Viscosities of Quark-Gluon Plasmas

H. Heiselberg

Nuclear Science Div., MS 70A-3307, Lawrence Berkeley Laboratory, Berkeley, CA 94720, USA

The quark and gluon viscosities are calculated in quark-gluon plasmas to leading orders in the coupling constant by including screening. For weakly interaction QCD and QED plasmas dynamical screening of transverse interactions and Debye screening of longitudinal interactions controls the infrared divergences. For strongly interacting plasmas other screening mechanisms taken from lattice calculations are employed. By solving the Boltzmann equation for quarks and gluons including screening the viscosity is calculated to leading orders in the coupling constant. The leading logarithmic order is calculated exactly by a full variational treatment. The next to leading orders are found to be very important for sizable coupling constants as those relevant for the transport properties relevant for quark-gluon plasmas created in relativistic heavy ion collisions and the early universe.
I. INTRODUCTION

Transport and relaxation properties of quark and gluon (QCD) plasmas are important in a number of different contexts. They determine the time it takes a quark-gluon plasma formed in a heavy-ion collision to approach equilibrium, and they are of interest in astrophysical situations such as the early universe, and possibly neutron stars.

The basic difficulty in calculating transport properties of such plasmas, as well as of relativistic electron-photon (QED) plasmas, is the singular nature of the long-range interactions between constituents, which leads to divergences in scattering cross sections similar to those for Rutherford scattering. This makes the problem of fundamental methodological interest, in addition to its possible applications. The first approaches to describe the transport properties of quark-gluon plasmas employed the relaxation time approximation \[ \tau_{r} \] for the collision term. This approximation simplifies the collision integral enormously and transport coefficients are related directly to the relaxation time \[ \tau_{r} \]. The latter is typically estimated from a characteristic cross section times the density of scatterers. In Refs. 3, 4 the divergent part of the total cross section at small momentum transfers was assumed to be screened at momentum transfers less than the Debye moment. However, Debye screening influences only the longitudinal (electric) part of the QED and QCD interactions, and the transverse (magnetic) part is unscreened in the static limit.

Recently it has been shown that this physics is responsible for cutting off transverse interactions at small momenta is dynamical screening 3. This effect is due to Landau damping of the exchanged gluons or photons. Within perturbative QCD and QED rigorous analytical calculations of transport coefficients to leading order have been made for temperatures high \[ T \] as well as low \[ T \] compared with the chemical potentials of the constituents.

Transport processes depend on a characteristic relaxation time, \[ \tau_{r} \], of the particular transport process considered. For example, in high temperature plasmas the viscosities, \[ \eta_{i} \], of particle type \( i \) are proportional to the characteristic times for viscous relaxation, \[ \tau_{\eta,i} \approx \tau_{tr} \], which are first calculated in 3 to leading order in the coupling constant. More generally one finds that the typical transport relaxation rates, that determines momentum stopping, thermal and viscous relaxation, is in a weakly interacting QCD plasma

\[
\frac{1}{\tau_{tr}} \propto \alpha_{s}^{2} \ln(1/\alpha_{s})T + O(\alpha_{s}^{2}).
\]

where the expansion is in terms of the fine structure constant \( \alpha_{s} \) = \( g^{2}/4\pi \). The coefficients of proportionality to the leading order in \( \alpha_{s} \) (in the following called the leading logarithmic order) has been calculated analytically for a number of transport processes in high temperature plasmas 3. Likewise in a QED plasma the typical transport relaxation rates for viscous processes, momentum stopping, thermal and electrical conduction have the same dependence as (1) on the QED fine structure constant \( \alpha \).

The dependence of the transport rates on the coupling constants is very sensitive to the screening. Besides the factor \( \alpha_{s}^{2} \) from the matrix element squared of the quark and gluon interactions, the very singular QCD interactions for small momentum transfers lead to a logarithmic dependence \( \ln(q_{max}/q_{min}) \), of the maximum and minimum momentum transfers. The typical particle momenta limits to the maximum momentum transfer, \( q_{max} \approx T \), and Debye and dynamical screening leads to effective screening if \( q \) is small momentum transfers of order \( q_{min} \approx q_{D} \approx g \alpha_{s}^{2} T \). This gives the leading logarithmic order in the coupling constant, \( \ln(T/q_{D}) \approx \ln(1/\alpha_{s}) \), to the transport rates.

The calculations in 3-5 were brief and dealt only with the leading logarithmic order in the coupling constant, and with an ansatz for the distribution function. Here we give a summary and discuss generalizations of the methods developed here to other transport coefficients. More detailed calculations of the quark and gluon viscosities in the high temperature quark-gluon plasmas are presented. The leading logarithmic order is calculated exactly by a variational method and the next to leading order - the \( \alpha_{s}^{2} \) term in (1) - is calculated as well. Because \( \alpha_{s} \) is not exponentially small, the next to leading order is important in many realistic physical situations as relativistic heavy ion collisions and the early universe. Furthermore when the Debye screening length is larger than the interparticle screening, which occur when \( \alpha_{s} \lesssim 0.1 \), we shall see below, Debye and dynamical screening break down. Instead lattice gauge calculations have found that quark-gluon plasmas seem to develop a constant screening mass, \( m_{pl} \approx 1.1T \), for temperatures \( T > 2 - 3T_{c} \), and is important to see what effects this alternative screening mechanism has in strongly interacting plasmas.

We shall first describe in section II the transport theory, we use, namely the Boltzmann equation, and the screening of long range QCD and QED interactions. In section III, we describe the process of shear flow and the variational calculation necessary in order to find the viscosity. In section IV we then evaluate the collision term to leading logarithmic order with a simplifying ansatz for the trial function and refer to Appendix A for a full exact variational calculation. In section V we calculate the viscosity to higher orders in the coupling constant and discuss strongly interacting plasmas. Finally, in section VI we give a summary and discuss generalizations of the methods developed here to other transport coefficients.

II. TRANSPORT THEORY

Transport processes are most easily described by the Boltzmann equation

\[
(\frac{\partial}{\partial t} + v_{1} \cdot \nabla_{r} + F \cdot \nabla_{p_{1}})n_{1} = 2\pi\nu_{2} \sum_{\{M\}} |M|^{2}
\]
where $\epsilon_i$ is the energy and $p_i$ the momentum of the quasi-particles, $F$ some force acting on the quasi-particles, and the right-hand side of (2) is the collision term. $n_i(p_i)$ are the Fermi and Bose quasi-particle distribution functions for quarks and gluons and the signs ± include stimulated emission and Pauli blocking. The spin and color statistical factor $\nu_2$ is 16 for gluons and $12N_f$ for quarks and antiquarks with $N_f$ flavors. $|M|^2$ is the squared matrix element for the scattering process $1 \to 2$, summed over final states and averaged over initial states. It is related to the Lorentz-invariant matrix element $|M|^2$ by $|M|^2 = |M|^2/(16\epsilon_1\epsilon_2\epsilon_3\epsilon_4)$. For gluon-gluon scattering (see Fig. (1))

$$|M_{gg}|^2 = \frac{9}{4}g^4 \left( 3 - \frac{u s}{t^2} - \frac{s t}{u^2} - \frac{u t}{s^2} \right), \quad (3)$$

where $s$, $t$, and $u$ are the usual Mandelstam variables. In Eq. (3) the double counting of final states has been corrected for by inserting a factor 1/2. For quark-gluon scattering

$$|M_{qg}|^2 = g^4(u^2 + s^2) \left( \frac{1}{t^2} - \frac{4}{9us} \right), \quad (4)$$

and for scattering of two different quark flavors

$$|M_{q_1 q_2}|^2 = \frac{4}{9}g^4 \frac{u^2 + s^2}{t^2}. \quad (5)$$

The matrix element for scattering of the same quark flavors or quark-antiquark scattering is different at large momentum transfers but the same as (3) at small momentum transfers.

The $t^{-2}$ and $u^{-2}$ singularities in Eq. (3) lead to diverging transport cross sections and therefore vanishing transport coefficients. Including screening, it was shown in (3) that finite transport coefficients are obtained. In fact, the leading contribution to transport coefficients comes from these singularities. In the $t = \omega^2 - q^2$ channel the singularity occurs for small momentum $q$ and energy $\omega$ transfers (see Eq. (1)).

For small momentum transfer, $q \ll \epsilon_1, \epsilon_2 \sim T$, energy conservation implies that $\omega = \epsilon_1 - \epsilon_2 \simeq v_1 \cdot q = -v_2 \cdot q$ where $v_i = p_i$. Therefore the velocity projections transverse to $q$ have lengths $|v_{1,T}| = |v_{2,T}| = \sqrt{1 - \mu^2}$, where $\mu = \omega/q$. Consequently $v_{1,T} \cdot v_{2,T} = (1 - \mu^2) \cos \phi$, where $\phi$ is the angle between $v_{1,T}$ and $v_{2,T}$. For $q \ll T$ we thus have

$$s \simeq -u \simeq 2p_1p_2(1 - \cos \theta_{12}) \simeq 2p_1p_2(1 - \mu)(1 - \cos \phi), \quad (6)$$

and the interactions split into longitudinal and transverse ones, (3)

$$|M_{gg}|^2 = \frac{9}{8}g^4 \left( \frac{1}{q^2 + \Pi_L} \right) \left( 1 - \mu^2 \right) \cos \phi \right|^2. \quad (7)$$

The interactions are modified by inclusion of the gluon or photon, self energies, $\Pi_L$ and $\Pi_T$ (see also Fig. (1)). In the random-phase approximation the polarizations are given in the long wavelength limit ($q \ll T$) by

$$\Pi_L(q, \omega) = \frac{q^2}{2} \left[ 1 - \frac{\mu}{2} \ln \left( \frac{\mu + 1}{\mu - 1} \right) \right], \quad (8)$$

$$\Pi_T(q, \omega) = \frac{q^2}{8} \left[ \frac{\mu^2 + \mu(1 - \mu^2)}{4} \ln \left( \frac{\mu + 1}{\mu - 1} \right) \right], \quad (9)$$

where $\mu = \omega/q$ and $q_D = 1/\lambda_D$ is the Debye wavenumber.

In a weakly-interacting high temperature QCD plasma

$$q_D^2 = 4\pi(1 + N_f/6)\alpha_sT^2, \quad (10)$$

where $\alpha_s = g^2/4\pi$ is the fine structure constant for strong interactions, the factor $(1 + N_f/6)$ is the sum of contributions from gluon screening, the “1,” and from light mass quarks, of number of flavors, $N_f$. In a high temperature QED plasma, $q_D^2 = 4\pi\alpha T^2/3$, where $\alpha$ is the QED fine structure constant.

One should keep in mind that the self energies of (8) and (9) are only valid in the long wavelength limit, i.e., for $q \ll T$. When $q \sim T$ other contributions of order $\alpha_s qT$ enter (see, e.g., (3)) which may be gauge dependent (14). However, as long as $\alpha_s$ is small all contributions from the self energies can be ignored in the gluon propagator when $q \sim T$ because the matrix element squared already carry the order $\alpha_s^2$.

In the above derivations we have consistently assumed that the screening was provided in RPA by the gluon self energies which give the Debye and dynamical screening of longitudinal and transverse interactions respectively. Both effects provide a natural effective cutoff for momentum transfer less than $q_{min} \sim q_D$. These perturbative ideas must, however, break down when the screening length becomes as short as the interparticle spacing, i.e. $q_D \sim T$, or in terms of the coupling constant $\alpha_s \lesssim (4\pi(1 + N_f/6))^{-1} \sim 0.1$ according to Eq. (10). In lattice gauge calculations of quark-gluon plasma above twice the temperature of the phase transition, $T_c \simeq 180$ MeV, one finds strong nonperturbative effects in the plasma so that the typical screening mass is $m_{pl} \sim 1.1 T$ (14). One may argue (13) that perturbation theory still applies for large momentum transfers so that the matrix elements are given by the simple Feynman tree diagrams, but that perturbation theory does not apply for small momentum transfers of order $q \sim q_D$ and that one should rather insert the effective cutoff found by lattice gauge calculations,

$$\Pi_L \simeq T \simeq m_{pl}, \quad \alpha_s \sim 0.1. \quad (11)$$

The phenomenological screening mass of (11) provides with a method to extend our calculations of transport coefficients to larger values for $\alpha_s$ and it can be combined with the Debye and dynamical screening in weakly interacting quark-gluon plasmas.
III. THE VISCOSITY

With screening included in the interaction we can now proceed to calculate transport properties as the viscosity. In the presence of a small shear flow, \( u(y) \), in the \( x \)-direction we obtain from the Boltzmann equation

\[
p_{1x} v_{1y} \frac{\partial n_1}{\partial x} \frac{\partial u_x}{\partial y} = 2\pi \nu_2 \sum_{234} |M|^2 n_1 n_2 (1 \pm n_3)(1 \pm n_4)
\]

\[
\times \delta(\epsilon_1 + \epsilon_2 - \epsilon_3 - \epsilon_4) \delta(p_1 + p_2 + p_3 + p_4).
\]

(12)

For small \( u \) we can furthermore linearize the quasiparticle distribution function

\[
n_i = n_i^{LE} + \frac{\partial n_1}{\partial \epsilon} \Phi \frac{\partial u_x}{\partial y},
\]

where the local equilibrium distribution function is

\[
n_i^{LE} = (\exp[(\epsilon_i - u \cdot p_i)/T] + 1)^{-1},
\]

(14)

and \( \Phi \) is an unknown function that represents the deviations from local equilibrium. By symmetry \( \Phi \) has to be on the form

\[
\Phi = \hat{p}_y \, \hat{p}_y f(p/T),
\]

(15)

where now the function \( f \) must be determined from the Boltzmann equation. Inserting (13) in the Boltzmann equation we find

\[
p_{1x} v_{1y} \frac{\partial n_1}{\partial x} = 2\pi \nu_2 \sum_{234} |M|^2 n_1 n_2 (1 \pm n_3)(1 \pm n_4)
\]

\[
\times \delta(\epsilon_1 + \epsilon_2 - \epsilon_3 - \epsilon_4) \delta(p_1 + p_2 + p_3 + p_4)
\]

\[
\times (\Phi_1 + \Phi_2 - \Phi_3 - \Phi_4).
\]

(16)

It is very convenient to define a scalar product of two real functions by:

\[
\langle \psi_1 | \psi_2 \rangle = -\nu_2 \sum_p \psi_1(p) \psi_2(p) \frac{\partial n_1}{\partial \epsilon}.
\]

(17)

Thus Eq. (16) may be written on the form \(|X⟩ = I|Φ⟩ \) where \(|X⟩ = p_x v_y \) and \( I \) is the integral operator acting on \( Φ \). The viscosity is given in terms of \( Φ \) and can now be written as

\[
\eta = -\nu_2 \sum_p p_x v_y \Phi_p = \langle X | Φ \rangle.
\]

(18)

Equivalently, the viscosity is given from (16) as

\[
\eta = \frac{⟨X| Φ⟩^2}{⟨Φ| I| Φ⟩}.
\]

(19)

Since \( ⟨.|.⟩ \) defines an inner product, the quantity \( ⟨X| Φ⟩^2/⟨Φ| I| Φ⟩ \) is minimal for \( Ψ = Φ \) with the minimal value \( η \). Equation (19) is therefore convenient for variational treatment, which will be carried out in Appendix A.

To find the viscosity we must solve the integral equation (16) for which we have to evaluate

\[
⟨Φ| I| Φ⟩ = 2\pi \nu_2 \sum_{p_1, p_2, q} |M|^2 n_1 n_2 (1 \pm n_3)(1 \pm n_4)
\]

\[
\times (\Phi_1 + \Phi_2 - \Phi_3 - \Phi_4)^2 \delta(\epsilon_1 + \epsilon_2 - \epsilon_3 - \epsilon_4).
\]

(20)

Momentum conservation requires that \( p_3 = p_1 + q \) and \( p_4 = p_2 - q \) where \( q \) is the momentum transfer. Introducing an auxiliary integral over energy transfers, \( ω \), the delta-function in energy can be written

\[
\delta(\epsilon_1 + \epsilon_2 - \epsilon_3 - \epsilon_4) = \int dq \frac{p_3}{p_1 q} \delta(\cos θ_1 - μ - \frac{t}{2 p_1 q})
\]

\[
\times \frac{p_4}{p_2 q} \delta(\cos θ_2 - μ + \frac{t}{2 p_2 q}),
\]

(21)

where \( θ_1 \) is the polar angle between \( q \) and \( p_1 \) and \( θ_2 \) the corresponding one between \( q \) and \( p_2 \) (see Fig. 2). Consequently, we find

\[
⟨Φ| I| Φ⟩ = \frac{1}{4π^2 T} \int_0^∞ dq \int_{-q}^q dω
\]

\[
\times ∫_{(q-ω)/2}^∞ dp_1 p_1^2 n_1 (p_1 + ω)(1 ± n_1 (p_1 + ω))
\]

\[
\times ∫_{(q+ω)/2}^∞ dp_2 p_2^2 n_2 (p_2 + ω)(1 ± n_2 (p_2 + ω))
\]

\[
\times ∫_0^2π dφ |M|^2 (Φ_1 + Φ_2 - Φ_3 - Φ_4)^2.
\]

(22)

This integral equation for \( Φ \) has been solved in a few cases under simplifying circumstances. E.g., in Fermi liquids the sharp Fermi surface restricts all particle momenta near the Fermi surface and with a simplified form for the scattering matrix element techniques have been developed to calculate a number of transport coefficients, exactly (10). For the QCD and QED plasmas the very singular interaction can, once screened, be exploited since it allows an expansion at small momentum transfers. Thus an analytical calculation of the transport coefficients can be carried out at least to leading logarithmic order in the coupling constant (11).

IV. VISCOSITY TO LEADING LOGARITHMIC ORDER

In Ref. (1), through solution of the Boltzmann kinetic equation, the first viscosity of a quark-gluon plasma was derived to leading logarithmic order in the QCD coupling strength. We will in the following give a more thorough and exact derivation of the quark and gluon viscosity.
The total viscosity, to leading order, is an additive sum of the gluon and quark viscosities, \( \eta = \eta_g + \eta_q \).

The leading logarithmic order comes from small momentum transfers because of the very singular matrix element \( \langle \Phi | I | \Phi \rangle \) dominates. For small \( q \) the kinematics simplify enormously and, as we will now show, the integrals separate allowing almost analytical calculations. First, we can set the lower limits on the \( p_1 \) and \( p_2 \) integrals to zero, however, then replacing the upper limit on \( q \) by the natural cutoff from the distribution functions which is \( q_{\text{max}} \sim T \). Thus we find from (23)

\[
\langle \Phi | I | \Phi \rangle = \frac{1}{2\pi s T} \int_0^\infty dp_1 p_1^2 n_1 (1 \pm n_1) \times \int_0^\infty dp_2 p_2^2 n_2 (1 \pm n_2) \times \int_{q_{\text{max}}}^\infty q dq \int_{-1}^1 \frac{d\mu}{2} \int_0^{2\pi} \frac{d\phi}{2\pi} \times |M|^2 (\Phi_1 + \Phi_2 - \Phi_3 - \Phi_4)^2 .
\]

to leading logarithmic order.

The solution to the integral equation or equivalently the variational calculation of (13) is quite technical and is for that reason given in Appendix A. A much simpler calculation is to make the standard assumption in viscous processes, i.e., to take the trial function as

\[ f(p/T) = (p/T)^2 . \]

As will be shown in Appendix A this turns out to be a very good approximation. It is accurate to more than 99% for reasons also explained in the appendix. \( f \) can be defined up to any constant which cancels in (19) and therefore never enters in the viscosity.

The quantity \( (\Phi_1 + \Phi_2 - \Phi_3 - \Phi_4)^2 \) can be averaged over \( x \)- and \( y \)-directions while keeping \( \mu \) and \( \phi \) fixed. This corresponds to keeping the relative positions of the three vectors \( q, p \), and \( p' \) fixed relative to each other and rotating this system over the three Euler angles (see also Appendix A). Consequently, we obtain

\[
(\Phi_1 + \Phi_2 - \Phi_3 - \Phi_4)^2 = \frac{q^2}{15T^4} [3(p_2 - p_1)^2 + (\hat{q} \cdot (p_2 - p_1))^2] = \frac{q^2}{15T^4} [(3 + \mu^2)(p_2^2 + p_2^2) - 2p_1 p_2 (4\mu^2 + 3(1 - \mu^2) \cos \phi)] .
\]

The integrals over \( p_1 \) and \( p_2 \) in (24) are elementary. Next we perform the integrations or averages over \( \mu \) and \( \phi \) required in (25). We note in passing that the term in (25) proportional to \( p_1 p_2 \) vanishes and that \( \mu^2 \) effectively can be replaced by \( 1/3 \) (see Appendix A). Let us first consider the case of gluon-gluon scattering inserting \( |M_{gg}|^2 \) from (3). We thus find

\[
\langle \Phi | I | \Phi \rangle = \frac{2^8 \pi^3}{45} \alpha_s^2 T^3 \int_0^{q_{\text{max}}} q^3 dq \int_0^1 d\mu \left[ \frac{1}{|q^2 + \Pi_L(\mu)|^2} + \frac{1/2}{|q^2 + \Pi_T(\mu)/(1 - \mu^2)|^2} \right] .
\]

This integral is discussed in detail in appendix B. For the longitudinal interactions \( \Pi_L \approx q_D^2 \) due to Debye screening and the leading term is a logarithm of the ratio of maximum to minimum momentum transfer \( \ln(q_{\text{max}}/q_{\text{min}}) \sim \ln(T/q_D) \). Likewise for the transverse interactions \( \Pi_T \approx i(\pi/4)\mu q_D^2 \) due to Landau damping and the dependence on \( \mu = \omega/q \) provides sufficient screening to render the integral finite and the leading term is the same logarithm as for the longitudinal interactions. Whereas the details of the screening are unimportant for the leading logarithmic order, they are important for the higher orders and they are calculated in detail in appendix B. The final result is thus to leading logarithmic order

\[
\langle \Phi | I | \Phi \rangle = \frac{2^7 \pi^3}{15} \alpha_s^2 T^3 (q_D)^3 ,
\]

Since \( \langle \Phi | X \rangle = (64\xi(5)/\pi^2) T^3 \), we find from (19) and (24)

\[
\frac{\eta_{gg}}{\Pi G} = \frac{2^5 15 \xi(5)}{\pi^2} \frac{T^3}{\alpha_s^2 \ln(T/q_D)}
\]

\[
\approx 0.342 \frac{\alpha_s^2}{\alpha_s^2 \ln(1/\alpha_s)} ,
\]

to leading logarithmic order in \( \alpha_s = g^2/4\pi \).

To obtain the full gluon viscosity we must add scattering on quarks and antiquarks which is calculated analogously and only has a few factors different. Firstly, from (3) and (4) we see that the matrix element squared is a factor \( 4/9 \) smaller. Secondly, the statistical factor \( \nu_2 = 12N_f \) instead of \( 16 \). Thirdly, in integrating over the factor \( (p_1^2 + p_2^2) \) in Eq. (25) we note that the distribution function, \( n_2 \), in Eq. (22) is now a fermion one. Consequently, the \( p_1 \) and \( p_2 \) integrations give a factor \((1/2 + 7/8)/2\) less for gluon-quark collisions as compared to gluon-gluon collisions and we find

\[
\eta_g = (\eta_{gg} - 1 + \eta_{qq})^{-1} = \frac{\eta_{gg}}{1 + 11N_f/48} .
\]

In (4) the slightly different result \( \eta_g = (1 + N_f/11) \eta_{gg} \) was obtained.

The quark viscosity can be obtained analogously to the gluon one. The quark viscosity due to collisions on quarks only, \( \eta_{qq} \), deviates by a factor \((4/9)\) from \( \eta_{gg} \) by a factor \((4/9)^2 \) in the matrix elements and differences in having Fermi and Bose integrals. By comparing to (19, 23, 24) we find

\[
\eta_{qq} = \eta_{gg} \frac{(15/16)^2}{(4/9)^2 (7/8)(1/2)} = \eta_{gg} \frac{5^{2/3} 6}{287} .
\]
Note that the statistical factors $\nu$ cancel in $\eta_{gg}$ and $\eta_{qg}$. Including quark scatterings on gluons lead to similar factors in $\langle \Phi | f | \Phi \rangle$, namely a factor $(9/4)$ from the matrix element, a factor $16/12N_f$ from statistics, and a factor $(8/7 + 2)/2$ from Bose instead of Fermi integrals. Thus

$$\eta_q = \frac{\eta_{qg}}{1 + 33/7N_f} \simeq 2.2 \frac{1 + 11N_f/48}{1 + 7N_f/33} N_f \eta_g,$$  

which for $N_f = 2$ results in $\eta_q = 4.4\eta_g$, a quark viscosity that is larger than the gluon one partly because the gluons generally interact stronger than the quarks and partly because of differences between Bose and Fermi distribution functions.

V. VISCOITY TO HIGHER ORDERS IN $\alpha_s$

The leading logarithmic order dominates at extremely high temperatures, where the running coupling constant is small, but it is insufficient at lower temperatures. The next to leading order correction to the viscous rate in the coupling constant is of order $\alpha_s^2$. It may be significant because the leading logarithm is a slowly increasing function. In the derivation of the leading logarithmic order, Eq. (27), we have been very cavalier with any order $\alpha_s^2$. It was only argued that the leading logarithmic order $\ln(q_{\text{max}}/q_{\text{min}}) \sim \ln(T/q_D)$ because $q_{\text{max}}$ and $q_{\text{min}}$ were of order $\sim T$ and $\sim q_D$ respectively. Finally, if thermal quark-gluon plasmas are created in relativistic heavy ion collisions at CERN and RHIC energies, the temperatures achieved will probably be below a GeV. We can thus estimate the interaction strength from the running coupling constant $\alpha_s \approx 6\pi/(33 - 2N_f) \ln(T/\Lambda)$, which, with $\Lambda \approx 150$MeV and $T \lesssim 1$GeV, gives $\alpha_s \gtrsim 0.4$. For such large coupling constants Delye and dynamical screening is replaced by an effective screening mass, $m_{qs}$, discussed above which will affect the viscosity considerably.

To calculate the viscosity to order $\alpha_s^2$ exactly, the 5-dimensional integral of Eq. (22) must be evaluated numerically and at the same time a variational calculation of $\Phi$ must be performed. This is a very difficult task and we shall instead use the information obtained in the previous section, that the trial function $f \propto p^2$ is expected to be an extremely good approximation. With that ansatz for the trial function, it is then straightforward to calculate the integral of Eq. (21) numerically and find the viscosity to order $\alpha_s^2$ for the given screening mechanism. The 5-dimensional numerical evaluation of the collision integral of Eq. (21) is a complicated function of the coupling constant. It is convenient to write it in terms of the function $Q$

$$\langle \Phi | f | \Phi \rangle_{gg} = \frac{27 \pi^3}{15} \alpha_s^2 Q\left(\frac{q_{\text{max}}}{q_{\text{min}}}\right) T^3,$$  

where the index $gg$ refers to gluon-gluon scattering but the analogous definitions apply to gluon-quark and quark-quark scattering. The function $Q$ and the effective maximum and minimum momentum transfer, $q_{\text{max}}$ and $q_{\text{min}}$, are given in Appendix B. In weakly interacting plasmas, where the screening is provided by Debye and dynamical screening, the function $Q$ is basically just a logarithm of the ratio of the maximum and minimum momentum transfer, i.e.,

$$Q\left(\frac{q_{\text{max}}}{q_{\text{min}}}\right) = \ln\left(\frac{q_{\text{max}}}{q_{\text{min}}}\right), \quad \alpha_s \lesssim 0.1 \quad (35)$$

By numerical integration we find that the distribution functions to an effective cutoff of $q_{\text{max}} \sim 3T$. This is because the distribution functions are weighted with several powers of particle momenta and thus contribute the most for $p \approx 3T$. The effective cutoff is slightly larger for quark-gluon and gluon-gluon scattering because the Bose distribution functions emphasize larger momenta than the Bose ones. Delye and dynamical screening leads to $q_{\text{min}} \approx 1.26q_D$ as described in Eq. (26) and so from (B3)

$$Q\left(\frac{q_{\text{max}}}{q_{\text{min}}}\right) = \ln\left(\frac{0.44}{\alpha_s(1 + N_f/6)}\right), \quad \alpha_s \lesssim 0.1 \quad (36)$$

The numerical factor inside the logarithm, which gives the order $\alpha_s^2$, is discussed in more detail in Appendix B. In the other limit, $q_D/T$ or equivalently $\alpha_s \lesssim 0.1$, perturbative ideas breaks down and we assume an effective screening mass taken from lattice calculations, $q_{\text{min}} \approx 1.1T$, as described by Eq. (32). Thus we find (see (B10))

$$Q\left(\frac{q_{\text{max}}}{q_{\text{min}}}\right) = 0.626, \quad \alpha_s \lesssim 0.1 \quad (37)$$

and similarly for quark-gluon and gluon-gluon scattering $Q\left(\frac{q_{\text{max}}}{q_{\text{min}}}\right) = 0.819$ and $Q\left(\frac{q_{\text{max}}}{q_{\text{min}}}\right) = 1.0$, respectively.

Adding gluon-gluon and gluon-quark scatterings we obtain the gluon viscosities

$$\eta_g = \frac{215\xi(5/2)^3 T^3}{\pi^7} \alpha_s^2 \left[Q\left(\frac{q_{\text{max}}}{q_{\text{min}}}\right) + \frac{11N_f Q\left(\frac{q_{\text{max}}}{q_{\text{min}}}\right)}{48}\right]^{-1}, \quad (38)$$

which extends Eq. (17) to higher orders. In weakly interacting plasmas (8) reduces to

$$\eta_g \approx 0.342 \alpha_s^2 \left[0.44 \ln\left(\frac{0.44}{\alpha_s(1 + N_f/6)}\right) + \frac{0.72}{48} \ln\left(\frac{0.72}{\alpha_s(1 + N_f/6)}\right)\right]^{-1}, \quad \alpha_s \lesssim 0.1 \quad (39)$$

to leading orders in $\alpha_s$. In strongly interacting plasmas we obtain by inserting (B10) in (12)

$$\eta_g \approx 0.55 \frac{T^3}{\alpha_s^2} \left[1 + \frac{11N_f}{48}\right]^{-1}, \quad \alpha_s \lesssim 0.1 \quad (40)$$
In Fig. (3) we show the gluon viscosity with the various assumptions for screening. With dash-dotted curve the result of Eq. (38) assuming a constant screening mass, \( m_{pl} = 1.1T \), is shown. With dashed curve the numerical result assuming Debye and dynamical screening of Eqs. (37) and (38) is shown. For \( \alpha_s \lesssim 0.05 \) it is given by Eq. (37) to a good approximation whereas for \( \alpha_s \gtrsim 0.05 \) the result of Eq. (38) is better. The final viscosity shown by full curve is obtained by combining the two limits, i.e., applying Debye and dynamical screening in weakly interacting plasmas when \( q_D \gtrsim T \) or equivalently \( \alpha_s \gtrsim 0.1 \) but an effective screening mass \( m_{pl} = 1.1T \) as given by Eq. (37) when \( \alpha_s \gtrsim 0.1 \). This corresponds to choosing the smallest value of the viscosities as seen in Fig. (3), i.e., the two limits of Eqs. (37) and (38) are not when extended to the region \( \alpha_s \gtrsim 0.5 \). This explains the results found in Fig. (3), where it was claimed that estimates of the next to leading order \( \alpha_s^2 \) could lead to a negative viscosity.

Contributions from vertex corrections should also be considered. In fact for the calculation of the quasi-particle damping rate, \( \gamma_p \), Braaten and Pisarski found that vertex corrections contributed to leading order \( \gamma_p^{(g)} \approx 6.6a_s \) for zero gluon momenta, \( p \). Vertex corrections do also contribute to order \( \alpha_s \) for large quasi-particle momenta, \( p \gg gT \), but they can here be ignored since the leading order is \( \gamma_p^{(g)} = 3\alpha_s \ln(1/\alpha_s) \) as explained in Fig. (4). For the viscosity, however, vertex corrections can be ignored since the extra vertices adds a factor \( \alpha_s^2 \). Even though integration over soft momenta may cancel a factor \( \alpha_s \) the result is still of higher order in the coupling constant.

Writing each of the viscosities \( \eta_i \) (i = g, q) in terms of the viscous relaxation time, \( \tau_{ni} \), as

\[
\eta_i = \frac{\tau_{ni}}{\alpha_s^2},
\]

we find the quark viscosity

\[
\eta_q = \frac{536 \xi(5)^2}{2911 \pi^7} \frac{T^3}{\alpha_s^2} \left[ \frac{\eta_q}{q_D} - \eta_q(\eta_{max}/q_D) \right]^{-1},
\]

which in weakly interacting plasmas gives

\[
\eta_q \simeq 0.752 N_f T^3 \ln \left( \frac{0.72}{\alpha_s(1 + N_f/6)} \right) + \frac{7N_f}{33} \ln \left( \frac{1.15}{\alpha_s(1 + N_f/6)} \right)^{-1}, \alpha_s \lesssim 0.1,
\]

and in the strongly interacting plasmas

\[
\eta_q \simeq 0.92N_f T^3 \left[ 1 + \frac{7N_f}{33} \right]^{-1}, \alpha_s \gtrsim 0.1.
\]

The quark viscosity increases with the number of quark flavors, \( N_f \), whereas the gluon viscosity decreases as can be seen in Fig. (3) and (4), where the viscosities are shown for two and three flavors respectively. The total viscosity of a quark-gluon plasma, \( \eta = \eta_g + \eta_q \), is dominated by the quark viscosity.

From the definition of the viscosity in terms of the collision integral (15) and (20), which only contains positive quantities, it follows trivially that the viscosity is positive as is a physical necessity. The resulting viscosities of Eqs. (36) and (39) are positive quantities whereas the \( \alpha_s \gtrsim 0.1 \) expansions of Eqs. (37) and (40) are not when extended to the region \( \alpha_s \lesssim 0.5 \). This explains the results found in Fig. (3), where it was claimed that estimates of the next to leading order \( \alpha_s^2 \) could lead to a negative viscosity.

The viscous relaxation times, \( \tau_{ni,g} \), \( \tau_{ni,q} \), and \( \tau_n = 1/(\tau_{ni,g}^{-1} + \tau_{ni,q}^{-1}) \) are thus very similar to the corresponding viscosities when divided by a factor of \( T^4 \). The curves on Fig. (4) and (5) therefore applies to the viscous relaxation times (times temperature) as well when divided a factor of \( \sim 1.4 \) and \( \sim 0.92N_f \) for gluons and quarks respectively, according to Eq. (2).

In weakly interacting plasma the viscous rates can be approximated by

\[
\tau_{ni,g} \simeq 4.11 \alpha_s^2 \ln \left( \frac{0.44}{\alpha_s(1 + N_f/6)} \right) + \frac{11N_f}{48} \ln \left( \frac{0.72}{\alpha_s(1 + N_f/6)} \right) \quad \text{for} \quad \alpha_s \lesssim 0.1
\]

and

\[
\tau_{ni,q} \simeq 1.27 \alpha_s^2 \ln \left( \frac{0.72}{\alpha_s(1 + N_f/6)} \right) + \frac{7N_f}{33} \ln \left( \frac{1.15}{\alpha_s(1 + N_f/6)} \right) \quad \text{for} \quad \alpha_s \lesssim 0.1.
\]

VI. SUMMARY

By solving the Boltzmann equation for quarks and gluons the viscosities in quark-gluon plasmas were calculated to leading orders in the coupling constant. Including
of dynamical screening of transverse interactions, which controls the infrared divergences in QED and QCD, is essential for obtaining finite transport coefficients in the weakly interacting plasmas. The solution of the transport process was extended to strongly interacting plasmas by assuming an effective screening mass of order $m_{pl} = 1.1 T$, as found in lattice calculations, when the Debye screening length became larger than the interparticle distance or when $\alpha_s > 0.1$. The Boltzmann equation was solved exactly to leading logarithmic order numerically but the result only differed by less than a percent from an analytical result obtained by a simple ansatz for the deviation from local equilibrium, $\Phi \propto p_x p_y$. The next to leading orders was also calculated and found to be very important for the transport properties relevant for quark-gluon plasmas created in relativistic heavy ion collisions and the early universe. For $\alpha_s > 0.1$ we find $\eta_i = C_{i,1} T^3/\alpha_s^2 \ln(C_{i,2}/\alpha_s)$ whereas for $\alpha_s > 0.1$ we find $\eta_i = C_{i,3} T^3/\alpha_s^2$ with coefficients $C_{i,j}$ given above.

The viscosity in degenerate plasmas of quarks, i.e., for $T \ll \mu_q$ was calculated in [3]. Several differences were found. In the high temperature quark-gluon plasma the chemical potential can be ignored and the transport processes depend on two momentum scales only, namely $T$ and $q_D \sim g T$. In degenerate quark matter three momentum scales enter, namely $\mu_q$, $T$, and $q_D \sim g \mu_q$, and the transport process depends considerably on which of $q_D$ and $T$ is the larger. In fact for $T \ll q_D$ transverse interactions turn out to be dominant in contrast to the high temperature quark-gluon plasma where transverse and longitudinal interactions contribute by similar magnitude. Furthermore, the existence of a relative sharp Fermi surface allows an almost analytical calculation of both the leading (logarithmic) order as well as the next order $\alpha_s^2 T$.

The techniques for calculating the viscosities to leading orders in the coupling constants can be applied to other transport coefficients as well. The leading logarithmic orders to momentum stopping, electrical conductivities and thermal dissipation in QCD and QED plasmas have been estimated with simple ansätze for the distribution functions in [3]. Based on the experience with the viscosity studied here, we do not expect the leading logarithmic order for these transport coefficients to decrease by much when a full variational calculation is performed. The next to leading logarithmic order for these transport coefficients can also be estimated with the experience obtained above for the viscosity. Good estimates are obtained if one in [33] replaces $q_{max}$ by the average particle momenta entering the collision integral for the relevant transport process and $q_{min}$ by $\sim q_D$.

A few transport coefficients are, however, different. The second viscosity $\zeta$ is zero for a gas of massless relativistic particles [3] and one cannot define a thermal conductivity in a plasma of zero baryon number. One can, however, consider thermal dissipation processes [3] where the leading orders also can be calculated with the above methods. The effective soft cutoff will, however, be different for thermal dissipation processes as described in [26]. Because the transport of energy introduce dependences on $\omega$ which also is present in the transverse screening $\Pi_T(\omega/q)$.

All the transport processes discussed above depend only on momentum scales from the typical particle momentum, $q_{max} \sim T$ down to the Debye screening wavenumber $q_{min} \sim q_D \sim g T$ which also is the momentum scale for dynamical screening. There is, however, a shorter momentum scale of order the magnetic mass $m_{mag} \sim g^2 T$, at which perturbative ideas of the quark-gluon plasma fails [17]. As shown in [16] the quark-gluon quasiparticle decay rates depend on this infrared cutoff, $m_{mag}$. Furthermore, recent studies [19] find that the color diffusion and conductivity also depend on this cutoff and therefore the rate of color relaxation is a factor $\sim 1/\alpha_s$ larger than Eq. (1).

**APPENDIX A: EXACT VARIATIONAL CALCULATION TO LEADING LOGARITHMIC ORDER**

In this appendix we solve the Boltzmann equation and find the deviation from local equilibrium, $\Phi$, by a variational treatment of Eq. (18).

For a general function $\Phi = \hat{p}_x \hat{p}_y f(p/T)$ we have

$$\Phi_1 + \Phi_2 - \Phi_3 - \Phi_4 = \hat{p}_{1,x} \hat{p}_{1,y} f(p_1) + \hat{p}_{2,x} \hat{p}_{2,y} f(p_2)$$

$$- \hat{p}_{3,x} \hat{p}_{3,y} f(p_3) - \hat{p}_{4,x} \hat{p}_{4,y} f(p_4)$$

$$= - (\hat{q}_x \hat{p}_y + \hat{q}_y \hat{p}_x) f(p) - \mu \hat{p}_x \hat{p}_y f_1(p)$$

$$+ (\hat{q}_x \hat{p}_y' + \hat{q}_y \hat{p}_x') f(p') + \mu \hat{p}_x' \hat{p}_y' f_1(p') ,$$

where we have changed notation to $p = p_1 + q/2$, $p_3 = -q/2$ and $p' = p_2 - q/2 = p_4 + q/2$. We have used that the energy conserving $\delta$-functions of (24) imply $\hat{p} \hat{q} = \hat{p}' \hat{q}' = \mu$. Furthermore, have defined the function

$$f_1(p) = p^2 d(f(p^2)/dp)/dp = p f' - 2 f ,$$

that vanishes when $f \propto p^2$ which was the case for the ansatz used in section V.

For small momentum transfer the matrix element (24) depends only on energy and momentum transfer and the azimuthal angle $\phi$. The $\delta$-functions of (24) taking care of energy conservation fixes the polar angularities $\theta_1$ and $\theta_2$ with respect to $\hat{q}$. Thus all the angular integrals for fixed $\theta$ and $\phi$ reduces to rotating the three vectors $\hat{q}$, $\hat{p}$ and $\hat{p}'$.
over all Euler angles keeping them fixed relatively to each other. Only \((\Phi_1 + \Phi_2 - \Phi_3 - \Phi_4)^2\) depends on the Euler angles and the integration or averaging over the three Eulerian angles, while keeping the relative positions of the vectors \(q, p\) and \(p'\) fixed, i.e. keeping \(\mu\) and \(\phi\) fixed, gives

\[
(q_x p_x + q_y p_y)^2 = (q_x p'_x + q_y p'_y)^2 = \frac{3 + \mu^2}{15}, \tag{A3}
\]

\[
(p_x p_y)^2 = \left(\frac{p_x p'_y - p_y p'_x}{\mu}\right)^2 = \frac{1}{15}, \tag{A4}
\]

\[
(q_x p_y + q_y p_x)(p_x p_y) = \frac{2}{15} \mu^2, \tag{A5}
\]

\[
(q_x p'_y + q_y p'_x)(p'_x p'_y) = \frac{2}{15} \mu^2, \tag{A6}
\]

\[
(q_x p_y + q_y p_x)(q'_x p'_y + q'_y p'_x) = \frac{1}{15} (3 \mu^2 - \mu^2), \tag{A7}
\]

\[
(q_x p_x + q_y p_y)(q'_x p'_x + q'_y p'_y) = \frac{\mu^2}{15} (3 \mu^2 - 1), \tag{A8}
\]

\[
(q_x p_x + q_y p_y)(p'_x p'_y) = \mu^2 (1 - \mu^2) \cos \phi. \tag{A10}
\]

Next we integrate over \(\mu\) and \(\phi\). The \(\mu\) integration averages \(\mu^2\) to 1/3 whereas the \(\phi\) integration is weighted by a factor \((1 - \cos^2 \phi)\) from the matrix elements. Thus we find that \((A7, A9)\) vanishes whereby all combinations mixing \(p_1\) and \(p_2\) very conveniently disappear. After averaging over both Euler angles and \(\mu\) and \(\phi\) we obtain

\[
\langle(\Phi_1 + \Phi_2 - \Phi_3 - \Phi_4)^2\rangle = \frac{q^2}{p^2} \frac{1}{15} (10 f^2 + f_1^2 + 4 f f_1), \tag{A11}
\]

\[
\frac{q^2}{p^2} \frac{2}{5} (f^2 + \frac{1}{6} p^2 f'^2). \tag{A12}
\]

Let us first consider the pure gluon plasma for which \((23)\) gives

\[
\langle \Phi | I | \Phi \rangle = \frac{8 \pi}{15} g^4 \ln(T/q_D) T^3
\times \int_0^\infty \left[ f^2 + \frac{1}{6} p^2 f'^2 \right] \left( - \partial_n \frac{\partial I}{\partial \epsilon_p} \right) dp, \tag{A12}
\]

where \(n = (\exp(p/T) - 1)^{-1}\) is the gluon distribution function. Since

\[
\langle \Phi | X | \Phi \rangle = \frac{8}{15 \pi^2} \int f p^3 \left( - \partial_n \frac{\partial I}{\partial \epsilon_p} \right) dp, \tag{A11}
\]

we find from \((3)\)

\[
\eta = \frac{15}{8 \pi g^2 \ln(T/q_D)} \left( \int_0^\infty \left( f^2 + \frac{1}{6} p^2 f'^2 \right) n' dx \right), \tag{A11}
\]

where \(x = p/T\). As mentioned above, the function \(f(x)\) is determined by minimizing \((A14)\). A functional variation with respect to \(f\) results in a second order inhomogeneous differential equation for \(f\)

\[
f'' + \left( \frac{2}{x} + \frac{n''}{n'} \right) f' - \frac{6}{x^2} f = -C x, \tag{A10}
\]

where \(n''/n' = -(1+2n)\). \(C\) is an arbitrary constant that, by rescaling \(f\), can be chosen as \(C = 2\) for convenience.

For \(x \gg 1\) we can approximate \(n \simeq 0\) and so we find the solution to \((A13)\), that does not increase exponentially for \(x \to \infty\), to be

\[
f(x) = x^2, \quad x \gg 1. \tag{A11}
\]

For \(x \ll 1\) we can approximate \(n \simeq 1/x\) and the solution to \((A13)\) that is finite at the origin is

\[
f(x) = x^3(C - \frac{1}{2} \ln x), \quad 0 \leq x < 1, \tag{A12}
\]

where \(C \simeq 0.7\) is a constant that can only be determined by finding the full solution to \((A13)\) and matching it \((A17)\). This is done by a numerical Runge-Kutta integration and the result is shown in Fig. 3. The viscosity is now found by inserting \(f\) in \((A14)\). The exact value for \(\eta\) thus obtained is only 0.523% less than the approximate value, \(\eta_{approx}\), of Eq. \((16)\). Since the exact value is a variational minimum, it has to be smaller than that of \((23)\) is only slightly less because \(f \simeq x^2\) for large as just the ansatz of \((23)\) and \(f\) is mainly sampled over values \(p/T \gg 1\) because the integrals over \(p_1\) and \(p_2\) in \((23)\) have powers \(\sim p^4\) to \(\sim p^5\) times \(n_{p_1}(1 + n_{p_2})\). In Ref. 4, a variational calculation with trial functions \(f(p) \propto p^2\) lead to a minimal viscosity for \(\nu = 2.104\). This result is close to the quadratic power of \((16)\) but tends slightly towards the asymptotic form of \((A13)\) (see also Fig. 3). It has almost the same slope and curvature as the exact solution around \(p = 5T\) (note that the absolute values are unimportant since it cancels in the viscosity). The corresponding viscosity was 0.364% smaller than that of \((23)\), i.e., in between the exact result and the ansatz \(f \propto x^2\).

The above analysis was restricted to a pure gluon plasma. As mentioned above the distribution functions are weighted with several powers of momentum and we do not find much difference between fermions and bosons. Therefore the deviation from local equilibrium for quarks will not be much different from gluons and we can be confident that the ansatz, \(\Phi \propto p_{12} p_{10}\), of Eq. \((23)\) will be a good approximation for quarks as well accurate within less than a percent.
APPENDIX B: SOFT AND HARD CONTRIBUTIONS

The essential contribution to $\langle \Phi | I | \Phi \rangle$ is the integral
\[ Q \left( \frac{q_{\text{max}}}{q_{\min}} \right) = \frac{1}{3} \int_{-1}^{1} d\mu \int_{0}^{q_{\text{max}}} q^3 dq \left[ \frac{1}{|q^2 + \Pi_L(\mu)|^2} + \frac{1}{2} \left( \frac{q^2 + \Pi_T(\mu)}{(1 - \mu^2)^2} \right) - \frac{1}{|q^2 + \Pi_T(\mu)|} \right]. \]  

(B1)

For dimensional reasons the function $Q$ can only depend on the ratio of $q_{\text{max}}$ to the momentum scale, $q_{\min}$, which is provided by the screening. For Debye and dynamical screening $q_{\min} \sim q_D$ whereas lattice calculations of strongly interacting plasmas give $q_{\min} \sim m_{pl} = 1.1T$.

As described in connection with screening non-perturbative effects become important when $q_D \gtrsim T$ which corresponds to $\alpha_s \lesssim 0.1$. We shall treat the two limits separately starting with the weakly screening non-perturbative effects. First make a simple analytical estimate. The main contribution to this integral can be obtained by including the leading terms in the self energies (B3) and (B4).

\[ \Pi_L(q, \omega) \simeq q_D^2, \quad \Pi_T(q, \omega) \simeq \frac{\pi}{4} \mu q_D^2. \]  

(B2)

Thus we find for (B3)
\[ Q \left( \frac{q_{\text{max}}}{q_{\min}} \right) \simeq \ln \left( \frac{q_{\text{max}}}{q_{\min}} \right), \quad q_{\text{max}} \gg q_D, \]  

(B5)

where
\[ q_{\min} = q_D \exp \left\{ \frac{1}{6} \left( 1 - \ln \frac{4}{\pi} \right) \right\} \simeq 1.13q_D. \]  

(B6)

The two terms in (B3) corresponding to $\ln q_{\text{max}}$ and $\ln q_{\min}$ are often referred to as “hard” and “soft” contributions in the literature (B1).

A numerical evaluation of (B3) with $\Pi_{L,T}$ given by Eqs. (B4) instead of (B2) and (B3) gives a slightly larger value for the effective minimum momentum transfer $q_{\min} = 1.26q_D$, because the additional terms in $\Pi_{L,T}$ lead to some additional screening besides the Debye screening and Landau damping of (B2) and (B4). This effective cutoff is determined by the screening only and is therefore the same for gluon-gluon, quark-gluon and quark-quark scattering.

Whereas $q_{\min}$ may serve as an effective “cutoff” of small momentum transfers interactions, it is not a parameter put in by hand as discussed in (B4). Contrarily, it is caused and determined by Debye and dynamical screening.

If the transverse interactions are assumed to be Debye screened like the longitudinal ones, i.e., $\Pi_T = q_D^2$, then the result would have been $q_{\min} = q_D \exp(0.5) = 1.65q_D$. This is because dynamical screening of Eq. (B3) is less effective than the Debye screening of (B2) and thus results in a smaller $q_{\min}$.

It is convenient to express the results in terms of $\alpha_s$.

In weakly interacting plasmas we find
\[ Q \left( \frac{q_{\text{max}}}{q_{\min}} \right) \simeq \ln \left( \frac{q_{\text{max}}}{q_{\text{min}}} \right) = \frac{1}{2} \ln \left( \frac{(q_{\text{max}}/T)^2}{1 + \pi/6} \right), \quad \alpha_s \lesssim 0.1. \]  

(B7)

The upper effective cutoff $q_{\text{max}}$ is provided by the quark and gluon distribution functions as discussed in connection with Eq. (22) and it therefore varies somewhat with particle type. Because Bose distribution functions emphasize smaller momenta than Fermi ones, $q_{\text{max}}$ is larger for quarks. We find $q_{\text{max}}^{(q)} = 3.0T$, $q_{\text{max}}^{(g)} = 3.8T$, and $q_{\text{max}}^{(qg)} = 4.8T$ for gluon-gluon, quark-quark, and quark-gluon scattering respectively. The lower effective cutoff $q_{\min}$ is, however, the same for the three cases because it only depends on the screening in the gluon propagator. Furthermore, we find that the extra terms in the matrix elements of (B3), (B4) and (B6) besides the $t^{-2}$ parts do not contribute much since they have varying signs and turn out to be partially cancelling. Thus the constant within the logarithms of (B7) and (B1) just reflects the different $q_{\text{max}}$ for gluon-gluon, quark-quark and quark-gluon scattering.

Lacking screening of transverse interactions in the static limit, it has often been assumed that some mechanism like Debye screening might lead to screening of transverse interactions as well, i.e., $m_{pl} = q_D$. Recent lattice gauge calculations of QCD plasmas have found effective screening masses of order $m_{pl} \approx 1.17T$ near the phase transition point, $T_c \approx 180\text{MeV}$. In both cases it is thus assumed that
\[ \Pi_L = \Pi_T/(1 - \mu^2) = m_{pl} \]  

in (B1) which leads to
\[ Q \left( \frac{q_{\text{max}}}{q_{\min}} \right) = \frac{1}{2} \left\{ \ln \left( 1 + \frac{q_{\text{max}}^2}{m_{pl}^2} \right) - \frac{q_{\text{max}}^2}{m_{pl}^2 + q_{\text{max}}^2} \right\}. \]  

(B8)
With \(q_{\text{max}}^{(gg)} = 3.0T\), \(q_{\text{max}}^{(gq)} = 3.8T\), \(q_{\text{max}}^{(qq)} = 4.8T\) and \(m_{pl} = 1.1T\) we find \(Q(q_{\text{max}}^{(gg)}/q_{\text{min}}) = 0.626\), \(Q(q_{\text{max}}^{(gq)}/q_{\text{min}}) = 0.819\) and \(Q(q_{\text{max}}^{(qq)}/q_{\text{min}}) = 1.024\). These values enter the \(\alpha_s > 0.1\) expressions of Eqs. (38) and (41).

FIG. 1. Feynman diagram for gluon-gluon scattering in the t-channel. The lines in the loops can be either quark or gluon propagators.

FIG. 2. The collision geometry. For small momentum transfer, $q \ll p_1, p_2$, energy and momentum conservation requires $\cos \theta_1 = \cos \theta_2 = \omega/q$.

FIG. 3. The gluon viscosity for $N_f = 3$ assuming Debye and dynamical screening (dashed curve), a constant screening mass $m_{pl} = 1.1T$ (dashed-dotted curve) and the minimal one (full curve).

FIG. 4. The quark, gluon and total viscosities for $N_f = 3$.

FIG. 5. The quark, gluon and total viscosities for $N_f = 2$.

FIG. 6. The function $f/x^2$ as determined by (A15). Also shown are the limits of (A16), (A17) and the simple ansatz $f = x^2$.
