{\uparrow \alpha} A^2 g_{\downarrow \beta} &= \delta_{\alpha \beta}, \\
g_{\downarrow \alpha} A g_{\uparrow \beta} &= \lambda_{\alpha} \delta_{\alpha \beta},
\end{align*}
\]

and also

\[
\begin{align*}
g_{\uparrow \alpha} A g_{\downarrow \beta} &= \delta_{\alpha \beta}, \\
g_{\downarrow \alpha} A^2 g_{\uparrow \beta} &= \lambda_{\alpha} \delta_{\alpha \beta}.
\end{align*}
\]

In this matrix notation we repeat eq. \(27\) as

\[
\hat{s}_{\uparrow \alpha} = \sum_{\beta=1}^{(L+1)^2} \left( g_{\uparrow \alpha}^T A^{-1} g_{\downarrow \beta} \right) \hat{s}_\beta.
\]

We note for future reference that, although the transformation matrix \( g_{\uparrow \alpha} A^{-1} g_{\downarrow \beta} \) may be banded, it is not in general possible to truncate it to circumvent having to calculate the full set of \( \hat{s}_\beta \) even if we are only interested in a truncated set of coefficients \( \hat{s}_{\uparrow \alpha} \).

Finally, eq. \(23\) and eqs \(88\)–\(94\) can now be combined to prove the equivalent results:

\[
\sum_{\alpha=1}^{(L+1)^2} s_{\alpha} g_{\alpha} = \sum_{\alpha=1}^{(L+1)^2} \hat{s}_{\uparrow \alpha} g_{\downarrow \alpha} = \sum_{\alpha=1}^{(L+1)^2} \hat{s}_{\downarrow \alpha} g_{\uparrow \alpha},
\]

which we use extensively in subsequent sections.

7 POTENTIAL FIELD ESTIMATION

We return to solving the geodetic problem stated in Section 2. We are given noisy data, \( d \), taken by a satellite at an altitude, \( a \), over an incomplete sampling domain, \( R \), and attempting to estimate the potential field, \( s \), that gives rise to these observations, at its source level on the unit sphere, \( \Omega \). Although the source field has an infinite bandwidth, we will practically only be able to make bandlimited estimates of it, which we denote by \( \hat{s} \). The spectral limitation to the bandwidth \( L \) as well as the spatial restriction of the observation domain to the region \( R \) motivates our seeking an estimate in terms of a set of basis functions that are spatiotemporally concentrated, rather than using the non-localized spherical harmonics \( Y_{lm} \) of more conventional approaches. This new function set is the Slepian basis, \( g_\alpha \), constructed in Sections \(26\) in a variety of geometries, but most notably for the axisymmetric case of a latitudinal belt around the equator, and its complement the double polar cap, representative of the polar gap in geodesy.

That the geodetic estimation problem is essentially a problem of spatiotemporal localization can be understood by considering a naive – and in practice unsuitable – estimation scheme. Suppose we construct estimate in the form of eq. \(23\).

\[
\hat{s} = \sum_{lm} \hat{s}_{lm} Y_{lm},
\]

by minimizing its aggregate squared misfit with the data over the sphere, given by eq. \(15\). This amounts to solving the variational problem

\[
\Phi = \int_R (\hat{s} - d)^2 \, d\Omega = \text{minimum},
\]

where the integration domain is the region \( R \) in which observations are available. Substituting eqs \(15\) and \(25\) into eq. \(27\) and requiring the partial derivatives \( \partial \Phi / \partial \hat{s}_{lm} \) to vanish yields the condition

\[
\int_R \hat{s}_{lm} Y_{lm} \, d\Omega = \int_R d Y_{lm} \, d\Omega,
\]

or

\[
\hat{s}_{lm} = \frac{1}{d_{lm}},
\]

where

\[
\begin{align*}
d_{lm} &= \int_R d Y_{lm} \, d\Omega, \\
d_{lm} &= \int_R d Y_{lm} \, d\Omega.
\end{align*}
\]
8 SPHERICAL HARMONIC SOLUTION

We have seen that a naive least-squares solution to the geodetic inverse problem in the spherical harmonic basis yields a solution (99) that is dependent on the inverse of the localization matrix and therefore in general impossible to stably compute. One of the many approaches to circumvent this difficulty is by adding a model norm to the penalty function (e.g. Hoerl & Kennard 1970; Marquart 1974; Jackson 1974; eq. 47) only minimized the norm of the data misfit. In this section we discuss the solution to this so-called damped least-squares approach.

8.1 Damped least-squares approach

To stabilize the solution we amend the variational problem of eq. (97) by including a weighted model norm:

$$\int_R (s_t - d)^2 d\Omega + \eta \int_R s_t^2 d\Omega = \text{minimum},$$  \hspace{1cm} (104)

where \(\eta \geq 0\) is a damping parameter. Retaining the spherical harmonic basis, once again we supply the bandlimited estimate

$$\hat{s} = \sum_{lm} \hat{s}_{lm} Y_{lm},$$  \hspace{1cm} (105)

and minimize (104) with respect to the unknown coefficients \(\hat{s}_{lm}\). After minimal algebra, involving eqs (25) and (46–47), we obtain the spectral-domain solution,

$$\hat{s}_{lm} = (1 + a)^{l+1} \sum_{l'm'} D_{lm,l'm'}^{-1} \int_R \hat{Y}_{l'm'} d\Omega, \hspace{1cm} (106)$$

which only holds at the degrees \(l \leq L\), since, when \(l > L\), no estimate is available, \(\hat{s}_{lm} = 0\). The case where \(a = 0\) and \(\eta = 1\), for which, from eq. (104), \(D + \eta = 1\), the identity matrix, was treated in some detail by Sneeuv & van Gelderen (1997). The integral over the data in eq. (106) is made explicit by substituting eq. (15) and using eqs (25) and (33) once again:

$$\int_R dY_{lm} d\Omega = \sum_{l'm'} D_{lm,l'm'} s_{l'm'} + \int_R n Y_{lm} d\Omega. \hspace{1cm} (107)$$

Comparing eq. (106) to eq. (99), we now require the inverse of the weighted sum of the operator localizing to \(R\) and the complementary operator localizing to the region of missing data \(\bar{R}\). The addition of the small quantity \(\eta D\) to the original matrix \(D\) improves its condition number. We postpone a discussion on determining the ideal value of the weighting parameter \(\eta\) but it is clear that the estimate of the field coefficients \(\hat{s}_{lm}\) in the form of eq. (106) is now computable.

In order to ascertain the statistical properties (106–108) of the new estimate (106–107) we first calculate the average of this estimate over all realizations of the noise. From eq. (16), this ensemble averaging of eqs (106–107) annihilates the random noise term, and we obtain

$$\langle \hat{s}_{lm} \rangle = (1 + a)^{l+1} \sum_{l'm'} (D_{lm,l'm'} + \eta \bar{D}_{lm,l'm'})^{-1} \times \sum_{l''m''} D_{l''m'',l'm'} s_{l''m''}. \hspace{1cm} (108)$$

Again, the coefficients \(\hat{s}_{lm}\) are defined only in the degree range \(l \leq L\). We note that, were the source signal to be similarly bandlimited, the coefficients \(\hat{s}_{lm}\) obtained by undamped (\(\eta = 0\)) estimation would be equal to the true source coefficients \(s_{lm}\). This follows directly from substituting the leftmost term of eq. (16) into eq. (108) and using eqs (15) and (47). The addition of the damping term (\(\eta > 0\)) biases...
the estimate away from the truth, hence the name “biased estimation” for this procedure (Hoerl & Kennard 1970b). It is the price we pay to be able to calculate the estimate at all.

There are other benefits as well. These are most easily seen by computing a spatial-domain representation of the estimate using the Slepian basis, as in eq. (24). Making use of the equivalence (95), we write for the (bandlimited) estimate

$$\hat{s} = \sum_{\alpha=1}^{(L+1)^2} \hat{s}^{\alpha} g_{L,\alpha}, \quad (109)$$

noting that the upward continued coefficients \(\hat{s}^{\alpha}\) in the Slepian basis are calculated according to eq. (27), and the downward continued Slepian basis functions according to eq. (89). A Slepian basis expansion of the (broadband) observations, combining eqs (15) and (25), is given by

$$d = \sum_{\alpha=1}^{(L+1)^2} s^{\alpha} g_{L,\alpha} + \sum_{l m > L} s_{l m} Y_{l m} + n. \quad (110)$$

This equation allows us to find an alternative expression for the data integral (107), for which we also use eqs (22), (35) and the double orthogonality of the Slepian functions (35), namely

$$\int_R d Y_{l m} d \Omega = \sum_{\alpha=1}^{(L+1)^2} g_{L,\alpha} \left( \lambda_{\alpha} s^{\alpha} + \int_R n g_{L,\alpha} d \Omega \right)$$

$$+ \sum_{l m' > L} D_{l m l m'} s^{\alpha} Y_{l m} Y_{l m'}. \quad (111)$$

Inserting eqs (27), (106) and (111) into eq. (109) and using the expressions (41) and (48) yields the spatial-domain estimate of the field as

$$\hat{s}(\vec{r}) = \sum_{\alpha=1}^{(L+1)^2} \lambda_{\alpha}^*(\eta) g_{L,\alpha}(\vec{r})$$

$$\times \left( \lambda_{\alpha} s^{\alpha} + \int_R n g_{L,\alpha} d \Omega + \sum_{l m > L} h_{L,\alpha} s^{\alpha} Y_{l m} \right), \quad (112a)$$

$$\lambda_{\alpha}^*(\eta) = \frac{1}{\lambda_{\alpha} + \eta(1 - \lambda_{\alpha})}. \quad (112b)$$

We have introduced the symbol \(\lambda_{\alpha}^*(\eta)\) for notational convenience. In the absence of damping, \(\lambda_{\alpha}^*(0) = \lambda_{\alpha}^{-1}\), i.e. the inverse of the concentration eigenvalue. Here, too, the necessity of damping is readily apparent: as the eigenvalues of the concentration operator, \(\lambda_{\alpha}\), become vanishingly small, their inverse grows exponentially, inflating the noise term and the term containing the signal at the unmodeled degrees \(l > L\), and rendering the stable computation of the estimate (114) impossible. Adding the damping factor is a useful way to prevent this.

The zero mean of the stochastic noise, eq. (16), guarantees that the ensemble average of the spatial estimate over all realizations of the noise is given by

$$\langle \hat{s}(\vec{r}) \rangle = \sum_{\alpha=1}^{(L+1)^2} \lambda_{\alpha}^*(\eta) g_{L,\alpha}(\vec{r})$$

$$\times \left( \lambda_{\alpha} s^{\alpha} + \sum_{l m > L} h_{L,\alpha} s^{\alpha} Y_{l m} \right). \quad (113)$$

Eq. (113) can be combined with eqs (95) and (20) to show that for bandlimited source fields and in the absence of damping, the mean of the spatial estimate \(\langle \hat{s}(\vec{r}) \rangle\) is identical to the source field \(s(\vec{r})\), even if the estimate \(\hat{s}(\vec{r})\) is impossible to compute stably without the damping term.

The introduction of the damping term stabilizes the solution at the cost of added bias. Following eq. (101) the latter is calculated by subtracting the full representation of the signal (20) from eq. (113), making use of eqs (48) and (95). The spatial estimation bias is then given by

$$\hat{b}(\vec{r}) = -\eta \sum_{\alpha=1}^{(L+1)^2} (1 - \lambda_{\alpha}) \lambda_{\alpha}^*(\eta) s^{\alpha} g_{L,\alpha}(\vec{r})$$

$$+ \sum_{\alpha=1}^{(L+1)^2} \lambda_{\alpha}^*(\eta) g_{L,\alpha}(\vec{r}) \sum_{l m > L} h_{L,\alpha} s^{\alpha} Y_{l m}$$

$$- \sum_{l m > L} s_{l m} Y_{l m}(\vec{r}). \quad (114)$$

We have brought forward the damping parameter \(\eta\) by using the identity \(\lambda^* \lambda - 1 = -\eta(1 - \lambda) \lambda^*\). In the absence of damping \((\eta = 0)\), the first term in this equation vanishes, leaving us with the unavoidable broadband leakage (the second term) and bias due to making bandlimited estimates of broadband fields (the third term).

An expression for the estimation variance from (104) is obtained by squaring eq. (112) and averaging the result, using the properties of the noise (16–17) and eq. (45), and subtracting from the result the square of eq. (113). The spatial estimation variance is

$$\nu(\vec{r}) = N \sum_{\alpha=1}^{(L+1)^2} \lambda_{\alpha} \lambda_{\alpha}^*(\eta) g_{L,\alpha}^2(\vec{r}). \quad (115)$$

We note that eq. (115) is the only one thus far to assume that the power spectrum of the noise is white, of magnitude \(N\). And one more time the necessity of the damping is apparent: in its absence, the estimation variance strongly amplifies the measurement noise. At the price of introducing additional bias, damping prevents this.

### 8.2 A bandlimited white stochastic source

In the previous section we have derived expressions for the average estimate of the spherical harmonic field coefficients, \(\langle \hat{s}_{l m} \rangle\), in eq. (108), and for the average of spatial expansions of the estimated field, \(\langle \hat{s}(\vec{r}) \rangle\), in eq. (113). The averaging was over different realizations of the stochastic noise process. Both expressions are valid in the most general sense; the only condition being that the average over all realizations...
of the noise, \( \langle n(\hat{r}) \rangle \), is zero. No further assumptions are necessary. We have drawn attention to the fact that without the damping term, both estimates are nearly impossible to calculate. However, in that case, they are unbiased when the source signal itself is strictly bandlimited to within a bandwidth \( L \) identical to that of the ensemble of signals. We notice from eq. (124) that to compute \( \langle b^2 \rangle \) we shall require the covariance \( \langle s_\alpha s_\beta \rangle \) of the expansion coefficients of the field in the Slepian basis. To facilitate the treatment and for easy comparison with the assumed white power spectrum of the noise process, we shall consider a bandlimited source signal that is “whitish”, i.e. white within the band \( l \leq L \), such that its covariances in the spherical harmonic and Slepian bases, respectively, are given by

\[
\langle s_{lm} s_{lm'} \rangle = S \delta_{lm} \delta_{mm'},
\]

(123a)

\[
\langle s_\alpha s_\beta \rangle = S \delta_{\alpha \beta},
\]

(123b)

while noting that, as far as the spatial covariance of this signal concerned,

\[
\langle s(\hat{r}) s(\hat{r'}) \rangle = S D(\hat{r}, \hat{r'}) \neq S \delta(\hat{r}, \hat{r'}),
\]

(124)

can be deduced by combining eq. (12) with eq. (123) and using eqs (8, 9) and (65). A last assumption introduced here is that the noise is wholly uncorrelated with the signal:

\[
\langle s(\hat{r}) n(\hat{r}) \rangle = 0.
\]

(125)

The average of the squared bias term \( \langle b^2 \rangle \) under these idealized assumptions is

\[
\langle b^2(\hat{r}) \rangle = \eta^2 S \sum_{\alpha=1}^{(L+1)^2} (1 - \lambda_\alpha^2) |\lambda_\alpha^*(\eta)|^2 g_\alpha^2(\hat{r}),
\]

(126)

and the mean-square estimation error, following eq. (122), is formed by combining this result with the expression for the variance in eq. (115). The latter expression is unchanged even if the source signal is stochastic, as long as the noise is uncorrelated with the signal, eq. (126). Thus, the mean-square error of the bandlimited estimation of a bandlimited white source field from incomplete observations at an altitude in the presence of white noise is given by

\[
\langle \epsilon^2(\hat{r}) \rangle = N \sum_{\alpha=1}^{(L+1)^2} \lambda_\alpha |\lambda_\alpha^*(\eta)|^2 g_\alpha^2(\hat{r})
\]

(127)

\[
+ \eta^2 S \sum_{\alpha=1}^{(L+1)^2} (1 - \lambda_\alpha^2) |\lambda_\alpha^*(\eta)|^2 g_\alpha^2(\hat{r}).
\]

(127)

All \( (L+1)^2 \) basis functions are required to form the mse. The first term in the expression for the mse is the variance: it is the only term that depends on the noise. We have seen that without damping \( (\eta = 0) \) this term becomes unmanageably large: the addition of damping counteracts this. In addition, the estimation variance also varies with the observation height \( a \) above the unit sphere: as \( a \) grows, so do the downward continued Slepian basis functions \( g_\alpha(\hat{r}) \), and with them, the noise. The second term in the mse is due to bias. This is the only term that depends on the characteristics of the signal. It is independent of the satellite altitude at which the measurements are taken.
over the entire sphere; the solution to the geodetic estimation problem for a bandlimited white signal and white noise. The \( \Omega \)-average mse (grey curves and right ordinate) is the average over the region of observation, the equatorial belt complementary to the polar gap of radius \( \Theta = 10^\circ \). The bandwidth of the signal and its estimate is \( L = 45 \). The measurement altitude is \( a = 0 \). The signal-to-noise levels shown are \( S/N = 4, 6, 8 \) and 10. We plot the normalized average mse values as a function of the damping parameter \( \eta \), and indicate by vertical lines the values of \( \eta \) that minimize them. The range of the \( R \)-average is much reduced compared to the \( \Omega \)-average values. Both ordinates are truncated below at \( N/S \), the mse value when the observation region is the entire sphere, \( R = \Omega \).

### 8.3 Optimal damping level

To illustrate the behavior of the mse in eq. (127) we will focus on the case where the measurement altitude is \( a = 0 \), hence \( g_\alpha = g_{L \alpha} = g_{\alpha} \). This simplifies the expressions to:

\[
\langle e^2(\hat{r}) \rangle = \sum_{\alpha=1}^{(L+1)^2} R_\alpha(\eta) g_{\alpha}^2(\hat{r}),
\]

(128a)

\[
R_\alpha(\eta) = [\lambda_\alpha^2(\eta)]^2 [N\lambda_\alpha + \eta^2S(1 - \lambda_\alpha)^2].
\]

(128b)

The function \( R_\alpha(\eta) \) combines the effects of data noise, damping, signal strength, and measurement geometry. We will compare the mean-square error with the mean-square signal strength over all realizations, which is given by

\[
\langle s^2(\hat{r}) \rangle = S \frac{(L + 1)^2}{4\pi}.
\]

(129)

The result (129) is obtained by combining eq. (124) with the definition (35) at \( \hat{r} \cdot \hat{r} = 1 \). We calculate the following two quantities. First, a normalized spatial average of the mse given by the ratio of the mean square error (128) to the mean square signal strength (129), both averaged over the entire sphere \( \Omega \). Using the orthogonality conditions (35) this "\( \Omega \)-average mse" is given by

\[
\frac{\int_{\Omega} \langle e^2(\hat{r}) \rangle \, d\Omega}{\int_{\Omega} \langle s^2(\hat{r}) \rangle \, d\Omega} = \frac{1}{S(L + 1)^2} \sum_{\alpha=1}^{(L+1)^2} R_\alpha(\eta).
\]

(130)

Second, a scaled "\( R \)-average mse" is given by the ratio of the same quantities, averaged over the covered region \( R \). Using eq. (35) and the definition (43) of the Shannon number \( K \), it is

\[
\frac{\int_{R} \langle e^2(\hat{r}) \rangle \, d\Omega}{\int_{R} \langle s^2(\hat{r}) \rangle \, d\Omega} = \frac{1}{KS} \sum_{\alpha=1}^{(L+1)^2} \lambda_\alpha R_\alpha(\eta).
\]

(131)

Both quantities are shown in Figure 10 for a double-cap polar gap of \( \Theta = 10^\circ \) and a bandwidth \( L = 45 \). They are plotted in different panels for different signal-to-noise ratios \( S/N = 4, 6, 8 \) and 10 as functions of the damping parameter \( \eta = 0 \rightarrow 1 \). We show eq. (130) in black, with the scale on the left of the panels, and eq. (131) in grey, with the scale on the right hand side. The range of \( \Omega \)-average mse values shown is much larger (5% in all four panels) than the equivalent range in \( R \)-average mse values (0.4% in all panels): the effects of damping on the overall mse over the entire globe are much more pronounced than its effects on the mse averaged over the region in which data were collected. The ordinate is truncated to aid the visualization. The maximum \( R \)-average mse is \( (N/S)/(\cos \Theta) \) which is attained when \( \eta = 0 \). This can be verified by noting that \( R_\alpha(0) = N\lambda_\alpha^{-2} \), using the definition of the Shannon number (43), and noting that the area of the covered region is equal to \( A = 4\pi \cos \Theta \). Thus, at a given signal-to-noise ratio only the size of the polar gap controls the upper bound on the \( R \)-average mse. A lower bound for all damping levels is found at full coverage, \( R = \Omega \). It thus applies to both measures of the average mse. Indeed with-
out a polar gap, $\Theta = 0$, $K = (L + 1)^2$, $\lambda_\alpha(\eta) = \lambda_\alpha = 1$, $R_\alpha(\eta) = N$, and the scaled average mse curves never drop below $N/S$, which we use as a lower cutoff for the vertical axes.

A statistically desirable estimator (e.g. Cox & Hinkley 1974; Bendat & Piersol 2000) is one that is unbiased and efficient, i.e. it minimizes the mean square error. We have seen that sacrificing the unbiasedness by introducing damping removes the obstacles in computing the estimate in the first place, and reduces the estimation variance. We can calculate the damping level that is overall optimal by minimizing the mse (128) with respect to the damping parameter $\eta$. However, minimization of the $R$-average and $\Omega$-average mse will yield slightly different optima. Minimizing, eq. (130), the normalized mse over the entire sphere we obtain an optimal damping coefficient $\eta_\Omega$ given by

$$
\eta_\Omega = \frac{N}{S} \frac{\sum_{\alpha=1}^{(L+1)^2}[\lambda_\alpha^2(\eta R)]^{3}\lambda_\alpha(1 - \lambda_\alpha)}{\sum_{\alpha=1}^{(L+1)^2}[\lambda_\alpha^2(\eta R)]^{3}\lambda_\alpha(1 - \lambda_\alpha)^2}.
$$

Likewise, minimization of eq. (133), the normalized mse over the region of coverage, yields an optimal damping coefficient $\eta_R$ given by

$$
\eta_R = \frac{N}{S} \frac{\sum_{\alpha=1}^{(L+1)^2}[\lambda_\alpha^2(\eta R)]^{3}\lambda_\alpha(1 - \lambda_\alpha)}{\sum_{\alpha=1}^{(L+1)^2}[\lambda_\alpha^2(\eta R)]^{3}\lambda_\alpha(1 - \lambda_\alpha)^2}.
$$

Although the unknown optimal damping levels $\eta_\Omega$ and $\eta_R$ appear on both sides of eqs (128) and (133), their values can be easily computed by iteration. They depend on the measurement geometry, the damping, and the signal-to-noise ratio. In Figure 11, $\eta_\Omega$ and $\eta_R$ are shown as black and grey vertical lines, respectively. At high signal-to-noise ratios both can be approximated as $\eta_R = \eta_\Omega \approx N/S < 1$.

When the coverage region is axisymmetric the mse (128) is independent of the longitude, as can be deduced from eq. (60). Thus, in Figure 11 we plot $(\epsilon^2(\theta))/\langle s^2(\theta) \rangle$, in percent, for different signal-to-noise ratios, as a function of colatitude and for various damping levels: i.e. in the undamped ($\eta = 0$), fully damped ($\eta = 1$) and optimally damped case ($\eta = \eta_\Omega$). The vertical axes are truncated at 100% as the undamped values exceed this value by many orders of magnitude.

### 9 Slepian Basis Solution

In the previous section we expanded the estimate of the signal into a bandlimited spherical harmonic basis and performed a damped least-squares inversion for the unknown coefficients. This estimation procedure resulted in a biased estimate, but the damping prevented the detrimental amplification of the measurement noise. We derived expressions for the optimal level of damping required for “whitish” signals measured at zero altitude. Adding a small amount of bias made the estimate computable and reduced its variance. We
used the (downward continued) Slepian basis to find expressions for the resultant damped Slepian harmonic estimate in the spatial domain and to find its bias, variance, and mse. Using the Slepian basis greatly simplified the expressions because of the fact that, as opposed to the spherical harmonics, the Slepian functions are orthogonal over both the entire sphere and the closed subdomains over which, by design, their energy is optimally concentrated.

Alternatively, we might have sought an estimate that is expressed in the spherical Slepian basis at the start. As we have seen, the first \( K \) Slepian eigenfunctions, where \( K \) is the Shannon number \( \left[ 43 \right] \), provide an excellent coverage of the region of observation. This implies that their associated eigenvalues \( \lambda \) are close to unity, avoiding any problems with their inversion. In this section we will explore the effect on the region of observation. This implies that their associated energetic contributions arise due to forming basis functions that are best concentrated whose kind we have encountered in eq. \( L \alpha \), and using eqs (22) and (48), every one of the expansion coefficients \( s\alpha \) would depend on a linear combination of all \( (L + 1)^2 \) terms \( \lambda \sum \int R d g_n d \Omega \) through a matrix term \( g_n \sum A_{n} g_{\alpha} \) whose kind we have encountered in eq. \( 24 \). This would therefore invalidate the method of truncation as a means to avoid the difficult-to-compute and unnecessarily influential large inverse eigenvalues. By choosing the representation \( 35 \) instead, we take advantage of eq. \( 45 \) to juxtapose upward and downward continuation, \( (1 + \alpha)^{-l+1}(1 + \alpha)^{-l-1} \), thereby canceling their effect altogether: eq. \( 136 \) shows that every coefficient \( s\alpha \) only depends on the inverse eigenvalue at the same rank \( \alpha \). The effect of the measurement at altitude has not disappeared: it is now contained in eq. \( 135 \) in the basis \( g_{\alpha} \), of which only the first \( J \) functions are required. These are calculated via eq. \( 59 \) and ultimately, by the stable Grünbaum algorithm central to our analysis.

The data integral \( 136 \) can be calculated by substituting into it eqs \( 117 \), \( 38 \), \( 42 \), \( 33 \) and \( 41 \), to yield

\[
\int_R d g_n d \Omega = \lambda s\alpha + \int_R n g_n d \Omega + \sum_{l m > L} h_{\alpha, l m} s\alpha, l m.
\]

Averaging the expressions \( 136 \) over many estimates annihilates the influence of the random noise by virtue of eq. \( 16 \), and gives

\[
\langle s\alpha \rangle = s\alpha + \lambda s\alpha^{-1} \sum_{l m > L} h_{\alpha, l m} s\alpha, l m.
\]

Combining eqs \( 135 \)–\( 137 \) yields the estimate in the space domain,

\[
\hat{s} = \frac{\sum g_{\alpha} (\hat{F})}{\sum \lambda^{-1} g_{\alpha} (\hat{F})} \times \left( \lambda s\alpha + \int_R n g_n d \Omega + \sum_{l m > L} h_{\alpha, l m} s\alpha, l m \right).
\]

The estimation bias, following eq. \( 101 \), is obtained by subtracting from eq. \( 140 \) the representation of the signal \( 20 \) and using the equivalence \( 105 \):

\[
b(\hat{F}) = -\sum_{\alpha > J} s\alpha g_{\alpha} (\hat{F}) - \sum_{l m > L} s_{lm} Y_{lm}(\hat{F})
\]

\[
+ \sum_{\alpha = 1}^{J} \lambda^{-1} g_{\alpha} (\hat{F}) \sum_{l m > L} h_{\alpha, l m} s\alpha, l m.
\]

Without truncation of the Slepian basis function set, i.e. when \( J = (L + 1)^2 \), the first term in this equation vanishes. The remaining contributions arise due to forming bandlimited estimates of broadband signals, leading to unavoidable leakage and broadband bias. Comparing eqs \( 112 \) and \( 141 \) we discover the parallel roles of damping and truncation. The introduction of the damping parameter \( \eta \) adds an extra bias term to the expression \( 112 \), and reduces the size of the leakage term by which the coefficients \( h_{\alpha, l m} \).
which we may again compare to the unbiasedness \(123\) of the undamped estimate \(120\). Explicitly, under the condition \(116\), the only contributing term in eq. \(141\) is given by

\[
b(\hat{r}) = - \sum_{\alpha > J} s_\alpha g_\alpha(\hat{r}). \tag{146}
\]

This term decreases with increasing \(J\), and vanishes altogether when \(J = (L + 1)^2\). It can be compared to eq. \(124\). The average over all realizations of the signal of the squared bias, for a “whitish” signal with covariance \(123\), is given by

\[
\langle b^2(\hat{r}) \rangle = S \sum_{\alpha > J} g_\alpha^2(\hat{r}), \tag{147}
\]

which should be compared with the corresponding eq. \(126\) in the damped spherical harmonic case. From this and eq. \(142\) we can calculate the mean-square estimation error following eq. \(122\), which is now

\[
\langle \epsilon^2(\hat{r}) \rangle = N \sum_{\alpha=1}^{J} \lambda_\alpha^{-1} g_\alpha^2(\hat{r}) + S \sum_{\alpha > J} g_\alpha^2(\hat{r}). \tag{148}
\]

The mse of the untruncated Slepian basis approach and that of the undamped spherical harmonic estimation method \(127\) are identical. This of course is a direct consequence of the fact that both bases are related to each other by the orthonormal transformation eqs \(24\) and \(26\). Of note is the very different form of the damped and truncated expressions, eqs \(127\) and \(148\), for the mse. Whereas eq. \(127\) consists of a weighted sum of all basis functions \(\alpha = 1 \rightarrow (L + 1)^2\) in a manner that appears to mix the influence of the noise, the damping, and the signal, the truncated expression \(148\) has disentangled the effects of the noise and the signal by distributing the influence of the variance over the basis functions \(\alpha = 1 \rightarrow J\) that are well concentrated inside the measurement area, and the effect of the bias over those \(\alpha = J + 1 \rightarrow (L + 1)^2\) that are concentrated in the region of missing data. To the one piece that is missing, the decision on where to truncate the data by the choice of \(J\), we now turn.

### 9.3 Optimal truncation level

To illustrate the behavior of the mse in eq. \(148\) we again focus on the zero-altitude case, for which

\[
\langle \epsilon^2(\hat{r}) \rangle = N \sum_{\alpha=1}^{J} \lambda_\alpha^{-1} g_\alpha^2(\hat{r}) + S \sum_{\alpha > J} g_\alpha^2(\hat{r}). \tag{149}
\]

In order to find the optimal truncation level, we consider the full-sphere and coverage-domain average mse (normalized by the corresponding quadratic signal averages) as in the damped spherical harmonic approach. Using eqs \(129\) and \(43\) we find from eq. \(149\) that the \(\Omega\)-average mse in the truncated Slepian case is

\[
\frac{1}{\Omega} \int_{\Omega} \langle \epsilon^2(\hat{r}) \rangle \, d\Omega = 1 - \frac{J}{(L + 1)^2} + \frac{N}{S} \sum_{\alpha=1}^{J} \lambda_\alpha^{-1}. \tag{150}
\]
Using the definition (153) of the Shannon number, we likewise find the \( R \)-average mse:

\[
\frac{\int_R \langle e^2(\hat{\rho}) \rangle \, d\Omega}{\int_R \langle s^2(\hat{\rho}) \rangle \, d\Omega} = \frac{N \, J}{S \, K} + \frac{1}{K} \sum_{\alpha > J} (L+1)^2 \lambda_\alpha. \tag{151}
\]

Both quantities are plotted in Figure 12 for different signal-to-noise ratios \( S/N = 4, 6, 8 \) and 10 and with the other parameters unchanged from those of Figure 10, a double-cap polar gap of \( \Theta = 10^\circ \), a bandwidth \( L = 45 \). In black, with the scale on the left of the panel, we show eq. (150) as a function of the truncation level ranging over \( J = K - 50 \) to \( (L+1)^2 \). The abscissa is inverted since \( J = (L+1)^2 \) corresponds to a situation without Slepian truncation, and as \( J \) decreases, the degree of truncation increases. In grey, we plot eq. (151), with a much reduced scale on the right hand side. The range of \( \Omega \)-average mse values shown is much larger (5\% in all four panels) than the equivalent range in \( R \)-average mse values (which varies from panel to panel but is less than 0.8\%): the effects of truncation on the overall mse over the entire globe are much more outspoken than its effects on the mse averaged over the region in which data were collected. This behavior mimics the one seen in Figure 10 for the damped spherical harmonic case. The ordinate is again truncated for clarity. The value of the untruncated \( R \)-average mse, attained when \( J = (L+1)^2 \), is \((N/S)/\cos \Theta\). This follows from the definition of the Shannon number (154) and the area of the covered region, \( A = 4\pi \cos \Theta \), and is identical to the corresponding value in the undamped spherical harmonic case. A lower bound is found at full coverage, when \( R = \Omega, \Theta = 0^\circ, K = (L+1)^2 \) and \( \lambda_\alpha = 1 \). In that case the minimal scaled mse, attained when \( J = (L+1)^2 \), equals \( N/S \), as it does in the damped spherical harmonic case. We use this value as a lower cutoff of the vertical axis on the left and the right.

We may obtain the truncation level that minimizes the \( \Omega \)-average mse by minimizing eq. (150) with respect to \( J \). This will yield an optimal truncation level \( J_\Omega \). Likewise, minimizing eq. (151) returns the truncation value \( J_R \) at which the \( R \)-average mse is minimal. Both minimization problems result in identical constraints on the eigenvalue of the \( J \)-th eigenfunction beyond which we truncate:

\[
\lambda_{J_\Omega} = \lambda_{J_R} \approx \frac{N}{S}, \tag{152}
\]

which is implicit but solvable. In Figure 12 the values \( J_\Omega = J_R \) identified by the top labels, are shown as a single solid black vertical line; the Shannon number, \( K = 2048 \), is shown by the dotted black line and the bottom labels.

The mse (149) for axisymmetric coverage regions is independent of the longitude, as can be understood from eq. (60). Thus, in Figure 13 we plot \( \langle e^2(\theta) \rangle/\langle s^2(\theta) \rangle \), in percent, as a function of colatitude for various truncation levels: the untruncated, \( J = (L+1)^2 \), and optimally truncated cases, \( J = J_\Omega = J_R \), and the case truncated at the Shannon number, \( J_\Omega = J_R \).
Figure 13. Mean-square error (as a percentage of the mean-square signal strength) of the truncated Slepian function solution to the geodetic estimation problem for a white signal and white noise. As in Figure 12, the signal-to-noise levels shown are \( S/N = 4, 6, 8 \) and 10, the measurement altitude \( \alpha = 0 \), the polar gap consists of caps with radius \( \Theta = 10^\circ \), and the bandwidth of the signal and its estimate is \( L = 45 \). As a function of colatitude, for an arbitrary longitude, we plot the mse of the untruncated solution, when \( J = (L + 1)^2 \), of truncation at the Shannon number, \( J = K \), and of the truncation levels which minimize the mse, i.e., \( J_\Omega = J_R = 2092, 2096, 2096, \) and 2098, that were marked by black vertical lines in Figure 12. The mse is symmetric about the equator. The ordinate is truncated at 100%; the mse of the untruncated solution in the region of the polar gap exceeds this value by several orders of magnitude.

Figure 14. Mean square error (mse), variance and bias for the damped least-squares solution and the truncated Slepian approach. The antipodal polar gap has a radius \( \Theta = 10^\circ \); the bandwidth is \( L = 45 \); signal-to-noise ratio \( S/N = 4 \). Panels a & b show the values averaged over the unit sphere, as in Figures 10 and 12; the squared bias is the difference between the mse and variance curves, indicated by the thin black vertical line. Panels c & d show the values at the optimal damping and truncation levels. The minimization of the mse reflects the trade-off between variance, which dominates the uncovered regions of the polar gap, and bias, dominant in the covered equatorial belt region.
ber $J = K$. The vertical axes are truncated at 100% since the untruncated values exceed this value by many orders of magnitude.

Finally, in Figure 14 we plot the relative contributions of variance and bias for both the damped spherical harmonic and the truncated Slepian case. The top panels show the mean square error, the variance and the squared bias, according to the relation as a function of the damping level (top left) or the truncation rank (top right). The bottom panels show the breakdown of mse, variance and bias in the spatial domain. For both estimation methods, the bias is predominantly concentrated in the areas over which no measurements are available, where it is generated by the power of the “missing signal”. The variance, on the other hand, arises in the areas of coverage and is influenced by the power of the noise. Both estimation methods show very similar results. Over the covered area, the mse is nearly identical, and in the uncovered region, the mse of the truncated Slepian case approaches that of the damped spherical harmonic case, but it is slightly higher. It is remarkable that eqs 128 and 149, despite their different form, both give rise to a nearly complete spatial separation of bias and variance. Only in eq. 149 is this separation immediately obvious by inspection: signal strength, and thus bias, affect the low-ranking Slepian functions, whose power is mostly concentrated inside of the polar gap, whereas noise, and thus variance, affect the high-ranking Slepian functions whose power is localized to the area of satellite coverage.

10 CONCLUSIONS

Spherical Slepian functions provide a natural solution to the geodetic problem of having a polar gap in the satellite coverage of planetary gravitational or magnetic fields. Indeed, the ill-posed geodetic estimation problem of finding the source-level potential from noisy observations taken at an altitude over an incomplete region of coverage has natural connections to Slepian’s spherical problem of spatio-spectral localization. We have proposed a new method that expands the source field in terms of a truncated basis set of spherical Slepian functions, and compared its statistical performance with the traditional damped least-squares method in the spherical harmonic basis. The optimally truncated Slepian method performs nearly as well as the optimally damped spherical harmonic method, but it has the significant advantage of an intuitive separation of the estimation bias and variance over those Slepian functions sensitive to the uncovered and covered regions, respectively. The construction of Slepian functions over axisymmetric domains such as the latitudinal belt or its complement, the polar gap, previously dismissed as computationally unstable, has been shown to be eminently tractable. We have shown that the operator that bandlimits a field on the unit sphere and projects it onto the polar caps commutes with a Sturm-Liouville operator. Its eigenfunctions, the Slepian functions, can be computed extremely accurately and efficiently by diagonalizing a tri-diagonal matrix with analytically prescribed elements. The gains in ease, speed, and accuracy thus achieved makes the use of spherical Slepian functions in earth and planetary geodesy practical, as our examples have shown.

The solutions to eq. (A.2) are functions both of the same parity, either even or odd. Depending on every other term in the interval from \(0\) to \(L\), which are either even or odd about the equator, as indicated by the subscript \(p\), determines the symmetric kernel, \(\eta\) acting on \(\h_p(\mu')\) in eq. (A.2),

\[
\int_0^1 D_p(\mu, \mu') h_p(\mu') d\mu' = \lambda h_p(\mu),
\]

where \(\lambda = \sum_{l=m_p}^{L_p} C_l m P_l m(\mu) P_l m(\mu')\).

The domain of eq. (A.2) is the interval \([-1, 1]\) of the double cap \(\{b: b \leq \mu \leq 1\} \cup \{-1 \leq \mu \leq -b\}\).

As in eqs (4)–(5), \(P_l m\) is the associated Legendre polynomial of degree \(l\) and order \(m\), and \(C_l m\) is a normalization constant. We remind the reader of our notation: \(h_p(\mu)\) is a cotidiously dependent function that is limited in space to the antipodal polar caps of radius \(\Theta = \cos^{-1} b\). It is either odd or even about the equator, as indicated by the subscript \(p:\)

\[
h_p(\mu) = 0, \quad -b \geq \mu \geq b, \quad h_e(\mu) = h_e(-\mu), \quad h_o(\mu) = -h_o(-\mu).
\]

The solutions to eq. (A.2) are functions \(h_p(\mu)\) that are specially concentrated in a spherical harmonic degree interval \(0 \leq l \leq L\); the eigenvalue \(\lambda\) is the quadratic measure of this concentration. The primed summation symbol skips every other term in the interval from \(m_p\) to \(L_p\), which are both of the same parity, either even or odd. Depending on the requested order \(m\) and concentration bandwidth \(L\) of the solutions, \(m_p\) is either \(m\) or \(m + 1\), and \(L_p\) is either \(L\) or \(L - 1\), following eq. (10). We further distinguish \(T\) acting on \(\mu\) from \(T'\) that acts on \(\mu'\).

To confirm commutativity we are required to show that

\[
\int_0^1 D_p(\mu, \mu') T_p h_p(\mu') d\mu' = \int_0^1 T_p D_p(\mu, \mu') h_p(\mu') d\mu'.
\]

We first show that the left side of eq. (A.6) can be rewritten as

\[
\int_0^1 D_p(\mu, \mu') T_p h_p(\mu') d\mu' = \int_0^1 T_p D_p(\mu, \mu') h_p(\mu') d\mu',
\]

and then we verify that

\[
T_p D_p(\mu, \mu') = T_p' D_p(\mu, \mu').
\]

The first result (A.7) is easily verified by integration by parts:

\[
\int_0^1 (b^2 - \mu^2)(1 - \mu^2) d\mu = \int_0^1 (b^2 - \mu^2)(1 - \mu^2) d\mu + L_p(L_p + 3)\mu^2 \zeta + m^2(b^2 - \mu^2)(1 - \mu^2)^{-1}\zeta d\mu = \int_0^1 (T_p \zeta) \eta d\mu.
\]

To verify the second result (A.8) we use the Laplace-Beltrami identity \(\nabla^2 P_l m = -l(l+1)P_l m\) (Dahlen & Tromp 1998) to write

\[
(T_p - T_p') D_p(\mu, \mu') = (\mu^2 - \mu'^2) \sum_{l=m_p}^{L_p} C_l m P_l m(\mu) P_l m(\mu') \times [l(l+1) - L_p(L_p + 3)]
- 2\mu(1 - \mu^2) \sum_{l=m_p}^{L_p} C_l m P_l m(\mu) P_l m(\mu')
+ 2\mu'(1 - \mu'^2) \sum_{l=m_p}^{L_p} C_l m P_l m(\mu) \frac{d}{d\mu} P_l m(\mu').
\]

Two well-known Legendre identities help us simplify the above: a derivative identity and a recursion relation (Dahlen & Tromp 1998):

\[
\frac{dP_l m}{d\mu} = \frac{(l + 1)\mu P_l m - (l - m + 1)P_{l+1} m}{1 - \mu^2}, \quad (A.11a)
\]

\[
\mu P_l m = \frac{(l - m + 1)P_{l+1} m + (l + m)P_{l-1} m}{2l + 1}, \quad (A.11b)
\]

Applying eq. (A.11a), then eq. (A.11b), transforms
where \( p(\mu) = (\mu^2-b^2)(1-\mu^2)/2 \), \( q(\mu) = m^2(1-\mu^2)^{-1}(\mu^2-b^2) - L_p(L_p+3) \mu \), \( p(\mu) = 1 \), and the prime denotes differentiation with respect to \( \mu \). Since \( T_p \) is a Sturm-Liouville operator, the eigenvalue spectrum of eq. (A.10) is simple: the spacing between adjacent fixed-order eigenvalues is roughly equant, as we illustrated in Figure [9].

**APPENDIX B: THE GRÜNBÄUM MATRIX**

The domains of eqs (A.2) or (A.16), originally restricted to the area contained within the double polar caps, may be extended to the entire sphere, \( 0 \leq \cos \theta \leq \pi \), by writing

\[
T_p g_p(\mu) = \chi g_p(\mu) , \quad -1 \leq \mu \leq 1 .
\]  

(B.1)

The unknown functions, see eq. (68), must now be bandlimited rather than spacelimited:

\[
g_p = \sum_{l=m_p}^{L_p} \sum_{m} \tilde{g}_{lm} X_{lm}(\theta) ,
\]  

(B.2)

where, as in eq. (79), depending on the requested order \( m \) and concentration bandwidth \( L \) of the solutions, \( m_p \) is either \( m \) or \( m+1 \), \( L_p \) is either \( L \) or \( L-1 \), and the primed summation skips every second integer. As a result, \( g_{lm} \) requires no further identification. Inserting the representation of eq. (B.2) into eq. (B.1) multiplying both sides by \( 2\pi \sin \theta X_{l\prime m}(\theta) \), integrating over all colatitudes \( 0 \leq \theta \leq \pi \), and invoking the orthogonality eq. (4) easily transforms eq. (B.1) into an algebraic eigenvalue equation for the coefficients of the unknown functions \( g \):

\[
T_p g_p = \chi g_p ,
\]  

(B.3)

where we define

\[
T_{l\prime m} = 2\pi \int_0^\pi X_{lm}(T_{l\prime m}) \sin \theta d\theta .
\]  

(B.4)

To avoid clutter, we have changed the subscript \( p \) indicating the parity of the solutions into a superscripted \( p \) on the matrix elements \( T_{l\prime m} \). These are indexed by the integer degrees \( l \) and \( l' \). Since in \( T_p \) the only degrees involved range from \( m_p \) to \( L_p \), with every second degree skipped, when \( m = 0 \), the first element of the matrix \( T_c \) is thus \( T_{00}^c \), the second \( T_{20}^c \), and so on, whereas the first and second elements of \( T_o \) are \( T_{11}^o \) and \( T_{30}^o \), and so on, respectively. The matrix whose diagonalization leads to the even functions \( g_e \) is thus given by

\[
T_c = \begin{pmatrix}
T_{mm}^c & T_{m+1m}^c & \cdots & T_{mL_o}^c \\
T_{m+2m}^c & T_{m+3m}^c & \cdots & T_{mL_o}^c \\
& \cdots & \cdots & \cdots \\
T_{L_m}^c & T_{L_m+1}^c & \cdots & T_{L_o}^c
\end{pmatrix} .
\]  

(B.5)

Its dimensions are \([L_e - m]/2 + 1) \times [(L_o - m)/2 + 1] \). The \([(L_o - m - 1)/2 + 1) \times [(L_o - m - 1)/2 + 1] \)-dimensional matrix yielding the odd functions \( g_o \) is

\[
T_o = \begin{pmatrix}
T_{m+1m+1}^o & T_{m+1m+3}^o & \cdots & T_{mL_o+1}^o \\
T_{m+3m+1}^o & T_{m+3m+3}^o & \cdots & T_{mL_o+3}^o \\
& \cdots & \cdots & \cdots \\
T_{L_m+1}^o & T_{L_m+3}^o & \cdots & T_{L_o}^o
\end{pmatrix} .
\]  

(B.6)
The dimensions of the combined matrix
\[ T' = \text{diag} \left( T_e, T_o \right) \] (B.7)
are thus \((L - m + 1) \times (L - m + 1)\), as expected. Such a matrix can be thought of as a permutation of a “full form”
\[
T = \begin{pmatrix}
T_{mm} & \cdots & T_{mL} \\
\vdots & \ddots & \vdots \\
T_{Lm} & \cdots & T_{LL}
\end{pmatrix},
\] (B.8)
where the degrees are arranged in the correct order, without skipping entries. It is this matrix \(T\) that commutes with the matrix \(D\) of eq. (56), which is also in the form
\[
D = \begin{pmatrix}
D_{mm} & \cdots & D_{mL} \\
\vdots & \ddots & \vdots \\
D_{Lm} & \cdots & D_{LL}
\end{pmatrix}
\] (B.9)
and whose elements are given by eq. (56),
\[
D_{ll} = 2\pi \int_{\Theta}^0 X_m X_{l'm} \sin \theta d\theta.
\] (B.10)
Deriving the form of the matrix entries \(T_{ll'}^p\) of eq. (B.4) requires the Grünbaum operator \(T_p\) of eq. (A.1) as a function of colatitude, i.e.
\[
T_p = (b^2 - \cos^2 \theta) \nabla^2_m + 2 \cos \theta \sin \theta \frac{d}{d\theta} - L_p(L_p + 3) \cos^2 \theta.
\] (B.11)
Evaluating eq. (B.4) is perhaps not as pedestrian as by “simply reading off directly the inner products” as claimed by Grünbaum et al. (1982), but since only the result is of any practical consequence here, we will simply state it:
\[
T_{ll'}^p = \begin{align*}
T_{ll'}^p &= -l(l + 1) \cos^2 \Theta + \frac{2}{2l + 3} \left( (l + 1)^2 - m^2 \right) \\
&\quad + \left( (l - 2)(l + 1) - L_p(L_p + 3) \right) \\
&\quad \times \left[ \frac{1}{3} - \frac{2}{3} \frac{3m^2 - l(l + 1)}{(2l + 3)(2l - 1)} \right], \quad (B.12a)
\end{align*}
\]
\[
T_{ll'+2}^p = \frac{l(l + 3) - L_p(L_p + 3)}{2l + 3} \times \sqrt{\frac{[(l + 2)^2 - m^2] [(l + 1)^2 - m^2]}{(2l + 5)(2l + 1)}}, \quad (B.12b)
\]
\[
T_{ll'}^p = 0 \quad \text{otherwise}. \quad (B.12c)
\]
This is the result given as eq. (86) in the main text. The elements again are specified in terms of the degree and not by the matrix index. Both \(T_e\) and \(T_o\) are thus not only real and symmetric, but also tridiagonal. The important result is that the coefficients of the even or odd optimally concentrated antipodal polar cap eigenfunctions \(g_e(\theta)\) or \(g_o(\theta)\) both only require the numerical diagonalization of a tridiagonal matrix. Both matrices have analytically prescribed elements, and a spectrum of eigenvalues that is guaranteed to be simple.
