ABSTRACT

We present GMRT H\textsc{i} observations and deep CFHT MegaCam optical images of the gas-rich interacting galaxy group NGC 871/NGC 876/NGC 877 (hereafter NGC 871/6/7). Our high-resolution data sets provide a census of the H\textsc{i} and stellar properties of the detected gas-rich group members. In addition to a handful of spiral, irregular and dwarf galaxies, this group harbours an intriguing H\textsc{i} feature, AGC 749170, that has a gas mass of \(\sim 10^{9.3} M_{\odot}\), a dynamical-to-gas mass ratio of \(\sim 1\) (assuming the cloud is rotating and in dynamical equilibrium) and no optical counterpart in previous imaging. Our observations have revealed a faint feature in the CFHT g'- and r'-bands; if it is physically associated with AGC 749170, the latter has \(M/L_g > 1000 M_{\odot}/L_{\odot}\) as well as a higher metallicity (estimated using photometric colours) and a significantly younger stellar population than the other low-mass gas-rich group members. These properties, as well as its spectral and spatial location with respect to its suspected parent galaxies, strongly indicate a tidal origin for AGC 749170. Overall, the H\textsc{i} properties of AGC 749170 resemble those of other optically dark/dim clouds that have been found in groups. These clouds could represent a class of relatively long-lived H\textsc{i}-rich tidal remnants that survive in intermediate-density environments.

Key words: galaxies: interactions – galaxies: dwarf

At the current epoch, most galaxies can be found in medium density group environments (e.g. Eke et al. 2004, Tago et al. 2008), where tidal interactions within these systems play important roles in galactic evolution. Several nearby, gas-rich groups exhibit clear signs of these interactions (e.g. Freeland, Stilp & Wilcots 2009), providing a snapshot of this evolutionary process in action. Material pulled from spiral-rich interacting systems forms gaseous filaments that can harbour second-generation tidal knots and tidal dwarf galaxies (TDGs), which differ from classical satellite dwarf galaxies – dwarf galaxies have masses \(\lesssim 10^9 M_{\odot}\) – by their lack of dark matter, higher metallicity content and higher star formation rates (e.g. Bournaud et al. 2004). In recent neutral hydrogen (H\textsc{i}) surveys of groups and clusters, large detached gaseous clouds with no apparent stellar component have also been detected (e.g. Kilborn et al. 2000, Ryder et al. 2001, Kent et al. 2007). Some of these objects were initially suspected as being extremely rare primordial “dark galaxies” and gained considerable amounts of attention (e.g. Minchin et al. 2005); however, due to their environment, it is currently believed that these so-called dark galaxies are actually another form of tidal debris (e.g. Bekki, Koribalski & Kilborn 2005, Haynes, Giovanelli & Kent 2007, Duc & Bournaud 2008). The number of detected optically dark clouds is growing and although most of the galaxy-sized H\textsc{i}-rich clouds are found in regions where interaction events and other environmental processes could explain their origin, their actual formation properties are still unclear (e.g. Walter, Skillman & Brinks 2005, English et al. 2010, Kent 2010, Matsuka et al. 2012, Oosterloo, Heald & de Blok 2013, Serra et al. 2013). Broad searches for isolated H\textsc{i} clouds...
have yet to confirm the existence of primordial dark galaxies (e.g. Doyle et al. 2005; Wong et al. 2009; Haynes et al. 2011).

In concert with the distributions of intra-group gas and stars, tidal and classical dwarf galaxy populations provide important evolutionary diagnostics and cosmological constraints in group environments. For merging systems, the formation of any tidal object also greatly constrains the type of interaction and the properties of the original objects involved in the process (see Kaviraj et al. 2012). Although TDGs are frequently produced in simulations and several candidates have been reported (see Sheen et al. 2009 and references therein), very few are widely accepted as authentic. One of the main reasons for this discrepancy is the variety of corroborating observations that are required to unambiguously distinguish between classical satellites, TDGs and unbound tidal knots (e.g. Duc et al. 2011).

Given the properties of tidal systems as well as the environments in which they form, H\textsc{i} observations are useful preliminary search tools as they can indicate regions of potential star formation, trace the location of tidally formed features and have been routinely used to map the gas distribution in and around various systems (e.g. Kent et al. 2009; Stierwalt et al. 2009). The Arecibo Legacy Fast ALFA survey (ALFALFA; Giovanelli et al. 2005) unbiasedly maps H\textsc{i} in the local volume. The recent data release of 40 per cent of the ALFALFA catalog (\textalpha\text{40}; Haynes et al. 2011) has a wealth of H\textsc{i}-rich objects with intriguing features that warrant further follow-up. In this paper, we target NGC 871/NGC 876/NGC 877 (hereafter referred to as NGC 871/6/7), a galaxy group with a fairly extensive H\textsc{i} envelope.

As shown in Lee-Waddell et al. (2012; hereafter referred to as Paper 1), high-resolution H\textsc{i} imaging using the Giant Metrewave Radio Telescope (GMRT) is able to resolve the sizes and dynamics of low-mass gas-rich galaxies on kpc scales. The configuration of the array can produce H\textsc{i} images with various synthesized spatial resolutions, from a single set of data, using post-processing techniques (see Section 1.1). As well, the versatility of the recently added GMRT software correlator can produce high spectral resolution observations (see Roy et al. 2010 for details on the software processing pipeline).

The properties of the stellar populations in dwarf galaxies also help distinguish tidal systems. The Canada-France-Hawaii Telescope (CFHT) MegaCam used in conjunction with the Elixir+ELIXIR-LSB processing pipeline, which has been developed for the deep optical surveys used in the ATLAS3D and NGVS projects (Duc et al. 2011; Ferrarese et al. 2012), can produce high resolution optical images down to a limit of 29 mag arcsec\(^{-2}\) in the \(g'\)-, \(r'\)- and \(i'\)-bands, suggesting a collisional origin for this feature. Similarly, a deep analysis of the stellar components of the NGC 871/6/7 group members will give insight into their properties and can eventually be used constrain the interaction history of the system (see Paudel et al. 2013).

NGC 871/6/7 is a gas-rich interacting group located at a distance of \(\sim 50\) Mpc and consists of at least three spirals: NGC 871, NGC 876 and NGC 877 and one irregular galaxy: UGC 1761 (Springob et al. 2007; Springob et al. 2009) properties listed in Table 1. This group resides in a common H\textsc{i} distribution, as mapped by ALFALFA, that spans 0.5 deg\(^2\) and has a total H\textsc{i} mass of \(M_{H\textsc{i}} > 6 \times 10^{10} M_{\odot}\) (Fig. 1).

| Name       | Coordinates (J2000) | Morphology | \(cz_{\odot}\) (km s\(^{-1}\)) |
|------------|---------------------|------------|-----------------------------|
| NGC 871    | 02 17 11, +14 32 53  | SB(s)c     | 3740 \(\pm 1\)             |
| UGC 1761   | 02 17 26, +14 31 49  | Im         | 4010 \(\pm 5\)             |
| NGC 876    | 02 17 53, +14 31 16  | SAc        | 3894 \(\pm 1\)             |
| NGC 877    | 02 18 00, +14 32 39  | SAB(rs)bc  | 3913 \(\pm 1\)             |

Within the spatial and spectral location of the group, \(\alpha\text{40}\) also indicates four low-mass gas-rich objects with \(M_{H\textsc{i}} \sim 10^9 M_{\odot}\) (see Section 2). One of these H\textsc{i} peaks, AGC 749170, appeared to have no detectable stellar component in the existing data and warranted detailed follow-up. “First-look” observations using the Karl G. Jansky Very Large Array (VLA) in C-configuration completed in 2009, from program AC963 and PI J. Cannon, confirmed the spatial and spectral location of the eight gas-rich group members.

In this paper, we present our multi-wavelength follow-up campaign of NGC 871/6/7. Using high-resolution observations from the GMRT, we have isolated the H\textsc{i} belonging to each gas-rich group member, thereby enabling gas mass calculations and dynamical mass estimates (Section 2). Deep optical imaging from the CFHT MegaCam and ancillary Galaxy Evolution Explorer (GALEX) data were used to identify likely optical counterparts as well as estimate the stellar properties for detectable low H\textsc{i} mass – \(M_{H\textsc{i}} \lesssim 10^9 M_{\odot}\) – group members (Section 3). We then discuss our results for AGC 749170 and its likely tidal origin while comparing its properties to similar objects found in the literature (Section 4).

1 OBSERVATIONS OF NGC 871/6/7
1.1 GMRT Observations

Using the ALFALFA map as a guide and following a similar observational set-up and reduction technique as Paper 1, the GMRT data consist of three pointings observed over a total of four nights in the late summer of 2012 (Fig. 1). Due to
Figure 1. ALFALFA total H\textsc{i} intensity contours at $N_{\text{H}_\text{i}} = (1.8, 4.8, 12, 16, 24, 36, 48) \times 10^{19}$ atoms cm$^{-2}$ superimposed on a DSS2 r-band greyscale image of the NGC 871/6/7 group. The heliocentric velocity of the H\textsc{i} contained within the lowest contour ranges from 3550 to 4000 km s$^{-1}$. The 4 arcmin (60 kpc) ALFALFA beam is in the bottom left corner and the blue x’s indicate the locations of the ALFALFA H\textsc{i} detections. The large red circles show the GMRT follow-up pointings.

Table 2. GMRT observation set-up and image properties.

| Parameter                        | Value | Units |
|----------------------------------|-------|-------|
| Number of pointings              | 3     |       |
| Average time on source per pointing | 320   | min   |
| Primary beam HPBW per pointing   | 19.7  | arcmin|
| Mosaicked map size               | 30    | arcmin|
| Central observing frequency      | 1402.2| MHz   |
| Observing bandwidth             | 4.16  | MHz   |
| Observing spectral resolution    | 8.1   | kHz   |
| Final cube spectral resolution   | 24.4  | kHz   |
| Final cube spectral resolution   | 5.3   | km s$^{-1}$|
| Map spatial resolutions          | 30 and 45 | arcsec |
| Peak map sensitivity (45 arcsec res.) | 1.6   | mJy beam$^{-1}$ |
| Peak map sensitivity (30 arcsec res.) | 1.3   | mJy beam$^{-1}$ |

technical difficulties with the array, the observations from the first night were unusable and an additional eight hours of observing were granted. The 24h of usable telescope time, which included calibration observations using standard flux calibrators (3C48 and 3C147) and a nearby phase calibrator 0204+152, were equally divided between the three pointings. The observing and map parameters are summarized in Table 2.

Data editing and reduction was completed using the Astronomical Image Processing System (AIPS) version 31Dec12 (Greisen 2003) in the same manner as presented in Paper I. The calibrated data cubes were mosaicked and imaged with natural weighting and tapering to respectively produce $\sim$45 arcsec (11 kpc at the distance of NGC 871/6/7) and $\sim$30 arcsec (7 kpc) synthesized beams, which constrain the H\textsc{i} mass, size and structure of the low-mass features while minimizing the noise. A three-channel spectral average, resulting in a resolution of 5.3 km s$^{-1}$ (complementary to the ALFALFA resolution of 5.2 km s$^{-1}$) was used to produce the final image maps as shown in Fig. 2, which indicates eight gas-rich objects.

### 1.2 CFHT Observations

Using the CFHT MegaCam, we obtained $g'r'i'$-band imaging of NGC 871/6/7 in September 2012. MegaCam’s 1 deg$^2$ field of view imaged the 0.5 deg$^2$ group while simultaneously observing sufficient background to allow for sky modelling and subtraction using the Elixir+Elixir-LSB processing pipeline. Each filter used a seven-point large dithering pattern (LDP-CCD-7) with exposures sequenced within a one hour time window in order to minimize sky variations.

The MegaCam images were stacked using Elixir to characterize and subtract the background and then processed through Elixir-LSB to remove the scattered light components (Ferrarese et al. 2012). The final image pixels are binned 3 $\times$ 3 to boost the signal-to-noise ratio of the background. The resultant images are at least five times more sensitive than the SDSS optical imaging limit (Stoughton et al. 2002). The set-up parameters and resulting image properties are summarized in Table 3. A composite image is shown in Fig. 3 along with our GMRT H\textsc{i} detections.

Subtraction of contamination from foreground stars and background galaxies used the Secker (1995) ring-filter technique embedded within Elixir+Elixir-LSB. The $\sim$6 arcmin (90 kpc) diameter reflection halos in Fig. 3 from two bright stars, HD 14108 (V = 8.62 $\pm$ 0.02 mag) and HD 14192 (V = 7.67 $\pm$ 0.01 mag), within the field of view at 02 17 17.1, +14 27 57 and 02 18 03.7, +14 28 00 could not be excised and have left artifacts in the final optical images. Fortunately, these artifacts lie just outside the spatial location of our gas-rich detections.

### 2 HI DATA ANALYSIS

The eight gas-rich group members (three large spirals, one large irregular and four low-mass features) detected by ALFALFA were also detected in the GMRT data as shown in Fig. 2. No additional H\textsc{i} sources were detected in the spatial and spectral region of the group. The H\textsc{i} column density is computed using:

$$N_{\text{H}_\text{i}} [\text{atoms cm}^{-2}] = \frac{2.228 \times 10^{24}}{\theta_1 \theta_2 \nu^2} \int I_v dv$$

where $\theta_1$ and $\theta_2$ are the semi-major and semi-minor axes of the beam in arcsec, $\nu$ is the central band frequency in GHz and $\int I_v dv$ is the contour level in Jy beam$^{-1}$ km s$^{-1}$.
from the mom$_0$ maps (Irwin et al. 2009). Equation 1 assumes that the source uniformly fills the beam and therefore corresponds to an average column density per resolution element.

Measurements of the flux density from the higher sensitivity 45 arcsec resolution GMRT maps were used to produce the global profiles in Fig. 4. As in Paper 1, the HI mass is calculated using:

$$M_{\text{HI}} [M_\odot] = 2.356 \times 10^4 d^2 S_{\text{HI}}$$

where $d$ is the distance to the source in Mpc and $S_{\text{HI}}$ is the flux density of the global profiles integrated over velocity.

The basic properties of the GMRT HI detections are in Table 4. A comparison of the GMRT data (which are consistent with the results from the noisier first-look VLA data) and ALFALFA observations indicate that a significant portion of the gas (roughly 50 per cent) is diffusely distributed around the interacting spirals and throughout the system on scales of the gas (see Fig. 5). This object also shows no distinguishable velocity gradient perpendicular to the line of sight in Fig. 5f. This object also shows no distinguishable velocity gradient perpendicular to the line of sight in Fig. 5f.

Accordingly, the dynamical mass for AGC 121467 has not been computed. The assumption of dynamical equilibrium is likely valid for AGC 748849, UGC 1761 and AGC 748853, given the coincidence of the HI and optical counterparts.
An extremely optically dim tidal feature in NGC 871/6/7

Figure 3. CFHT $g'r'i'$-band composite image with the GMRT 45 arcsec resolution intensity contour at $N_{HI} = (1, 2, 3) \times 10^{20}$ atoms cm$^{-2}$ to show the span of H$\text{I}$ associated with each gas-rich detection.

Figure 4. Global profiles derived from the GMRT 45 arcsec resolution data. Left: Large spiral galaxies. Right: Low H$\text{I}$ mass group members.
Table 4. HI detections in NGC 871/6/7. Column 1: detection name; column 2: right ascension and declination of peak HI flux density; column 3: centroid of the most probable optical counterpart. An optical feature coincident with AGC 749170 has been detected, for the first time, during this work; column 4: noise in region of detection in 45 arcsec GMRT maps; column 5: integrated HI flux density computed from the global profiles in Fig. 4. The uncertainty was determined by propagating the error from the global profile and adding a 10 per cent calibration error; column 6: HI mass calculated from GMRT observations; column 7: HI mass from ALFALFA α.40 data release (Haynes et al. 2011).

Figure 5. Top: GMRT mom₀ maps at 30 arcsec resolution superimposed on CFHT $g'$-band images. Contours are at $N_{HI} = (1, 2, 3.5, 5, 7, 9.5) \times 10^{20}$ atoms cm⁻². Bottom: GMRT mom₁ maps at 30 arcsec resolution. The velocity contours are at increments of 10 km s⁻¹. (a and e) AGC 748849; (b and f) AGC 121467; (c and g) UGC 1761; (d and h) AGC 748853.

the clear velocity gradient across the HI detection and the optical morphology of the counterparts (Fig. 5).

Fig. 6 shows the total intensity and various velocity maps of AGC 749170 at three different angular resolutions. Additional tapering was applied to the data to produce the 15 arcsec resolution maps of AGC 749170 in an attempt to further investigate its structure. The datacube at this level of spatial resolution is quite noisy and accordingly, corresponding HI images were not produced for the other group members. The top row of images in Fig. 6 reveal, for the first time, a possible faint optical counterpart – located at the point of highest $N_{HI}$ – in the $g'$ and $r'$-bands for this previously dark feature. Nevertheless, the feature is not visible in the noisier $i'$-band data. The first and second velocity maps for AGC 749170 (Fig. 6 middle and bottom rows) show a velocity gradient. We discuss whether or not this gradient represents a self-gravitating, rotating disk in Section 4.

3 STELLAR POPULATION ANALYSIS

SExtractor (Bertin & Arnouts 1996), an automated source extraction algorithm, was utilized for the detection and measurement of the optical components to each low HI mass feature. Photometric properties for AGC 748849, UGC 1761 and AGC 748853, which all have previously established and well-defined optical counterparts, were readily extracted while processing the entire image. The optical flux from a foreground star could not be accurately separated from AGC 121467 and consequently, no photometric information has been reported for this source. The optical properties of the fainter AGC 749170 counterpart were extracted from a 120 × 110 pixel sub-image centred on this source, with the detection and deblending thresholds tailored to this feature. The $r'$-band image was used as the reference for data extraction, with the exception of AGC 749170 as its tentative optical counterpart is more apparent in the higher sensi-
An extremely optically dim tidal feature in NGC 871/6/7

Figure 6. Top: GMRT mom₀ maps at various angular resolutions (45 arcsec for a, d and g; 30 arcsec for b, e and h; 15 arcsec for c, f and i) of AGC 749170 superimposed on three bands of CFHT images. The black contours are at (a) \( N_H = (1, 2, 3, 4) \times 10^{20} \) atoms cm\(^{-2}\) (b) \( N_H = (1, 2, 3, 4, 5) \times 10^{20} \) atoms cm\(^{-2}\) (c) \( N_H = (1, 3, 5, 7, 9) \times 10^{20} \) atoms cm\(^{-2}\). The red ellipse in (b) indicates the region used by SExtractor to calculate the optical properties (see Section 3). Middle: GMRT mom₁ maps. Velocity contours are at increments of 10 km s\(^{-1}\). Bottom: GMRT second velocity moment maps (mom₂).

We will ultimately use SExtractor to catalog all dwarf galaxy candidate members in the group through statistical source counts; we defer this analysis to a future publication. Optical spectroscopy, using a similar manner as presented in [Duc et al., 2014], on each detection in NGC 871/6/7 will also be explored in further follow-up work.

The extracted MegaCam magnitudes for each feature were converted to more conventional SDSS AB magnitudes for comparison to models found in the literature. The colour differences between each band (i.e. \( g - r \) and \( g - i \); listed in Table 6) were directly compared to [Bruzual & Charlot, 2003] stellar population models – which utilize several stellar evolution prescriptions and various spectral libraries – for a range of stellar ages and metallicities. Some objects had varying levels of stellar population degeneracies that could...
were computed using the equation:

$$\log M_i = 1.15 + 0.7(g - i) - 0.4M_i$$

(5)

where $M_i$ is the absolute magnitude of each object in the $i$-band (Taylor et al. 2011). Commonly used stellar mass estimation models, such as Bell et al. (2003), are quite robust for massive galaxies ($M_* \gtrsim 10^{10} M_\odot$) but tend to overestimate at low masses (Huang et al. 2011); however, Taylor et al. (2011) include a census of $10^{8} < M_* < 10^{10} M_\odot$ galaxies to calibrate their model, for a better representation of dwarf galaxies. The computed stellar masses were added to the gas masses to produce total baryonic masses, which – in comparison to the dynamical mass of each detection – enables dark matter content estimates.

Since the $i'$-band component of the faint tentative optical counterpart to AGC 749170 was not detected, an object with the same angular size as that detected in the $g'$-band, assumed to be lying just below the $i'$-band detection threshold, was used to estimate an upper limit $i'$-band magnitude and the associated stellar properties. For the age and metallicity estimates of AGC 749170, the allowed range for $g - i$ below the upper limit was conservatively chosen to be five times the standard deviation of the $g - i$ values of the other low HI mass group members (i.e. $g - i$ ranges from 0.7 to 0.4 mag). The negative value of $g - r$ strongly indicates a younger stellar population for the possible optical component of AGC 749170 and variations in the estimate of $g - i$ have negligible effects on the results.

The SFR for each low HI mass detection was computed using the far-ultraviolet (FUV) flux measured from archival GALEX GR6 data – in the same manner that is presented in Paper 1 – and the formula from Kennicutt (1998) with a conversion factor that has been modified for dwarf galaxies with solar ($Z_\odot = 0.02$) or sub-solar metallicities:

$$\text{SFR}_{\text{FUV}} [M_\odot \text{yr}^{-1}] = 1.27 \times 10^{-28} L_{\text{FUV}}$$

(6)

where $L_{\text{FUV}}$ is the luminosity of each object in erg s$^{-1}$ Hz$^{-1}$ (Hunter, Elmegreen & Ludyk 2010). No correction for dust has been made to our SFR estimations. Although AGC 749170 appears to have a solar to super-solar metallicity, it has no detectable FUV component. Therefore, its SFR is an upper limit (see Paper 1) and modifications of the conversion factor used have minimal effect on the estimation.

A final summary of the properties of the gas-rich low HI mass group members is provided in Table 7. The total gas mass for each detection was computed using a factor of 1.33 to account for helium and other elements (see equation 3 from Paper 1). The average column density $N_{HI, \text{avg}}$ of each detection has been calculated using Equation 1 and the mean intensity measured within the $1 \times 10^{20}$ atoms cm$^{-2}$ contour of the 30 arcsec resolution mom0 maps (see Figs 5 & 6).

### Table 5. Dynamical information for NGC 871/6/7 group members. Column 1: detection name; column 2: global profile width measured at 20 per cent of the peak flux density; column 3: inclination as computed using Equation 3, where applicable; column 4: beam-corrected major axis diameter of object in 30 arcsec resolution maps; column 5: heliocentric velocity of the profile midpoint at 20 per cent of the peak flux density; column 6: total dynamical mass, where applicable. The uncertainty is half the difference between $M_{dyn}$ estimated using $W_{20}$ and the velocity difference across $a_{HI}$ in Equation 3. The values for AGC 121467 were not computed due to contaminating foreground star, see text for details.

4 DISCUSSION AND CONCLUSIONS

We have presented high-resolution HI observations from the GMRT and deep optical imaging from the CFHT MegaCam of the interacting galaxy group NGC 871/6/7. Seven of the eight gas-rich detections (three spirals and four dwarfs) have prominent stellar components and appear to be standard dark-matter dominated galaxies that were built hierarchically during the epoch of galaxy assembly. The other object, AGC 749170, has significant HI ($M_{HI} > 10^6 M_\odot$) but only a
An extremely optically dim tidal feature in NGC 871/6/7

Table 6. Optical properties of low H\textsc{i} mass detections. AGC 121467 has been omitted from this table due to source extraction inaccuracies from an overlapping foreground star. Column 1: detection name; column 2: Kron radius; column 3: resolution moment\textsubscript{0} maps density; column 4: baryonic mass to gas mass ratio, where applicable; column 5: age determined within the systematic uncertainties of the [Br\textsubscript{2}/Ha] models. A range of values is presented for objects with degeneracies; column 6: metallicity (Z = 0.02) determined within the systematic uncertainties of the well known models. Objects with degeneracies are shown with a range of values. An estimated g - i colour range was used to determine the age and Z values for AGC 749170 (see text for details); column 9: star formation rate for each object.

very faint tentative optical counterpart. Assuming that this gas cloud is self-gravitating and in dynamical equilibrium, then M\textsubscript{dyn}/M\textsubscript{baryon} = 1.7 ± 0.5, which indicates a lack of associated dark matter. An optical feature – with an apparently young (~10 Myr) stellar population and a relatively higher metallicity than the other low H\textsc{i} mass group members – that is spatially located within the contour of the peak H\textsc{i} column density of AGC 749170 has been detected in both the g' and r'-band photometry. These properties corroborate that AGC 749170 is not a primordial dark galaxy and was formed as a result of a previous tidal interaction.

The middle row of Fig. [Fig. 6] shows a clear velocity gradient across AGC 749170; however, this gradient might not be indicative of rotation across the entire source. In the 15 arcsec resolution images, AGC 749170 breaks up into three “clumps”. The smallest northwest clump is likely a tidal extension. If the two larger southern clumps form a self-gravitating disk, then the optical counterpart should reside between the two lobes rather than in the centre of the southeast clump, where it currently appears. As well, the second moment maps (bottom row of Fig. [Fig. 6], a measure of the velocity dispersion, would peak near the centre of the two southern clumps. It is possible that deeper optical observations may reveal a more extensive optical counterpart and that our velocity dispersion maps are noisy. Nevertheless, our observations suggest that only the southeast clump – with there is a possible optical counterpart – is rotating and in dynamical equilibrium while the other H\textsc{i} two components are tidal extensions. In this scenario, the self-gravitating feature would have M\textsubscript{gas} ≈ 8 × 10\textsuperscript{8} M\odot and M\textsubscript{dyn}/M\textsubscript{baryon} ∼ 1 as well as a young metal-rich stellar population, which still indicate tidal origins for AGC 749170.

Presuming that a tidal interaction did produce AGC 749170, the global profiles of the large spiral galaxies may provide some insight into its origin. The fairly symmetrical double-horned profile for NGC 871 suggests that its gas content has had minimal disturbances within the past few Gyr. Whereas, the HI components of NGC 876 and NGC 877 overlap both spatially and spectrally while Fig. [Fig. 4] shows gas disturbances for each galaxy at heliocentric velocities between 3850 and 4050 km s\textsuperscript{-1}. This range includes the velocity of AGC 749170 (e\textsubscript{z0} = 3905 ± 3 km s\textsuperscript{-1}, W20 ≈ 60 km s\textsuperscript{-1}). If NGC 876 and NGC 877, which have a combined HI mass of 1.5 × 10\textsuperscript{8} M\odot, are standard Sc and Sbc spirals, galaxies, they would each contain M\textsubscript{HI} ∼ 10\textsuperscript{8} M\odot (Robert & Haynes 1994). As such, a gaseous cloud of 10\textsuperscript{7} M\odot (i.e. AGC 749170) could be added to their combined mass and the two galaxies would still be consistent with field spirals. Two other dwarf galaxies also appear in the spectral range of the interaction between the two large spirals; however, the projected distance of AGC 748849 (~250 kpc away) from the current interaction site and the symmetry of the HI in UGC 1761 (in both the global profile and the gas distribution in relation to its stellar component, see Fig. [Fig. 5]) suggest that these dwarfs are neither involved in the current interaction nor are they likely progenitors of AGC 749170.
Based on the dynamical masses of the suspected parent galaxies (NGC 876 and NGC 877), AGC 749170 is likely the result of a 2.5:1 mass ratio interaction event. Major mergers in both observations and numerical simulations have been shown to produce mass condensations of $10^9 M_\odot$ located at the tips of extended tidal tails ($\sim 100 - 1000$ kpc in length; e.g. Bournaud et al. 2004 [Mullan et al. 2011]). AGC 749170 is located at a projected distance of $\sim 100$ kpc from its possible progenitors; however, the lack of a tidal tail and a readily detectable stellar component precludes its classification as a typical TDG or tidal knot.

The systemic velocity difference between AGC 749170 and the two large spirals is sufficient enough to have possibly moved the cloud to its current separation distance over the past few Gyr, during which time any gaseous trace of a tidal tail would have faded away (Holwerda et al. 2011). Nevertheless, if a cloud of $M_{H_i} > 10^9 M_\odot$ has existed for such a length of time, its low stellar content and young stellar age ($M_{stellar} \lesssim 10^6 M_\odot$, $t \sim 9$ Myr) is unusual compared to other tidal objects with similar gas masses (e.g. Schaye 2004 [Bournaud et al. 2007]). It is also valid to note that a reflection halo in the optical photometry due to HD 14192, a bright foreground star, could be obscuring a possible stellar tidal tail in that region (see Fig. 3).

The critical column density below which no star formation is expected to occur is $N_{H_i, crit} = (3 - 10) \times 10^{20} \text{ atoms cm}^{-2}$ (Schaye 2004). As reported in Table 7, AGC 749170 has an average column density of $(2.44 \pm 0.04) \times 10^{20}$ atoms cm$^{-2}$ within the lowest contour of the 30 arcsec resolution H$\alpha$ maps (which falls below the critical threshold) but at 15 arcsec resolution, $N_{H_i, avg} = (4.6 \pm 0.1) \times 10^{20}$ atoms cm$^{-2}$ and its peak column density, which coincides with the spatial location of its possible optical counterpart, is well above this value. In a recent study of stellar formation within tidal debris, Maybhate et al. (2007) found that two tidal tails with $N_{H_i} \gtrsim 4 \times 10^{20}$ atoms cm$^{-2}$ have no significant star cluster populations. In that paper, the gas volume density is presented as a more useful diagnostic tool, where one of the tails in NGC 4038/9 has a high column density that spans a small area ($\sim 10$ kpc$^2$), which makes its unlikely to form a significant amount of stars. The high column density region of AGC 749170 spans at least $300$ kpc$^2$ and even though our deep optical imaging clearly shows star clusters for each of the other low H$\alpha$ mass group members, AGC 749170 remains extremely optically dim.

Table 8 compares various dark gas-rich galaxy-like features from the literature. It appears that AGC 749170 is not unique and shares similar properties to other puzzling objects, in particular the SW clump in H$\alpha$ 1225+01 (assumed to be tidal by Chengalur, Giovanelli & Haynes 1995, but recently revisited as being a possible dark galaxy by Matsuo et al. 2012) and Vela C (English et al. 2010). The three clouds have roughly the same H$\alpha$ mass, velocity width and separation distance from their likely parent galaxies. AGC 749170 and Vela C also have comparable diameters and a similar “clumpiness” in their H$\alpha$ maps. The lower H$\alpha$ column density of Vela C could be attributed to smearing effects from the larger beam size, as implied by Equation 1. Considering the fact that the tentative optical counterpart to AGC 749170 is barely visible in deep CFHT photometry, similar sensitivity observations for Vela C are required to search for a comparable optical feature. The SW clump of H$\alpha$ 1225+01 appears to have an H$\alpha$ bridge linking it to the NE clump, the latter shows clear signs of tidal interactions (Chengalur et al. 1995). Nevertheless, deep optical imaging (down to a limit of $R_{AB} = 28.3$ mag arcsec$^{-2}$) of the region has not revealed any optical component to the SW clump (Matsuoka et al. 2012). Overall, the star formation properties of these clouds are extreme compared to typical tidal dwarfs but this result could be the effect of the group environment.

AGC 749170, the SW clump of H$\alpha$ 1225+01, Vela B and Vela C appear to have relatively higher gas masses than other compact (i.e. not diffuse and/or extended structures as found in Ryder et al. 2001) and optically dark clouds. It is possible that these objects lie on the extreme end of a rare class of dark/dim tidal features. Hydrodynamic simulations could be used to determine the likelihood of a $10^9 M_\odot$ gas cloud moving $\sim 100$ kpc from its location of origin while dissipating the tidal tail and remaining relatively star-less. A future paper could also investigate the interplay between a merging event, the intrinsic group dynamics or the overall tidal effect of the environment in producing such objects as most dark/dim features are detected in groups or on the outskirts of clusters rather than in isolation.

We thank the staff of the GMRT that made our interferometric observations possible. Thank-you to the reviewer for his/her suggestions to improve the clarity of this paper. We also thank J. A. Irwin for her input on the overall research project. K. S. acknowledges funding from the National Sciences and Engineering Research Council of Canada. The ALFALFA team at Cornell is supported by U.S. NSF grants AST-0607007 and AST-1107390 to R. G. and M. P. H. and by grants from the Brinson Foundation. The GMRT is run by the National Centre for Radio Astrophysics of the Tata Institute of Fundamental Research. This research used optical observations obtained with MegaPrime/MegaCam, a joint project of CFHT and CEA/DAPNIA, at the Canada-France-Hawaii Telescope (CFHT) which is operated by the National Research Council (NRC) of Canada, the Institute National des Science de l’Univers of the Centre National de la Recherche Scientifique de France, and the University of Hawaii.
