ABSTRACT Studies were initiated for two consecutive years to examine the effects of transplanting date on the yield and quality of early maturing rice cultivars and to select rice cultivars capable of adapting to early transplanting in the middle plain area. The experiment was laid out in a split-plot design with 3 replications. The main plots consisted of two transplanting dates viz. early (25th of April) and ordinary (25th of May), with sub-plots containing eight cultivars. For early transplanting the mean temperature at the grain filling stage was lower than for ordinary transplanting, while the rice grain quality traits and palatability values were improved. Early transplanting results in 11 days earlier heading, higher head rice yield and lower milled rice yield than ordinary transplanting. Significant differences among the eight cultivars tested in this study were observed for most traits. Among cultivars, ‘Joami’ demonstrated the highest palatability. ‘Joami’ also performed better in head rice ratio and head rice yield than ‘Unkwang’, which is widely cultivated in the middle plain area. Palatability value (PV) showed significant positive correlations with head rice ratio (HR) and amylose content (AC), and negative correlations with chalky rice ratio (CR) and protein content (PC). Mean temperature (MT) was positively correlated with CR and PC, and negatively correlated with HR and AC. The highest positive and negative correlations among the rice quality traits were observed between HR and AC (r = 0.734), and HR and CR (r = -0.944), respectively. Based on the research findings, ‘Joami’ is suitable for early transplanting for cultivation in the Chungnam plain area.

Keywords Early maturing rice, Transplanting time, Yield, Quality, High temperature

INTRODUCTION Early season cultivation of early maturing rice cultivars in plains area is very attractive for many reasons. Farmers can disperse the farm work in other periods and sell the raw rice at a high price before ‘Chuseok’, Korean Thanksgiving Day. In addition, Rice Processing Complexes (RPC) efficiently operates utilities and use the newly harvested rice as a good marketing tool to manage existing customers and pioneer a new market. As of 2011, the early transplanting cultivation area containing early maturing cultivars reached 42,000 ha, accounting for 46% of the total area for early maturing cultivars (Lee et al. 2012). For this reason, RPCs make contracts with farmers to grow early maturing rice cultivars by early season cultivation. However, early maturing rice cultivars which have been bred to grow in mid-mountain and mountainous regions tend to display worse grain appearance and eating quality than late maturing rice cultivars when grown in plains areas, mainly due to the high temperature at the grain filling stage (Choi et al. 1994; Choung et al. 2004).

With improvement of the standard of living, the demand for superior rice grain quality has become a priority issue (Yoshinobu et al. 2007; Hao et al. 2009; Lee et al. 2012). The definition of rice grain quality is complex, involving many components such as appearance, cooking quality and eating quality. Among these properties, consumers often pay more attention to appearance (Guo et al. 2011). Rice grain quality can be affected by genetic and environmental factors, especially temperature at the grain filling stage.
High temperature during the grain filling stage causes increase in the occurrence of chalky grain and decrease of the head rice ratio (Lisle et al. 2000; Adoration et al. 1977). The most favorable temperature to produce high quality japonica rice was reported to be about 25°C at the filling stage (Jin et al. 2005). For this reason, early maturing rice cultivars grown in plains areas display bad grain appearance and eating quality compared with those grown in mid-mountain and mountainous regions (Choi et al. 1994; Choung et al. 2004), because they experience higher temperature during the ripening stage. The reason for the decrease in rice quality is that the high temperatures interfere with kernel development and reduce the carbohydrates in the plant during the grain filling stage, leading to a decrease in the head rice ratio as well as the appearance traits (He et al. 1990; Morita 2008; Morita and Nakano 2011).

A number of early maturing rice cultivars have been grown in plains areas for early harvest. Rice grain quality was reported to be different among cultivars tested under high temperatures (Nishimura et al. 2000). ‘Unkwang’, widely grown since 2004 due to its high yield, showed the worst appearance and grain quality among cultivars tested when cultivated in plains areas by early season cultivation (Lee et al. 2008). For these reasons, there is a need to replace Unkwang with other early maturing cultivars with better quality. Although the early maturing cultivars grown in plains areas after late transplanting display similar quality traits compared with medium maturing cultivars (Choi et al. 2005), it is difficult to harvest the rice before ‘Chuseok’ with late transplanting, and it has been used only for double cropping.

Improving the heat tolerance of rice is one way to solve this problem (Morita 2008), and genetic studies have been carried out to examine heat tolerance for the breeding of heat-tolerant cultivars. In Japan, heat-tolerant rice cultivars such as ‘Nikomaru’ (Sakai et al. 2010), ‘Kumasannochikara’ (Fuji et al. 2009), ‘Genkitsukushi’ (Wada et al. 2010) and ‘Akisakari’ (Tanoi et al. 2010) were developed. The heat-tolerant cultivars showed better appearance with lower chalky rice ratio at high temperatures during the ripening stage than other cultivars (Kohei et al. 2009). Early maturing rice cultivars adaptable to plains areas should be tolerant to high temperature during the ripening stage. However, a limited number of studies have investigated the adaptability of early maturing rice cultivars to plains areas, or for tolerance to high temperature in Korea (Choi et al. 2005; Choung et al. 2004; Lee et al. 2008; Lee et al. 2012). The present study was conducted to determine the effects of transplanting date on the yield and quality of early maturing cultivars, and to select the cultivars adaptable to early transplanting in middle plains areas.

**MATERIALS AND METHODS**

**Plant materials and field trial**

Eight early maturing japonica cultivars were used to evaluate variation in yield and quality traits (Table 1). They were developed between 2000 and 2008, and had close relationships. Three cultivars, ‘Goun’, ‘Joan’, and ‘Odae 1,’ shared ‘Jinbu 10’ as the crossing parent. Seedlings of eight early maturing commercial rice cultivars were raised

| Cultivar | Line designation | Cross combination | Year of development |
|----------|------------------|-------------------|---------------------|
| Goun     | Jinbu 36         | Jinbu 10/Jinbu 17 | 2004                |
| Joami    | Sangju 36        | Sambaeg/Yukara/Tonggae 112 | 2008          |
| Joan     | Suweon 478       | Jinnibyeo/Jinbu 10 | 2003                |
| Jokwang  | Milyang 213      | Milyang 187/YR21113-B-B | 2007          |
| Junamjosaeng | Milyang 208 | Milyang 165/Koshikari | 2006           |
| Odae 1   | Jinbu 37         | Ilpumbyeo/Jinbu 10 | 2005                |
| Taebong  | Cheolweon 59     | SR13330-13-3-5/Jinbubyeo  | 2000          |
| Unkwang  | Unbong 30        | Sobibyeo/Cheolweon 54 | 2004                |
Variation of Yield and Quality in Early Maturing Rice Cultivars by Transplanting Date in Chungnam Plain Area in Korea

in greenhouses for 30 days after sowing and then transplanted on the 25th of April and the 25th of May, respectively. A total of 4-5 seedlings were planted per hill, with the spacing of 15 cm between plants and 30 cm between rows, in the experimental field of the Chungcheongnam-do Agricultural Research and Extension Services (CNARES) in 2009 and 2010. A split plot design with three replications was employed with the transplanting date as the main plot, and cultivars as the subplots. In the subplots, seedlings of each cultivar were planted in 7 lines, with 32 plants per line. Fertilizer (N-P₂O₅-K₂O) was applied at the rate of 90-45-57 kg/ha.

**Trait evaluation**

Nine agronomic traits were investigated according to the standard of research and investigation for agronomic traits (RDA 2003): days to heading (DTH; the number of days from sowing to emergence of 50% of the panicle head); culm length (CL; the distance between the soil surface to the tip of the tallest panicle neck); panicle length (PL; the distance between the panicle neck and panicle tip); panicle number (PN; the number of productive tillers per hill); spikelets per panicle (SPP; the average number of spikelets counted on all panicles of 3 plants); milled rice yield (YD); ripened grain ratio (the average no. of fully ripened grains counted on 3 plants). Yield of milled rice (YD) was measured and calculated as the average weight of bulked grain harvested from 100 plants per line. The YD was corrected for 15% grain moisture content.

Each rice sample was harvested when the accumulated mean temperature reached 1,100°C after heading. After harvesting, rice grains were air-dried until the moisture content reached 15%, and then dehulled to yield brown rice. Each brown rice sample was milled to 92% milling yield by a polishing machine (Toyo, Japan), and then the milled samples were stored in a refrigerator (15°C) to prevent change of quality. Head rice ratio (HR, unbroken and broken translucent grains with at least 3/4 of a whole grain), chalky rice ratio (CR, grains with an opaque, chalky appearance covering at least half of the body of the grain), and the broken and defected rice ratio (damaged and discolored rice) were calculated with an RN-300 automatic rice grader using a sample of 1,000 grains. Protein content (PC) and amylose content (AC) of milled rice was measured with a Grain Analyzer (AN700 Kett, Japan) using 100g milled rice samples. Palatability value (PV) was calculated for 33g samples of milled rice by the Toyo taste meter (MA-90A and 90B, Toyo, Japan), in accordance with the operation manual (TRCM Co., Japan). Meteorological data were collected from the Korean Meteorological Administration homepage (http://www.kma.go.kr), and the mean temperature (MT), diurnal range (DR) and sunshine hours (SH) for 30 days after heading were calculated.

**Statistical analysis**

Data were analyzed with year, transplanting date and cultivar as the main, subplot and sub-subplot, respectively, using a split-split plot design. ANOVA indicated that F-values for the effect of main-plot and all interaction terms were not significant, so averages of the data for the two years were used in statistical analysis. The t-test, analysis of variance and correlation analysis were performed using SPSS software (Ver. 18.0.0). Phenotypic means of each cultivar were compared using Duncan’s multiple range test.

**RESULTS**

**Meteorological data**

The meteorological data for 30 days after heading, according to transplanting time and cultivar, are shown in Table 2. No differences were observed among cultivars for three components. However, there was a significant difference between the two transplantation times. Early transplanting showed a lower mean temperature and diurnal range, with shorter sunshine hours than ordinary transplanting. Mean air temperatures during the growing season in 2009 and 2010, and the average of five years from 2004 to 2008, are shown in Fig. 1. In July and August, the mean temperature for 2009 was lower than 2010, while the mean temperature in 2010 was higher than the five-year average examined.
Fig. 1. Mean air temperature during the growing season in 2009 and 2010, and the average of five years from 2004 to 2008. Black, gray, and broken lines indicate air temperature in 2009, 2010, and the average of 5 years, respectively. Data were obtained from the website of the Korean Meteorological Administration (http://www.kma.go.kr).

Table 2. Meteorological data for 30 days after heading, by transplanting time and cultivar.

| Transplanting time | Cultivar     | Heading date | Mean temperature (℃) | Diurnal range (℃) | Sunshine hour (hr) |
|-------------------|--------------|--------------|----------------------|-------------------|-------------------|
| Early (April 25)  | Goun         | July 13      | 24.3                 | 8.40              | 129.1             |

\[\text{Difference}^{(2)} = -8.179^{**} -6.012^{**} -3.747^{**}\]

\(^{(2)}\) *, **: Significantly different between two transplanting times at \(P = 0.05\) and \(0.01\), respectively.
**Variation of agronomic traits**

Upon early transplanting, the days to heading was an average of 11 days shorter than ordinary transplanting, with ‘Goun’ and ‘Taebong’ being the earliest among the cultivars tested (Table 3). Culm length and panicle length showed significant differences according to the transplanting date. Those in early transplanting were 7.5 and 0.6 cm shorter, respectively. No differences were observed in the number of panicles and spikelets, and in the grain filling ratios between the two transplanting dates. However, differences among the cultivars were detected for all agronomic traits according to transplanting date. Among the cultivars tested, Unkwang showed the shortest culm and the longest panicle. Long panicles may be associated with large numbers of spikelets and lower grain filling ratios. ‘Goun’ showed the reverse trend of ‘Unkwang,’ while ‘Joami’ had the highest number of panicles among the cultivars.

Grain yield is the most important element in rice production, and is also affected by environmental factors. As shown in Table 4, significant differences were observed in all yields between the two transplanting dates. Milled rice yield was lower for early transplanting than late transplanting. In addition, ‘Unkwang’ recorded the highest milled rice yield, while ‘Goun’ was the lowest in both transplanting. Head rice yield was higher for early transplanting, with differences between the transplanting times. When transplanted early, ‘Joami’ and ‘Joan’ had the

highest head rice yield, while ‘Joami’ and ‘Jokwang’ were the highest for the ordinary transplanting time.

Rice appearance traits

Rice appearance quality is the most important trait in rice production because it influences customer selection when buying rice. For example, rice with high head and low defects is considered to be high quality, and the appearance quality can easily be compared by customers in a short time without any equipment. For this reason, RPCs try to improve the head rice ratio, with the penalty of low milling yield. The results of rice appearance traits according to transplanting times and cultivars are summarized in Table 5. Most of the traits showed significant interaction between transplanting time and cultivar. Head rice ratio showed significant differences between the two times, with the early transplanted rice displayed 5.8% more head. ‘Joan’ showed the highest head rice ratio in early transplanting, while ‘Jokwang’ was the highest for the ordinary time. ‘Unkwang’ had the highest proportion of chalky rice among the eight rice cultivars for both transplanting dates.

Physicochemical traits and palatability value

Protein and amylose content of the rice also showed significant differences between the transplanting dates and among the cultivars examined herein (Table 6). The protein content was lower for early transplanting by 0.35%. The highest protein content was observed in ‘Joan’ with the lowest in ‘Junamjosaeng’ for both dates. Amylose content ranged from 18.06% (Unkwang) to 18.61% (Goun). As for

the palatability value, ‘Joami’ recorded the highest score among the eight cultivars, while ‘Unkwang’ was the lowest for both transplanting times.

Correlation analysis showed that all traits were significantly correlated with each other (Table 7). PV was positively correlated with HR, AC, DR and SH, but negatively correlated with CR, PC and MT. In addition, MT was positively correlated with CR and PC, but negatively correlated with HR and AC. The highest positive and negative correlations observed among rice the quality traits were between HR and AC ($r = 0.734^{**}$), and HR and CR ($r = -0.944^{**}$), respectively. These results suggested that the rice quality traits are dependent on each other, and are affected by environmental factors.

DISCUSSION

Nowadays, early maturing rice cultivars suitable for growth in mid-mountain and mountainous areas are being cultivated in plains areas to sell new crop rice before ‘Chuseok’, the Korean Thanksgiving Day. The quality of rice grain deteriorates when early maturing rice cultivars are cultivated in plains areas due to the high temperature during the grain filling stage. Yun and Lee (2001) reported that the optimum temperature for the grain filling stage which leads to the production of high quality japonica rice ranged from 21°C to 23°C. The mean temperatures of all rice cultivars tested in this study were over 24.0°C, leading to a high ratio of chalky rice, while ‘Unkwang’ was the highest. Chalky rice is easily broken during milling, and has less stickiness than head rice when cooked, which

decreases the palatability. The increase in the ratio of chalky rice might be due to interference with kernel development and reduction in carbohydrates in the plant at the grain filling stage due to the high temperature (Nagata et al. 2004). In addition, high temperature at the grain filling stage influences the physiochemical properties, such as protein and amylose content (Jin et al. 2005; Aboubacar et al. 2006). Several QTL studies reported the colocalization of QTL for heading date and grain quality (Li et al. 2011; Takeuchi et al. 2007, 2008). Nishimura et al. (1985) reported that heading date affected the chemical components such as ADV, and the amylose and protein content, which
could affect the eating quality. These results imply a causal relationship between heading date and grain quality, because the heading date might determine the timing of the grain filling stage of each cultivar, which is in turn associated with the grain quality traits. In this study, the mean temperature at grain filling stage was positively correlated with PC, but negatively correlated with amylose content. Jin et al. (2005) evaluated the influence of temperature at the filling stage on the activities of key enzymes related to grain starch synthesis to gain an understanding of how temperature influences the biochemical characteristics, and demonstrated that starch synthesis is dependent on temperature. The activity of SBE (starch branching enzyme) was especially sensitive to temperature, reaching a maximum at 25°C, after which the activity decreased with further rise in temperature. In general, protein content was reported to be negatively correlated with eating quality (Juliano et al. 1965; Ishima et al. 1974), as rice with higher protein content displayed lower adhesiveness and water uptake ratio than that with low protein content, which was also associated with a decrease in the glossiness, taste and stickiness of cooked rice (Yoshinobu et al. 2007; Yanase et al. 1984). The results obtained in the present study also support these observations. Mean temperature during the grain filling stage (MT) for early transplanting was lower than for ordinary transplanting, which may lead to better rice grain quality. MT was negatively correlated with HR and PV, but positively correlated with CR, suggesting that MT clearly affected the rice quality. In addition, early transplanting decreased the number of days to heading by 11 days compared to the ordinary transplanting time, and increased the head rice yield, although the milled rice yield decreased by an average of 21 kg/10a. These results suggest that early transplanting is more advantageous for the production of high quality rice in the middle plains area. Among the 8 rice cultivars tested in this study, ‘Unkwang’ showed the highest yield, but the lowest values for the rice quality traits, including HR, AC and PV. This is likely due to the fact that the rice quality traits were highly correlated with each other.

In conclusion, early maturing cultivars in the middle plains areas had less desirable grain quality at the ordinary transplanting time than at early transplanting, mainly due to high temperatures during the grain filling stage. Varietal differences were observed among the eight cultivars, depending on the transplanting times. Although ‘Joan’ had the highest head rice yield for early transplanting, ‘Joami’ showed the highest palatability value during both times. ‘Joami’ also performed better in head rice ratio, head rice yield and palatability values than ‘Unkwang’. Based on the research findings, ‘Joami’ might be most suitable for early transplanting cultivation in middle plains areas.
