**Abstract**

We present our investigation of the extended ultraviolet (XUV) disk galaxy, NGC 3344, conducted as part of Deciphering the Interplay between the Interstellar medium, Stars, and the Circumgalactic medium survey. We use surface and aperture photometry of individual young stellar complexes to study star formation and its effect on the physical properties of the interstellar medium. We measure the specific star formation rate (sSFR) and find it to increase from $10^{-10}$ yr$^{-1}$ in the inner disk to $>10^{-9}$ yr$^{-1}$ in the extended disk. This provides evidence for inside-out disk growth. If these sSFRs are maintained, the XUV disk stellar mass can double in ~0.5 Gyr, suggesting a burst of star formation. The XUV disk will continue forming stars for a long time due to the high gas depletion times (τ$_{dep}$). The stellar complexes in the XUV disk have high-$\Sigma_{H_1}$ and low-$\Sigma_{SFR}$ with $\tau_{dep}$ ~ 10 Gyr, marking the onset of a deviation from the traditional Kennicutt–Schmidt law. We find that both far-ultraviolet (FUV) and a combination of FUV and 24 μm effectively trace star formation in the XUV disk. Hα is weaker in general and prone to stochasticities in the formation of massive stars. Investigation of the circumgalactic medium at 25.5 kpc resulted in the detection of two absorbing systems with metal-line species: the stronger absorption component is consistent with gas flows around the disk, most likely tracing inflow, while the weaker component is likely tracing corotating circumgalactic gas.

**1. Introduction**

The connection between star formation and cold interstellar gas is paramount to the understanding of galaxy evolution. The interstellar medium (ISM) provides the essential matter and hospitable environment that facilitate the conversion of cold atomic gas (H$_1$) to its molecular (H$_2$) form, which further collapses to form stars. In general, this relation between stars and gas follows the empirical Kennicutt–Schmidt law (K–S law; Schmidt 1959; Kennicutt 1998a). However, when extended to the outskirts of galaxies where gas mass surface density is $\Sigma_{gas} \lesssim 9 M_\odot$ pc$^{-2}$, a considerable drop in the star formation rate (SFR) per unit gas is observed (Kennicutt 1989; Bigiel et al. 2010b). Discerning the origin of this downturn calls for a thorough investigation of the causal nexus between the low surface mass density ISM and star formation.

The discovery of extended ultraviolet (XUV) disks in the nearby universe (Gil de Paz et al. 2005; Thilker et al. 2005, 2007) enabled by Galaxy Evolution Explorer (GALEX); Martin et al. 2005; Morrissey et al. 2007) strengthened the notion of star formation beyond the optical disk ($\gtrsim R_{25}$). These galaxies showed UV bright extended disks at large galactocentric distances (Type-I XUVs) or exhibited large blue ($UV - K$) color low surface brightness zones outside the optical disks (Type-II XUVs). Deep Hα imaging and spectroscopy (Ferguson et al. 1998; Lellièvre & Roy 2000) also uncovered young stellar populations in the outer disk of spiral galaxies where $\Sigma_{gas}$ falls below 10 $M_\odot$ pc$^{-2}$. These regions can be distinguished from the inner metal-rich disks by their subcritical conditions for star formation, such as low densities, low dust abundances, and an H I dominated ISM. Nevertheless, these environments do support star formation. The outer, predominantly high angular momentum zones in a galaxy begin star-forming activity later than the inner disk, causing the disk to grow (theory of inside-out growth; Barden et al. 2005; Muñoz-Mateos et al. 2007; Roškar et al. 2008; Gogarten et al. 2010; González Delgado et al. 2014). Therefore, understanding the physics of star formation in these confounding regions would be pivotal for understanding galaxy growth and evolution.

One approach to studying the growth of galaxy disks is to probe channels of gas from the circumgalactic medium (CGM) to the star-forming disks of galaxies. The condensation of gas into the H I disk is expected to be active in the disk–CGM interface (Sancisi et al. 2008). We designed the Deciphering the Interplay between the Interstellar medium, Stars, and the Circumgalactic medium (DIISC) survey that aims to do so by tracing the cycle of gas from the CGM to H I disks, finally to regions where young stars are forming. The Cosmic Origins Spectrograph-GALEX Arcetri SDSS (COS-GASS) survey using quasi-stellar object (QSO) absorption lines tracing the CGM (Borthakur et al. 2015, 2016) discovered a significant correlation between the strength of Ly$\alpha$ absorbers and the H I-21 cm gas mass of the galaxies, thus suggesting a connection between gas content of the CGM and the disk of galaxies. This correlation is believed to be a consequence of the CGM feeding...
the H I disks, which will then fuel star formation. On the other hand, outflowing gas would enrich the CGM, although outflows are believed to not be the primary origin of cool CGM in low-\(z\) galaxies.

In this paper, we present the results of a pilot study investigating the interplay between star formation, ISM, and CGM in the low-density, H I dominated regions of one special case within the DIISC sample, NGC 3344. This galaxy is known to exhibit a Type-I extended UV disk showing UV-bright structures at large galactocentric distances (>\(R_{25}\)), indicating recent star formation in the outer disk (Thilker et al. 2007). NGC 3344 is ideal to probe the connections between gas flows and young stars, as (1) it is undergoing active star formation in the outer disk, where stellar densities are low, thus making it easy to identify individual star-forming regions; (2) it possesses a huge gas reservoir in the form of an extended H I disk of \(M(H\ I) = 2.2 \times 10^9 M_\odot\) that is sustaining star formation; and (3) there is a UV-bright QSO at an impact parameter of 29.5 kpc that allows us to probe the CGM close to the disk (Figure 1). We summarize some of the key properties of the galaxy in Table 1. For this study, we adopt a distance of 8.28 ± 0.7 Mpc for NGC 3344 from Sabbì et al. (2018). This corresponds to a linear scale of 40.14 pc/\(\arcsec\). An updated distance of 9.83 ± 1.7 is provided by Anand et al. (2021), for which the linear scale is 47.65 pc/\(\arcsec\) (or 1.18 times our adopted scale).

In this pilot work, we investigate the radial variations in the optical, UV, and H I emission and various galaxy properties. We also identify bright stellar complexes to explore the connections between \(\Sigma_{\text{SFR}}\) and gas properties and detect absorption tracing the inner CGM of the galaxy. The paper is organized as follows. In Section 2, we describe the UV, H\(\alpha\), 24 \(\mu\)m, H I 21 cm imaging and QSO UV-absorption spectroscopy data used in this study. This is followed by mapping the surface densities of SFR (\(\Sigma_{\text{SFR}}\)) using far-ultraviolet (FUV), FUV+24 \(\mu\)m, H\(\alpha\), and H\(\alpha\)+24 \(\mu\)m tracers, stellar mass (\(M_\star\)), and properties of H I gas, such as mass, velocities, velocity dispersion, and kinetic energy in Section 3. We present the radial profiles of emission from stars and dust, the identification of stellar complexes, followed by the investigation of the CGM in NGC 3344 in Section 4. In Section 5, we study the dust-corrected FUV and H\(\alpha\) tracers and explore the implications of the observed relations between star formation and ISM kinematics, and the CGM. Finally, we summarize our findings and their implications in Section 6.

### 2. The Data

#### 2.1. GALEX UV Data

UV imaging data for our study comes from the archives of GALEX (Martin et al. 2005; Morrissey et al. 2007) obtained from the Mikulski Archive for Space Telescope (MAST). Figure 2(a) shows the FUV map of NGC 3344. The FUV and NUV maps were produced using GALEX Nearby Galaxy Survey (NGS) and All-Sky Imaging Survey (AIS) data by stacking all exposure time weighted tiles from the target field. Each resulting image stack was trimmed to the size of \(800 \times 800\) pixels centered at the galaxy...
The FUV ($\lambda_{\text{eff}} \sim 1538.6 \, \text{Å}$) and NUV ($\lambda_{\text{eff}} \sim 2315.7 \, \text{Å}$) observations have angular resolutions (FWHM) of 4" and 5", respectively. The background flux was estimated from flux-free regions away from the galaxy and then removed. Corrections for Milky Way extinction were calculated using Schlafly & Finkbeiner (2011) dust maps and the Galactic extinction curve for a total-to-selective extinction of $R_V = 3.1$ derived by Cardelli et al. (1989). FUV and NUV flux densities are hence corrected with $A_{\text{FUV}} = 7.29 \times E(B - V)$ and $A_{\text{NUV}} = 8.0 \times E(B - V)$. The 1\sigma sensitivity limit of the FUV and NUV maps are $1.75 \times 10^{-19} \, \text{erg} \, \text{s}^{-1} \, \text{cm}^{-2} \, \text{Å}^{-1}$ (28.38 mag/\″²) and $1.28 \times 10^{-19} \, \text{erg} \, \text{s}^{-1} \, \text{cm}^{-2} \, \text{Å}^{-1}$ (26.43 mag/\″²), respectively.

2.2. VATT Hα Data and Reduction

We obtained narrow-band Hα, continuum r-band, and g-band (in SDSS r and g) imaging of NGC 3344 on UT 2019 March 29, using the VATT4k CCD imager at the 1.8 m Vatican Advanced Technology Telescope (VATT) operated by the Mt. Graham Observatory. The VATT4k has a field of view of $\sim 12'5 \times 12'5$, with a scale of 1\"5 pixel$^{-1}$. The FUV ($\lambda_{\text{eff}} \sim 1538.6 \, \text{Å}$) and NUV ($\lambda_{\text{eff}} \sim 2315.7 \, \text{Å}$) observations have angular resolutions (FWHM) of 4" and 5", respectively. The background flux was estimated from flux-free regions away from the galaxy and then removed. Corrections for Milky Way extinction were calculated using Schlafly & Finkbeiner (2011) dust maps and the Galactic extinction curve for a total-to-selective extinction of $R_V = 3.1$ derived by Cardelli et al. (1989). FUV and NUV flux densities are hence corrected with $A_{\text{FUV}} = 7.29 \times E(B - V)$ and $A_{\text{NUV}} = 8.0 \times E(B - V)$. The 1\sigma sensitivity limit of the FUV and NUV maps are $1.75 \times 10^{-19} \, \text{erg} \, \text{s}^{-1} \, \text{cm}^{-2} \, \text{Å}^{-1}$ (28.38 mag/\″²) and $1.28 \times 10^{-19} \, \text{erg} \, \text{s}^{-1} \, \text{cm}^{-2} \, \text{Å}^{-1}$ (26.43 mag/\″²), respectively.
and a plate scale of 0.′′375 pixel$^{-1}$, after 2 × 2 pixel binning on read-out. The bandpass of the Hα narrow-band interference filter is centered at 658 nm and has a nominal bandwidth of 5 nm. The observing conditions were photometric, measured with seeing between 0′′90, and 1′′1.

The total integration times were 6000 s for the narrow-band Hα image, 1200 s for the continuum r-band image, and 120 s for the g-band image. The data were reduced using standard image processing routines in the Image Reduction and Analysis Facility (IRAF). The science images were bias subtracted and flat fielded using both dome and twilight sky flats. The sky level was measured by calculating the average intensity in the source-free regions of each exposure and subtracted from the images. Cosmic rays were removed using the L.A. COSMIC routine (van Dokkum 2001). Field stars were used as a reference to shift and align the narrow-band and continuum images. This was carried out using the IRAF routine, imregister. All images were smoothed to the resolution of the worst seeing image. Stacks were created for the narrow-band Hα, and continuum r-band images by appropriately weighting the images. The r image was then scaled to the Hα image. This involved measuring the ratio of count rates of individual field stars in the r-band and Hα image to compute the scale factor. The scale factor was estimated empirically to minimize over/under subtraction in the galaxy region. We note that this method implicitly assumes the galaxy disk spectral energy distribution matches the foreground stars and is invariant with location. An emission-line only image of NGC 3344 was obtained by subtracting the scaled r-band image from the Hα image.

For flux calibration, we used SDSS DR7 r-band photometry of NGC 3344. We assumed a standard atmospheric extinction coefficient of 0.08 mag airmass$^{-1}$. Instrumental magnitudes of field stars were determined through aperture photometry from the r image. The photometric zero-point of the r-band image was then calculated by comparing the instrumental magnitudes to the SDSS-r magnitudes for the same stars. The photometric zero-point of the Hα image was calculated using the scale factor and the photometric zero-point of the r-band image.

The narrow-band filter used for the observation also covers the neighboring [N II] λ6548, 6583 Å forbidden lines along with Hα. Kennicutt et al. (2008) obtain disk-averaged [N II]/Hα = 0.52 for NGC 3344, which we use to scale the image to the net Hα surface brightness in order to account for contamination by [N II]. A foreground galactic extinction correction is also applied, with $A_{H\alpha} = 2.5 \times E(B-V)$. The final reduced Hα and r-band images are shown in Figures 2(b) and (c), respectively. The 1σ sensitivity limit of the final Hα image is $6.1 \times 10^{-21}$ erg s$^{-1}$ cm$^{-2}$ Å$^{-1}$.

2.3. MIPS 24 μm Data

NGC 3344 was observed at 24 μm as part of the Spitzer Local Volume Legacy survey (Dale et al. 2009), using the Multiband Imaging Photometer for Spitzer (MIPS) instrument (Rieke et al. 2004) with an effective exposure time of 147 s. The 24 μm image used in this work has a resolution of 6′′0 FWHM and a 1σ sensitivity limit of $6.81 \times 10^{-2}$ MJy sr$^{-1}$ and is shown in Figure 2(d).

2.4. VLA H I 21 cm Data

We combined archival and newly observed data for the atomic H I 21 cm emission from NGC 3344. The archival data were obtained from the program AB365 observed with the NSF’s Karl G. Jansky Very Large Array (VLA) in its D-configuration on UT 1985, December 6, with a total integration time of 11 h 52 m.10 These observations were made with a channel spacing of 48.8 kHz (10.36 km s$^{-1}$) in 31 channels. We used the Common Astronomy Software Application version 5.4.0 (CASA; McMullin et al. 2007) to reduce the data following the standard H I data reduction. We used 3C 286 as a flux calibrator and 1108+201 and 1040+123 as phase calibrators. These observations were observed in the B1950 coordinate frame and were converted to J2000 using CASA task axvis.

New observations were performed with VLA in C- and B- configurations (project id: 20A-125). The C-configuration observations were carried out for a total of 12 hr from UT 2020, April 13 to UT 2020, April 21, and the B-configuration observations were for a total of 36 hr from UT 2020, UT July 7 to UT 2020, August 28. These observations had a channel spacing of 7.812 kHz (1.65 km s$^{-1}$). The data reduction was performed with CASA 5.6.1 using 3C 286 as a flux calibrator and J1021+2159 as a phase calibrator. Hanning smoothing was applied to the data in order to reduce the Gibbs ringing, which made the effective velocity resolution to be 3.3 km s$^{-1}$. The target fields in the C- and B-configuration observations were also hampered by side lobes of two strong sources outside the primary beam. These were removed by modeling the point sources with the CASA task tclean and removing the modeled point sources with the task uvsol. The amplitude errors of the target image in C-configuration were observed and corrected by multiple self-calibrations with a solution interval of 40 s. The self-calibration was stopped when the range of gain phases in the self-calibration solution was less than 10$^\circ$.

After concatenating the data in each configuration with the task concat, we calculated the weight of each configuration data based on the scatters of visibilities in the line-free channels using the task statwt. The weights were estimated with channels outside the H I spectra to adjust relative weights among observations with different scales, i.e., D-, C-, and B- configurations. The final image cube was made using the task tclean with a cell size of 1′′5 and 1280 × 1280 pixels. The channel width of the final image cube is 48.8 kHz, the same as the D-configuration data. The final image cube was smoothed to a synthesized beam size of 6′′7 × 5′′4. The rms noise was ~185 μJy beam$^{-1}$ per channel in the line-free channels. Figure 1 shows the H I 21 cm column density contours at 3, 5, 10, 20 × 10$^{19}$ cm$^{-2}$.

2.5. QSO-absorption Spectroscopy with the Hubble Space Telescope

The inner CGM of NGC 3344 was probed via UV absorption spectroscopy of the background QSO, SDSS J104241.27 $+$250122.8, at an impact parameter of 29.5 kpc ($\sim$12/29). The sightline is 19.26 kpc from the closest point on the H I disk as mapped by VLA, down to an H I column density of $3 \times 10^{19}$ cm$^{-2}$.

The observations were carried out with G310M grating of the Cosmic Origins Spectrograph (COS; Green et al. 2012).

10 The National Radio Astronomy Observatory is a facility of the National Science Foundation operated under cooperative agreement by Associated Universities, Inc.
The Astrophysical Journal, 923:199 (22pp), 2021 December 20

Second component was only detected in Lyα column density and low-ionization state. The center of the disk. We detected HI around NGC 3344 at an impact parameter of 29.5 kpc from the Milky Way absorption feature associated with NGC 3344, which was located in the damping wings of the Milky Way’s Lyα profile. In spite of this correction, we were not able to completely recover the blueward (low-velocity end) Lyα absorption feature for NGC 3344 owing to low signal strength at the base of the DLA. The redward part of the profile was retrieved with high confidence. Hence, a full estimate of HI column density could not be made.

Fortunately, none of the metal lines were subject to blending with corresponding Milky Way’s lines. Therefore, we were able to use the metal-line profiles to derive the structure of the CGM bluelward of the galaxy’s systemic velocity. It is worth noting that we may have missed low-column-density clouds at velocities bluelward of the line center that are too weak to produce metal lines.

3. Derived Galaxy Properties

3.1. SFR Surface Density

For the comparison of different tracers of star formation, we compute unobscured and internal-dust corrected SFR surface densities ($\Sigma_{\text{SFR}}$). We calculate $\Sigma_{\text{SFR}}$ for both FUV and Hα luminosities and use 24 $\mu$m to correct for dust.

FUV flux is sensitive to recent star formation over timescales of 100 Myr (Kennicutt 1998b, and reference therein) as it stems from the photospheres of massive O and B stars. We use the prescription provided in Kennicutt (1998b), Verley et al. (2009), and Lee et al. (2009) to estimate FUV $\Sigma_{\text{SFR}}$. For FUV luminosity, $I_{\text{FUV}}$, in MJy sr$^{-1}$, $\Sigma_{\text{SFR}}$ is

$$\Sigma_{\text{SFR}}(\text{FUV}) [M_{\odot} \text{ yr}^{-1} \text{kpc}^{-2}] = 0.17 I_{\text{FUV}}. \quad (1)$$

However, high-energy UV photons originating from the photospheres of these massive stars are absorbed by small dust grains, which in turn produce thermal emission at 24 $\mu$m. As a result, a combination of FUV and 24 $\mu$m is required to recover both unobscured SFR via FUV (Salim et al. 2007) and dust-embedded SFR via 24 $\mu$m (Calzetti et al. 2007). To compute $\Sigma_{\text{SFR}}$ and $\Sigma_{\text{SFR}}$, we follow the method prescribed in Leroy et al. (2008). For FUV and 24 $\mu$m luminosity, $I_{\text{FUV}}$ and $I_{24}$, respectively, in MJy sr$^{-1}$, the $\Sigma_{\text{SFR}}$ is estimated as:

$$\Sigma_{\text{SFR}}(\text{FUV} + 24 \mu\text{m}) [M_{\odot} \text{ yr}^{-1} \text{kpc}^{-2}] = 0.081 I_{\text{FUV}} + 0.0032 I_{24}. \quad (2)$$

For the UV luminosity to SFR calibration, Equation (2) assumes a Kroupa (2001) initial mass function (IMF) with a maximum mass of $120 M_{\odot}$, while Equation (1) assumes a

Figure 3. COS FUV spectra of QSO, SDSS J104241.27+250122.8, tracing the circumgalactic medium of NGC 3344 at an impact parameter of 29.5 kpc from the center of the disk. We detected H I λ 1215 (Lyα), Si II λ λ 1193, 1260, C II λ 1334, Si III λ 1206, Si IV λ λ 1393, 1402. We detected two components in the absorption profile. The weighted average puts the strongest-line component at $-28.5$ km s$^{-1}$ and the weaker component at $89.9$ km s$^{-1}$. The second component was only detected in Lyα and Si II indicating its low-column density and low-ionization state.

---

aboard the Hubble Space Telescope (HST) for a total exposure of 10,069 s under the COS-DIISC Survey11 (S. Borthakur et al. 2021, in preparation). The spectra covered a wavelength range from 1140 to 1430 Å in the observed frame. The data were calibrated and reduced using the standard COS pipeline (procedure described in the COS Data Handbook; Rafelski et al. 2018). The spectral resolution of the data was $\approx 20$ km s$^{-1}$ ($\sim 15,000$). Owing to the low redshift of the galaxy ($z = 0.00194$), the rest-frame wavelength coverage is almost identical to that of the observed frame. The data covered multiple line transitions including H I λ 1215 (Lyα), Si II λ λ 1190, 1193, 1260, Si III λ 1206, Si IV λ λ 1393, 1402, and C II λ 1334. The COS FUV spectra are shown in Figure 3.

The spectra were normalized by identifying a continuum. Absorption-free regions within $\pm 1500$ km s$^{-1}$ from the line center were identified visually to fit a continuum except for the Lyα transition where we chose a region of $\pm 4000$ km s$^{-1}$ in order to cover the Milky Way damped Lyα profile (DLA). The continuum was estimated by fitting a Legendre polynomial of order between 1 and 5, similar to the procedure used by Sembach et al. (2004). This corrected for any low variations in the QSO flux near the position of the lines. Then we proceeded with fitting Voigt profile to the absorption features to estimate the velocity centroid, column density, and Doppler b-parameter, which defines the width of the observed spectral line of the profile. The fitting applied the appropriate line-spread functions (Osterman et al. 2011) for the aperture of the spectrograph from the COS Instrument Handbook (Dashamirova et al. 2019). The associated uncertainties were estimated using the error analysis method published by Sembach & Savage (1992). The prescription includes continuum placement uncertainties, Poisson noise fluctuations, and zero-point uncertainties. The estimated properties of the absorption features are shown in Table 2.

The Lyα transition associated with NGC 3344 was blended with the Milky Way’s Lyα absorption feature. Milky Way’s neutral hydrogen column produced a DLA profile at λ1215.67 Å, which we modeled based on the contamination-free regions. The model was then subtracted out of the data to enhance the absorption feature associated with NGC 3344, which was located in the damping wings of the Milky Way’s Lyα profile. In spite of this correction, we were not able to completely recover the blueward (low-velocity end) Lyα absorption profile for NGC 3344 owing to low signal strength at the base of the DLA. The redward part of the profile was retrieved with high confidence. Hence, a full estimate of H1 column density could not be made.

Notes:

$^a$ Due to a low signal-to-noise ratio in our data, equivalent widths were estimated based on the Voigt proﬁle ﬁts.

$^b$ Ly$\alpha$ proﬁle arising from the process of deblending it from the Milky Way’s Ly$\alpha$ proﬁle. Uncertainties from the deblending process add to the uncertainty in the H I column density and were not quantiﬁed.

$^c$ The ﬁt was produced by simultaneously ﬁtting the Si II 1260 and the 1193 transitions. Proﬁle is likely saturated as the ratio of the two equivalent widths is 1.8 as opposed to the predicted value of 2.

$^d$ No measurement could be made due to overlap with geocoronal O I, Milky Way Si II 1304, and a large set of intervening and QSO host galaxy line transitions.

$^e$ The ﬁts are likely saturated, although the level of saturation could not be determined.

$^f$ The ﬁt was produced by simultaneously ﬁtting the Si IV 1393 and 1402 transitions. The proﬁle is likely saturated as the ratio of the two equivalent widths is 1.8 as opposed to the predicted value of 2.

0.1–100 $M_\odot$ Salpeter (1955) IMF. A correction from Salpeter to Kroupa IMF is done by dividing the calibration constant by 1.59 (Leroy et al. 2008) in Equation (1).

Additionally, to trace the current star formation, we estimate $\Sigma_{\text{SFR}}$ from H$\alpha$ and 24 $\mu$m. Independent of the previous star formation history, H$\alpha$ emission from H II regions is sensitive to star formation over timescales of $\lesssim$10 Myr. Further, the combination of H$\alpha$ and 24 $\mu$m gives the total star formation (Kennicutt et al. 2007) from unobscured and dust-obscured components of star formation. For H$\alpha$ luminosity, $I(H\alpha)$ in MJy sr$^{-1}$, $\Sigma_{\text{SFR}}$ is:

$$\Sigma_{\text{SFR}}(H\alpha) [M_\odot \text{ yr}^{-1} \text{ kpc}^{-2}] = 4.32 \cdot I(H\alpha).$$  \hspace{1cm} (3)

The non-dust-corrected H$\alpha$ $\Sigma_{\text{SFR}}$ calculated using the calibration provided in Kennicutt (1998b), Blanc et al. (2009), and Kennicutt & Evans (2012) assumes solar abundance and 0.1–100 $M_\odot$ Salpeter IMF. Gallagher et al. (2018) provide a prescription for the H$\alpha$+24 $\mu$m $\Sigma_{\text{SFR}}$ with a 0.1–100 $M_\odot$ Kroupa IMF. For $I(H\alpha)$ and $I(24)$ in units of erg s$^{-1}$ cm$^{-2}$, and MJy sr$^{-1}$ respectively, H$\alpha$+24 $\mu$m $\Sigma_{\text{SFR}}$ is:

$$\Sigma_{\text{SFR}}(H\alpha + 24 \mu m) [M_\odot \text{ yr}^{-1} \text{ kpc}^{-2}] = 634 \cdot I(H\alpha) + 0.0025 \cdot I(24).$$

Converting $I(H\alpha)$ to MJy sr$^{-1}$, we obtain:

$$\Sigma_{\text{SFR}}(H\alpha + 24 \mu m) [M_\odot \text{ yr}^{-1} \text{ kpc}^{-2}] = 2.9 \cdot I(H\alpha) + 0.0025 \cdot I(24).$$ \hspace{1cm} (4)

Once again, correction from Salpeter to Kroupa IMF is obtained by dividing the calibration constant by 1.59.

Figures 4(a) and (b) show the FUV+24 $\mu$m and H$\alpha$+24 $\mu$m $\Sigma_{\text{SFR}}$ maps for NGC 3344, respectively. The resolution of these maps is 6$. These were generated by matching the PSFs of the GALEX FUV and VATT H$\alpha$ data to the PSF of MIPS 24 $\mu$m data. The FUV and H$\alpha$ images were grided to the pixel scale of the 24 $\mu$m image. Gaussian smoothing was performed to match the PSFs of FUV and H$\alpha$ images with widths $\sigma$ to the PSF of MIPS 24 $\mu$m image with width $\sigma_{24}$. The width of the convolution kernel, $\sigma_{24}$ in pixels was then calculated using $\sigma_{24} = \sigma_{\text{ker}}^2 + \sigma^2$ for the FUV and H$\alpha$ images. The images were individually smoothed using Python astropy functions Gaussian2DKernel and convolve.

3.2. Stellar Mass

To calculate the stellar mass surface density, we follow the prescription presented in Yang et al. (2007). They use the relation between the stellar mass-to-light ratio and color from Bell et al. (2003) and compute

$$\log \left[ \frac{M_*}{h^{-2} M_\odot} \right] = -0.406 + 1.097 (g - r) - 0.4 (M_r - 5 \log h - 4.64),$$ \hspace{1cm} (5)

where $(g - r)$ and $M_r$ refer to the color derived from the SDSS g- and r-bands and absolute magnitude in SDSS r-band, respectively. We adopt $h = H_0/(100 \text{ km s}^{-1} \text{ Mpc}^{-1}) = 0.73$ to derive the stellar mass. To create a spatial stellar mass map, we estimate $(g - r)$ at each pixel. The stellar masses are then converted to the stellar mass surface density ($\Sigma_*$) using a scale value of 40.14 pc$/''$ for NGC 3344 at a distance of 8.28 Mpc. Figure 5 shows the derived $\Sigma_*$ map of NGC 3344.

3.3. Properties of the Interstellar Medium

We trace the ISM in NGC 3344 using VLA H I 21 cm imaging. The velocity-integrated flux density ($I_{\text{vel}}$), flux-density-weighted velocity ($v_{\text{vel}}$), and the velocity dispersion ($\sigma_{\text{vel}}$) maps above 3$\sigma$...
were computed using the H I Source Finding Application-2 (SoFiA-2; Serra et al. 2015).

We estimate the H I mass surface density, $\Sigma_{H^I}$, and the kinetic energy surface density, $\Sigma_{KE}$, in units of $M_\odot$ pc$^{-2}$ and erg pc$^{-2}$, respectively, at each pixel using the relations presented in Mullan et al. (2013):

$$\Sigma_{H^I} = 1.0 \times 10^4 \frac{I_{tot}}{A_{beam}},$$  \hspace{1cm} (6)

$$\Sigma_{KE} = 1.5 \times 10^4 \frac{I_{tot} \sigma_{los}^2}{A_{beam}},$$  \hspace{1cm} (7)

where $I_{tot}$ and $\sigma_{los}$ have units of Jy beam$^{-1}$ km s$^{-1}$ and km s$^{-1}$, respectively, with the beam area, $A_{beam}$, expressed in square arcsecond. The resulting, $\Sigma_{H^I}$, $v_{los}$, $\sigma_{los}$, and $\Sigma_{KE}$, maps are shown in Figure 6. The $\Sigma_{H^I}$ map informs that the H I disk extends to 12.64 kpc at $\Sigma_{H^I} = 1 M_\odot$ pc$^{-2}$.

4. Results

4.1. Radial Profiles

The surface brightness ($\mu$) profiles of NGC 3344 are shown in Figure 7. We use IDL routine galprof,$^{12}$ which fits elliptical isophotes with fixed center positions, taking into account the ellipticity and position angle of a galaxy, to perform surface photometry. We show the surface brightness profiles in $r$, $g$, $B$, 24 $\mu$m, FUV, and Hα. The 24 $\mu$m surface brightnesses are estimated in Jy arcsec$^{-2}$, Hα in erg s$^{-1}$ cm$^{-2}$ arcsec$^{-2}$, while all others are in units of mag arcsec$^{-2}$. The B-band profile is created using the transformation $B = g + 0.33(g - r) + 0.20$ from Jester et al. (2005). We estimate $R_{25}$, i.e., the radius at 25 mag arcsec$^{-2}$, of 7.9 kpc from the B-band radial profile, which is indicated by the black arrow.

Using the method to derive the break radius prescribed in Pohlen & Trujillo (2006), we find that the r-band profile shows multiple break locations. Breaks are observed at 1.6, 3.3, 5.9, and 7.6 kpc, likely caused by asymmetries in the spiral arms. The FUV, Hα, and 24 $\mu$m profiles also show breaks at similar locations. However, at 6.0 kpc, the FUV emission in the disk shows a sudden increase along with an increase in Hα. We characterize this discontinuity at 6.0 kpc as the break radius, where a transition from the optical to the XUV disk occurs. This criterion differs from the definition in Thilker et al. (2007) of the starting point of an XUV disk beyond a single surface brightness contour corresponding to an FUV $\Sigma_{SFR}$ of $3.0 \times 10^{-4} M_\odot$ yr$^{-1}$ kpc$^{-2}$. At 6.0 kpc, for NGC 3344, we find an FUV $\Sigma_{SFR}$ of $3.8 \times 10^{-4} M_\odot$ yr$^{-1}$ kpc$^{-2}$. The XUV disk extends to a radius of 10.0 kpc at 3$\sigma$ FUV surface brightness, covering an annular area of $\sim$202 kpc$^2$. Following this, our XUV disk region is 1.3$\times$ larger in area than that of Thilker et al. (2007).

$^{12}$ http://www.public.asu.edu/~rjansen/idl/galprof1.0/galprof.pro
We also determine scale lengths \( h \) from the surface brightness profiles by fitting the exponential function: 
\[
\mu(R) = \mu_0 + 1.086 \times R/h.
\]
Scale lengths estimated from the radial profiles in the optical and XUV disks are summarized in Table 3. These measurements exclude the central part of the surface brightness profiles, which are dominated by the presence of a bulge. We find that the galaxy disk flattens from longer to shorter wavelengths. Scale lengths in the FUV are at least 1.4 times larger than those in the \( r \)-band. This implies that young stars show an extended distribution in the XUV disk, while older stellar populations are concentrated toward the center of the disk. Dust traced by 24 \( \mu m \) shows an even more centrally concentrated distribution.

4.1.1. SFR and Stellar Mass Profile

We use the surface brightness profiles and transform them into star formation rates, stellar masses, and atomic gas mass using the conversions provided in Section 3. The radial profiles of \( \Sigma_{s}, \Sigma_{\text{H} I}, \) and \( \Sigma_{\text{SFR}} \) (estimated using FUV, \( \text{H}\alpha, \) FUV +24 \( \mu m \), and \( \text{H}\alpha+24 \mu m \)), and the cumulative stellar and H I masses, \( M_{s} \), and \( M_{\text{H} I} (M_{\odot}) \) and SFRs \( (M_{\odot} \text{yr}^{-1}) \) are shown in Figures 8(a) and (b). Figure 8(c) shows the radial variation in specific SFR (sSFR), i.e., SFR per unit stellar mass, and H I star formation efficiency (SFE), i.e., SFR per unit H I mass.

The \( \Sigma_{s} \) profile shows a pure exponential profile, and we observe no break at 6.0 kpc as seen in the light profiles. This establishes that mass distribution has no impact on the location of the break, and it rather originates from the radial variation in the age of stellar populations (Bakos et al. 2008). At 6.0 kpc, we find \( \Sigma_{s} \) equals 15.8 \( M_{\odot} \text{pc}^{-2} \) closer to a typical value of 13.6 \( M_{\odot} \text{pc}^{-2} \) at the break radius of a typical galaxy exhibiting a truncated radial profile (Pohlen & Trujillo 2006; Bakos et al. 2008). We also find that only \( \sim 5\% \) of the total stellar mass resides in the XUV disk with \( \sim 14\% \) of the total SFR coming from this region.

The \( \Sigma_{\text{SFR}} \) profiles also provide an opportunity to study the radial variation in the different tracers of star formation. We...
find the four tracers of star formation: FUV, Hα, FUV+24 μm, and Hα+24 μm to show different behaviors in the optical and XUV disk. In the optical disk, dust plays an important role—both FUV+24 μm and Hα+24 μm show higher ΣSFR compared to FUV and Hα. However, as we move toward the XUV disk, FUV and FUV+24 μm tracers pick up more of the star formation. Additionally, the 24 μm data are dominated by noise, which is of the order of the low SFRs and hence, it is not sensitive to star formation in the XUV disk. Estimates from the cumulative profiles show that dust-corrected SFRs are higher, making them more effective in tracing star formation than non-dust-corrected SFRs. We note that SFR estimates from Hα and Hα+24 μm are consistently lower compared to FUV and FUV+24 μm SFRs. This is discussed in more detail in Section 5.1.

In the XUV disk, we also observe a rise in the sSFR after an almost flat trend in the optical disk, while the HI SFE declines as a function of galactocentric distance. The implications of this result are discussed in Section 5.2.

4.2. Young Stellar Complexes in NGC 3344

We extracted 320 young stellar complexes in NGC 3344 with typical physical sizes between 0.15 and 1 kpc. Figure 9 shows the individual star-forming complexes throughout the galaxy. Elliptical apertures above the 3σ threshold were identified by running SExtractor (Bertin & Arnouts 1996) on cutouts of different regions of the FUV and NUV images. We applied a 5 pixel wide top-hat filter to detect regions of low surface brightness in the XUV disk. Some apertures were redefined or added manually to optimally enclose faint regions. Any apertures belonging to background objects detected in the outer edge of the XUV disk were removed. This was done using the continuum-subtracted Hα image that enabled discerning objects present at the same redshift as the galaxy and utilizing SDSS DR 12 spectroscopy and imaging to verify if the objects were removed foreground stars or background galaxies. The aperture at the position of a bright foreground star near the

---

We note that SFR estimates from Hα and Hα+24 μm are consistently lower compared to FUV and FUV+24 μm SFRs. This is discussed in more detail in Section 5.1.

In the XUV disk, we also observe a rise in the sSFR after an almost flat trend in the optical disk, while the HI SFE declines as a function of galactocentric distance. The implications of this result are discussed in Section 5.2.

4.2. Young Stellar Complexes in NGC 3344

We extracted 320 young stellar complexes in NGC 3344 with typical physical sizes between 0.15 and 1 kpc. Figure 9 shows the individual star-forming complexes throughout the galaxy. Elliptical apertures above the 3σ threshold were identified by running SExtractor (Bertin & Arnouts 1996) on cutouts of different regions of the FUV and NUV images. We applied a 5 pixel wide top-hat filter to detect regions of low surface brightness in the XUV disk. Some apertures were redefined or added manually to optimally enclose faint regions. Any apertures belonging to background objects detected in the outer edge of the XUV disk were removed. This was done using the continuum-subtracted Hα image that enabled discerning objects present at the same redshift as the galaxy and utilizing SDSS DR 12 spectroscopy and imaging to verify if the objects were removed foreground stars or background galaxies. The aperture at the position of a bright foreground star near the
center, clearly visible in the $r$-band image but not in the FUV image, was taken out. Care was taken to avoid contamination from neighboring apertures. These apertures were further divided into optical and XUV regions based on their galactocentric distance and the estimated break radius. The red apertures are regions within the optical disk marked by the Figure 8.

Figure 8. Radial profiles of (a) $\Sigma_*$, $\Sigma_{HI}$, and $\Sigma_{SFR}$; (b) cumulative $M_*$, $M_{HI}$, and SFR; and (c) specific SFR and H I star formation efficiency of NGC 3344. The SFR and $\Sigma_{SFR}$ are estimated using FUV (green), FUV + 24 $\mu$m (blue), H$\alpha$ (pink), and H$\alpha$ + 24 $\mu$m (purple). The shaded area shows the uncertainty in the respective quantities. The vertical black dashed line at 6 kpc marks the break radius.
Figure 9. The grayscale FUV image of NGC 3344 with star-forming regions detected at 3σ significance using SExtractor. The black dashed circle represents the break radius of 6 kpc. The red apertures are regions within the optical disk, and blue apertures are regions in the XUV disk. 320 regions are extracted with 132 regions in the XUV disk. A physical scale of 2.4 kpc (1') is shown at the top left corner. Highlighted regions A and B (see Section 5.1.1) have SDSS DR12 spectra available.

black dashed circle covering an area of $\sim$113 kpc$^2$. The blue apertures are regions in the XUV disk. Of the 320 young star-forming complexes, 132 are in the XUV disk.

4.3. Circumgalactic Medium in NGC 3344

We detected two distinct absorbing systems in the QSO sightline probing NGC 3344 at 30 kpc. The strong component was seen in most of the metal-line transitions covering low-, intermediate-, and high-ionization states (Si II, C II, Si III, and Si IV). The weighted mean places the centroid of the strong component at $\sim$−28.5 km s$^{-1}$. The weaker component was seen in H I and Si II at a mean centroid of $\sim$88.9 km s$^{-1}$. As noted before, the H I line was blended with the damped Ly$\alpha$ profile of the Milky Way, so no measurements could be made for the atomic gas content of the first component. The measurements of the Ly$\alpha$ of the second component might suffer from uncertainties pertaining to continuum identification issues. A single component fit to the profile yields a column density of $N$ (H I) = 14.0. However, the column density log ($N$(Si II)) = 13.06 corroborates our assertion of large uncertainties in the continuum fit of Ly$\alpha$ most likely leading to a lower column density measurement for H I.

In general, the QSO sightline probes a metal-rich circumgalactic medium in NGC 3344. The total Si II content is $>1.3 \times 10^{14}$ cm$^{-2}$. Assuming a solar metallicity, we expect the total H I column density to be $\approx 3.7 \times 10^{18}$ cm$^{-2}$. Since we did not detect damping wings with the Ly$\alpha$ profile, we can also conclude that the metallicity of the gas in the CGM of NGC 3344 is no less than 0.1 Z$_{\odot}$ and is more likely $\approx 1 Z_{\odot}$. This indicates that the circumgalactic gas at 30 kpc is well enriched by the products of stellar nucleosynthesis. The weaker component also showed Si II indicative of a high-metallicity and low-ionization state of the gas.

The kinematics of the two absorbers allows us to determine if they are consistent with corotation. The observed projected velocity of the H I disk closest to the sightline is $665 \pm 5$ km s$^{-1}$, i.e., 85 km s$^{-1}$ from the systemic velocity of 580 km s$^{-1}$ (Figure 6(b)). The weaker component is consistent with rotation showing a deviation of 3.9 km s$^{-1}$, which is well within the uncertainties of our measurement. However, the stronger component observed at $-28.5$ km s$^{-1}$ with respect to the systemic shows a deviation of $-113.5$ km s$^{-1}$ from the part of the disk nearest to the sightline, thus indicating gas flow that is inconsistent with corotation. The direction of the flow is unknown and could either be an inflowing or outflowing cloud with respect to the disk. To put it into perspective, this cloud is consistent with high-velocity clouds (HVCs) seen in the halo of the Milky Way showing velocity offsets of $\geq 90$ km s$^{-1}$ (Wakker & van Woerden 1997) relative to the disk. The presence of similar clouds in the halos of other galaxies, such as in M31 and M100, have been reported (Thilker et al. 2004; Westmeier et al. 2005; Gim et al. 2021). The Milky Way HVCs are considered as one of the main pathways for bringing cold gas into the Milky Way disk. The same may be true for this cloud that is cold and metal-rich. We will discuss the likelihood of this cloud being an inflow or outflow in Section 5.4.

5. Discussion

5.1. Effectiveness of H$\alpha$ and UV SFR Tracers

We first tested how efficient the non-dust-corrected (H$\alpha$ and FUV) and dust-corrected (H$\alpha$+24 $\mu$m and FUV+24 $\mu$m) tracers are in probing star formation in the XUV disk. Both H$\alpha$ and FUV tracers are known to give consistent estimates of SFRs in the optical disk. On the other hand, previous studies investigating the H$\alpha$ and FUV emission in the outer disks of galaxies find the outer regions to be sparsely populated with H II regions (Ferguson et al. 1998; Gil de Paz et al. 2005; Meurer et al. 2009; Goddard et al. 2010; Werk et al. 2010; Barnes et al. 2011; Watkins et al. 2017) and hence, show lower levels of H$\alpha$. In Figures 10(a) and (b), we show the non-dust-corrected and dust-corrected H$\alpha$ SFRs against FUV SFRs for the young stellar complexes, respectively. The red and blue colors distinguish between the regions in the optical and the XUV disk, respectively, with the solid black line denoting the linear fit to the data. The one-to-one correlation between the H$\alpha$ and FUV SFRs is represented by the dashed line. The dotted lines show the best-fit line for non-dust-corrected FUV and H$\alpha$ SFRs and dust-corrected FUV and H$\alpha$ SFRs for log SFR(H$\alpha$) $< -1.5$ from Lee et al. (2009; Figures 2 and 5 therein, respectively). We note that the SFRs estimated using the prescriptions presented in Section 3.1 assume fully populated IMFs and a uniform distribution of ages of the regions. Lee et al. (2009) investigated ~300 local star-forming galaxies and found a systematic offset between the non-dust-corrected FUV and H$\alpha$ SFRs, where at SFRs $\lesssim 0.03 M_{\odot}$ yr$^{-1}$, H$\alpha$ began to underestimate SFR. While we study ~300 individual star-forming regions within a single galaxy, what is striking is the similarity in the best-fit line of our study (Figure 10(a) and the one from Lee et al. (2009) for the non-dust-corrected SFRs. Our results extend the distribution to lower values, log SFR(H$\alpha$) $< -2.0$, with H$\alpha$ SFRs already lower than FUV SFRs. This not only corroborates the result of Lee et al. (2009) but also demonstrates that SFRs obtained on
global scale and \( \lesssim 1 \) kpc scales show a similar relation in their FUV and H\( \alpha \) emission.

However, our dust-corrected H\( \alpha \) SFRs are higher compared to the expected trend from Lee et al. (2009), although still offset from the one-to-one line. In Figure 10(b), after accounting for internal dust correction via 24 \( \mu m \), the optical disk points shift by \( \lesssim 1 \) dex and the XUV disk points move by \( \lesssim 0.5 \) dex. The addition of 24 \( \mu m \) does, however, add noise to the estimate. The upper envelope of the distribution in Figure 10(b) has an almost constant offset from the one-to-one relation over a wide range in SFR that spans both the optical and the XUV portions of the disk. So, a subset of star

Figure 10. Comparison of the (a) non-dust-corrected H\( \alpha \) SFR and FUV SFR and (b) dust-corrected H\( \alpha \)+24 \( \mu m \) SFR and FUV+24 \( \mu m \) SFR, followed by (c) ratio of H\( \alpha \)-to-FUV \( \Sigma_{\text{SFR}} \) as a function of the galactocentric distance for the star-forming regions in NGC 3344. The red triangles and blue circles are regions in the optical disk and the XUV disk, respectively. In panels (a) and (b), the solid black line represents the best fit to the data. The dashed line shows the one-to-one correspondence between the two \( \Sigma_{\text{SFR}} \) estimates, and the dotted line is the best fit for non-dust-corrected and internal-dust-corrected SFRs from Lee et al. (2009), respectively. The parameters describing the line of best fit are stated at the bottom right. The solid red and dashed blue lines in panel (c) represent the best-fit line to the optical disk and XUV disk points, respectively. In general, H\( \alpha \) SFRs are found to be lower than FUV SFRs.
formation happens in the regions that behave similarly in the XUV disk and in the optical disk. The total $H\alpha+24\,\mu m$ SFR of the stellar complexes in the optical disk is $\sim0.09\,M_\odot\,yr^{-1}$. This is $\sim50\%$ lower than the total FUV+$24\,\mu m$ SFR of $\sim0.18\,M_\odot\,yr^{-1}$ in the optical disk. The offset further increases in the XUV disk. At SFRs $\lesssim 10^{-6}\,M_\odot\,yr^{-1}$ in the XUV disk, $H\alpha$ underpredicts the SFR by $\sim75\%$. This is better illustrated in Figure 10(c), which shows the ratio of $H\alpha$-to-FUV $\Sigma_{\text{SFR}}$ with the galactocentric distance. The ratio of $\Sigma_{\text{SFR}}$ range within factors of $0.03$–$0.88$. In the XUV disk, the ratios show a larger scatter with a steeper correlation compared to the optical disk. Since the galactocentric distance is representative of decreasing star formation rates, this scatter then indicates that $H\alpha$ SFRs drop faster at lower SFRs in the extreme outskirts of the galaxy.

We note that a fixed value of the $\text{[N II]}/H\alpha$ ratio of 0.52, adopted from Kennicutt et al. (2008), is an average over the optical disk. However, the $\text{[N II]}/H\alpha$ ratio varies with the galactocentric radius and is likely low in the XUV disk. This would lead to an overcorrection and a subsequent underestimation of $H\alpha$ SFRs in the XUV disk. We calculated $H\alpha$ SFRs without applying a $\text{[N II]}$ correction and found that the intercept in Figure 10(a) changes from 0.27 to 0.36, i.e., the data would shift upward by $\sim0.12\,\text{dex}$. So, even if a radially accurate $\text{[N II]}$ correction is applied, the deviations would be small and not greatly affect the results. In the following subsection, we explore other factors that cause lower $H\alpha$ SFRs in the XUV disk.

### 5.1.1. Possible Causes for Low $H\alpha$-to-FUV Ratios

The drop in the $H\alpha$-to-FUV ratios in the XUV disk can be associated with (1) stochastic sampling of the stellar IMF, (2) truncation and/or steepening of the upper end of the IMF, (3) noncontinuous star formation history, or (4) leakage of hydrogen-ionizing photons. Here we investigate these possibilities for lower levels of $H\alpha$ seen in the XUV disk.

The first possibility that can explain the discrepancy in the $H\alpha$ and FUV emission is the stochastic sampling of the IMF. In the optical disk, high SFRs preclude a large number of stars and hence a nearly complete sampling of the IMF. However, in the XUV disk, lower SFRs reduce the probability of finding massive O stars. As a result, the IMF may not be fully sampled (see Boissier et al. 2007; Goddard et al. 2010; Fumagalli et al. 2011; Koda et al. 2012). Calculations done by Lee et al. (2009) show that above SFR $\gtrsim 1.4 \times 10^{-3}\,M_\odot\,yr^{-1}$ or log SFR $\gtrsim -2.8$, the $H\alpha$ flux should be robust against stochasticities. In NGC 3344, SFRs of the stellar complexes are below this value, with SFRs yielded by $H\alpha$ mostly lower than the FUV SFRs. As a result, stochastic IMF sampling is likely to at least partially account for the observed $H\alpha$-to-FUV ratios.

The second possibility arises from the difference in the stellar mass ranges probed by $H\alpha$ and FUV. $H\alpha$ is sensitive to O stars more massive than $\sim17\,M_\odot$, while FUV traces both O and B stars that have masses $\gtrsim 4\,M_\odot$ (Lee et al. 2009; Meurer et al. 2009; Goddard et al. 2010; Koda et al. 2012). The observed $H\alpha$-to-FUV ratios could be a manifestation of a steeper upper IMF slope, possibly combined with an upper truncation (Meurer et al. 2009; Bruzzez et al. 2015, 2020; Watts et al. 2018). Previous studies have, however, found that $H\alpha$ and FUV ratios are consistent with a standard IMF (Goddard et al. 2010; Koda et al. 2012). In the XUV disk of M83, Koda et al. (2012) found that O stars may intermittently populate low-mass clusters. Certainly, O stars are forming in the XUV disk of NGC 3344, but the low $H\alpha$-to-FUV ratios may still be consistent with a steeper upper IMF and/or truncation along with stochastic IMF sampling.

Sensitivity to ages of stellar populations could also account for the decline in the $H\alpha$-to-FUV ratios. The star formation history of a galaxy, however, need not be uniform and may comprise of multiple bursts of star formation over the past 10–100 Myr. We find that the total SFR of $\sim0.43\,M_\odot\,yr^{-1}$ over a timescale of 10 Myr probed by $H\alpha$ is lower than the total SFR of $\sim0.46\,M_\odot\,yr^{-1}$ over a timescale of $\sim100$ Myr traced by FUV. The occurrence of a burst of star formation at a time $\gtrsim 10$ Myr but $\lesssim 100$ Myr in the past would lead to an increase in the FUV SFRs.

### 5.2. The Inside-out Disk Growth and XUV Disk Formation

Based on our analysis in Section 5.1, we find FUV+$24\,\mu m$ to be a more robust and effective tracer of star formation. Therefore, for the remainder of our analysis, we will use $H\alpha+24\,\mu m$ SFRs. We also note that the FUV-to-Balmer ratio may be affected by the presence of O stars in the XUV disk, which could lead to an overestimation of the FUV SFR. However, the FUV SFRs in the XUV disk are lower than the $H\alpha$ SFRs, indicating that the FUV SFRs are not dominated by O stars. Therefore, we will use FUV SFRs for the remainder of our analysis.
Figure 11. FUV SFRs of the star-forming regions as a function of the galactocentric distance in NGC 3344. The red triangles and blue circles are regions in the optical and the XUV disks, respectively, with the solid black line representing the best fit to the data. The parameters describing the line of best fit are stated at the top. Symbol sizes show the distribution of the area of the stellar complexes.

UV-based SFR and $\Sigma_{\text{SFR}}$. Figure 11 shows the FUV +24 $\mu$m SFR for each of the 320 stellar complexes identified in the disk of NGC 3344 as a function of the galactocentric distance. The distribution of the area of the regions is indicated by the size of the symbols. At large radii, the variation in the SFR between the stellar complexes can be up to 2 orders of magnitude versus a smaller scatter seen in the inner disk. As is evident by the radial profile of $\Sigma_{\text{SFR}}$ in Figure 8(a), star formation drops as a function of the radius. This can be linked to the low SFRs of individual stellar complexes and is not due to a deficit of star-forming regions. The total FUV+24 $\mu$m SFR in NGC 3344 is 0.458 $M_\odot$ yr$^{-1}$—only ~10% of which is in the XUV disk.

As discussed earlier in Section 4.1, FUV shows a larger scale length compared to the $r$-band illustrating an extended star formation. This also provides evidence for inside-out disk growth (Nelson et al. 2012). The claim of inside-out disk growth is further supported by the rise in sSFR (Figure 8(c)) beyond the break radius at 6 kpc. We observe an almost constant sSFR of $10^{-9.9}$ yr$^{-1}$ in the inner disk between ~1 and 6 kpc with a sudden rise in the sSFRs from $10^{-9.3}$ to $10^{-8.5}$ yr$^{-1}$ in the XUV disk. As a result, the inner disk is growing slowly while the XUV disk is actively forming stars suggesting an outward increase in the size of the galaxy.

This leads us to infer that the entire XUV disk could essentially be a starburst. A starburst can be defined as a region in which the mass-doubling time for stars is $\ll$ Hubble time, and a sudden infusion of gas has triggered the star formation. In the centers of the galaxies, this can happen rapidly due to the small size of the region (~kpc). On the contrary, the XUV disk is large and it is difficult to change things rapidly. The present stellar clumps in the XUV disk are a sprinkling of a recent activity on top of a longer-term-forming optical disk. The H1 map, however, does not show any strong dynamical perturbation in the XUV disk associated with a recent major accretion event. We find longer H1 gas depletion times (1/SFR) in the XUV disk (Figure 8(c)) which suggest that the XUV disk has had a big H1 reservoir that only recently started forming stars and it could continue for a very long time ($\sim$10 Gyr). Additionally, the observed high sSFRs, if maintained, would double the disk mass in under one orbital period ($\sim$0.5 Gyr), indicating a burst of star formation.

Simulations have shown spiral arms as being one possible mechanism for locally triggering the outer star formation and creating a Type-I XUV disk (Bush et al. 2008, 2010; Lemonias et al. 2011). A preliminary investigation showed a spatial offset between the H0 and FUV star-forming regions where the H0 regions in the XUV disk lead the UV along the direction of rotation of the galaxy. We believe that this observation confirms that spiral density wave propagation supports the formation scenario of XUV disks (M. Padave et al. 2021, in preparation).

5.3. Correlations between Star Formation and H1

In this subsection, we explore the relations between star formation and atomic gas (H1) and quantify the impact of stellar feedback on the ISM in the disk of NGC 3344. The H1 disk is a reservoir of cold gas that serves as the fuel for star formation. We correlate the FUV +24 $\mu$m $\Sigma_{\text{SFR}}$ (hereafter, $\Sigma_{\text{SFR}}$) with the H1 properties in the optical and XUV disk of NGC 3344 and investigate (1) atomic gas mass surface density ($\Sigma_{\text{HI}}$), (2) SFR efficiency ($\Sigma_{\text{SFR}}/\Sigma_{\text{HI}}$), and (3) star formation-driven feedback on the ISM using H1 kinematics (\(\sigma_{\text{rms}}, \Sigma_{\text{KE}}\)).

5.3.1. The Star Formation Law in NGC 3344

Figure 12(a) shows the relationship between $\Sigma_{\text{HI}}$ and $\Sigma_{\text{SFR}}$ for the 320 stellar complexes in the optical (red triangles) and XUV (blue circles) disk. The dashed green line marks the empirical K-S law that connects the total $\Sigma_{\text{SFR}}$ to the total gas surface density, $\Sigma_{\text{gas}}$, such that $\Sigma_{\text{SFR}} = A \Sigma_{\text{gas}}$ with $N = 1.4$ and $A = 2.5 \times 10^{-4}$ yr$^{-1}$ (Kennicutt 1998b). These plots only consider neutral gas and, hence, offsets from the K-S relationship are expected for regions where the contribution of molecular gas to $\Sigma_{\text{gas}}$ is significant. However, in that regime the points should lie systematically above the K-S relationship. This is seen in the star-forming regions in the optical disk, especially for regions at galactocentric distance $\lesssim 4$ kpc and $\Sigma_{\text{SFR}} \gtrsim 3.16 \times 10^{-3} M_\odot$ yr$^{-1}$ kpc$^{-2}$.

We find an overall lack of correlation between $\Sigma_{\text{SFR}}$ and $\Sigma_{\text{HI}}$ which is consistent with what Bigiel et al. (2010b), Roychowdhury et al. (2015) and others have seen in the spatially resolved star formation law, or what de los Reyes & Kennicutt (2019) see in the disk integrated H1 star formation law. The distribution of $\Sigma_{\text{SFR}}$ has no relation with $\Sigma_{\text{HI}}$ in the optical disk but shows a moderate correlation (Pearson $r = 0.51$) in the XUV disk (Figure 12(a)). This result is the consequence of a predominantly molecular (Bigiel et al. 2008) ISM around the highly star-forming inner parts of spiral galaxies and $\Sigma_{\text{HI}}$ alone is not a good tracer of $\Sigma_{\text{gas}}$. Meanwhile, a correlation between $\Sigma_{\text{SFR}}$ and $\Sigma_{\text{HI}}$ in the outer regions of galaxies points to the fact that high H1 column densities pave the way for star formation (Bigiel et al. 2010b).

In Figure 12(b), we show the median $\Sigma_{\text{SFR}}$ (and 1σ range) in four bins of $\Sigma_{\text{HI}}$ for both the optical (red triangles) and XUV
data for the sample of spirals and dwarf galaxies from Bigiel et al. shown in yellow squares. The respectively. In panel Schmidt law with an index of 1.4 cover a comparable range in \( \Sigma \) (Figure 12.). The Astrophysical Journal, galaxies studied by Bigiel et al. H2-dominated inner regions of these points connect the star formation efficiency in NGC 3344, along with median outer disk data trace the missing parameter space of high-HI disk and the missing regions in the outskirts of spiral and dwarf galaxies, thereby creating the “S-shape” distribution seen in Bigiel et al. (2010b), their Figure 13.). The drop in the \( \Sigma_{H_1} \)–\( \Sigma_{SFR} \) relation in the outer disk and the missing “forbidden region” points found by Bigiel et al. (2010b) give rise to the question of whether the transition from the efficiently star-forming inner disk to the inefficiently star-forming outer disk is gradual or discontinuous? The XUV disk data trace the missing parameter space of high-HI low-\( \Sigma_{SFR} \) points. And, the presence of the XUV points of NGC 3344 in the forbidden region in the \( \Sigma_{SFR} \)–\( \Sigma_{H_1} \) plot can be thought to connect the low-density outer disk to the H2-dominated inner disk completing the “S-shape” distribution. However, a larger sample of XUV disk data must be explored to investigate the origin of the break in the star formation law.

\( \Sigma_{SFR} \) and \( \Sigma_{H_1} \) for the star-forming regions in NGC 3344. In panel (a), the red triangles and blue circles represent regions in the optical and the XUV disk, respectively. In panel (b), the red triangles and blue circles show binned optical and XUV data, respectively, from panel (a) along with data from Bigiel et al. (2010b) shown in yellow squares. The solid black line depicts the line of best fit to XUV data and data from Bigiel et al. (2010b). The green (dashed) line shows the Kennicutt–Schmidt law with an index of 1.4 (Kennicutt 1998b).

5.3.2. H1 Star Formation Efficiency in NGC 3344

SFE or SFR per unit gas mass (here, H1 mass) indicates how good the available gas is at forming stars. It is the inverse of the gas depletion time, \( \tau_{dep} \), which is the time taken to exhaust the available supply of gas by the star formation at the current rate. In Figure 13, we plot the variation in the H1 SFE over the galaxy disk as a function of the galactocentric distance and \( \Sigma_{H_1} \). The dashed line marks the boundary between an H1-dominated and H2-dominated ISM discussed by Leroy et al. (2008). The dotted lines in Figure 13(a) illustrate H1 SFE proportional to the freefall time (\( \tau_{ff} \)) in a gas disk with a fixed scale height, which is SFE \( \propto \Sigma_{gas}^{0.5} \) (Kennicutt 1998a). Irrespective of the power-law coefficient, the dotted lines cannot reproduce the observed relation between \( \Sigma_{H_1} \) and H1 SFE due to the small range of \( \Sigma_{H_1} \) (\( \sim 2.5\)–\( 40\) \( M_{\odot} \) pc\(^{-2} \)). This suggests that \( \Sigma_{H_1} \) plays almost no role in governing the H1 SFEs.

We find that the H1 SFEs drop with the galactocentric distance for the star-forming complexes, also implying longer H1 depletion times (since SFE \( \propto \tau_{dep}^{-1} \)) in the XUV disk similar to what was observed with the SFE radial profile (Figure 8(c)). The correlation between \( \Sigma_{SFR} \) and H1 and the longer H1 depletion times in the XUV disk infer the importance of H1 in regulating the star formation in the outer disk. The in situ star formation, however, would take at least 10 Gyr to consume the current supply of H1. Meanwhile, the longer-lived H1 gas can also act as a necessary source for the star-forming optical disk (Shlosman et al. 1989; Blitz 1997; Bauermeister et al. 2010; Bigiel et al. 2010b), in order for it to keep forming stars.

Star formation presupposes that H2/giant molecular clouds will form from H1. Molecular gas has depletion times of
Stellar associations were extracted from the et al. 2008 toward the outer parts of the galaxy implies an increase in the HI depletion times. The line in panel solid in the optical and the XUV disks, respectively. The disk is only limited by the formation of molecular clouds depletion times then illustrate that star formation in the outer disk is only limited by the formation of molecular clouds (Bigiel et al. 2010a; Rafelski et al. 2016).

Figure 13. H I SFE as a function of (a) \( \Sigma_{H1} \) and (b) the galactocentric distance for the star-forming regions in NGC 3344. The red triangles and blue circles are regions in the optical and the XUV disks, respectively. The dashed line in panel (a) marks the transition from an H\(_2\)-dominated to an H I-dominated environment (from Leroy et al. 2008). The dotted lines show the H I SFE proportional to \( \tau_{H1} \) in a fixed scale height gas disk for power-law coefficients of -11.0, 10.5, 10.0, -9.5, and -9.0. The solid line in panel (b) represents the line of best fit to the points. In general, H I plays no major role in regulating H I SFEs. The decrease in the H I SFE as we move toward the outer parts of the galaxy implies an increase in the H I depletion times.

\(~2\) Gyr (Bigiel et al. 2008, 2010b; Leroy et al. 2008) while the observed H I depletion times in the XUV disk are much longer. Under the assumption that the depletion time of molecular gas stays the same in both the optical and XUV disk, longer H I depletion times then illustrate that star formation in the outer disk is only limited by the formation of molecular clouds (Bigiel et al. 2010a; Rafelski et al. 2016).

5.3.3. ISM Turbulence and Impact of Stellar Feedback in NGC 3344

To understand the connections between turbulence and star formation, we investigate the relationship between \( \Sigma_{\text{SFR}} \) and H I velocity dispersion (\( \sigma_{\text{los}} \)) and H I kinetic energy surface density (\( \Sigma_{\text{KE}} \)). In Figure 14(a), we observe H I velocity dispersion between 4.8 and 12.8 km s\(^{-1}\) for the stellar complexes in NGC 3344. In both the optical disk and the XUV disk, we find a weak (Pearson \( r \sim 0.15 \) and \( 0.36 \), respectively) correlation between \( \sigma_{\text{los}} \) and \( \Sigma_{\text{SFR}} \). Also, on the galactic scale, \( \Sigma_{\text{SFR}} \) varies by a few orders of magnitude, implying \( \Sigma_{\text{SFR}} \) does not really depend on \( \sigma_{\text{los}} \). This observation suggests that triggering of star formation by turbulence does not dominate over large scales (Tamburro et al. 2009) as the timescales for supercritical density fluctuations that promote star formation are shorter than gas freefall time ceasing cloud collapse (Klessen et al. 2000; Elmegreen 2002). In fact, some simulations have shown that velocity dispersion can be emulated from self-gravity without any contribution from star formation (Hopkins et al. 2011). However, in the outer disk where self-gravity is weak (Elmegreen & Hunter 2006), turbulence can be crucial in supporting the structure of the ISM (Larson 1981; Elmegreen & Scalo 2004; Mac Low & Klessen 2004; McKee & Ostriker 2007) and cloud formation (Krumholz & McKee 2005). This could explain the slightly higher Pearson \( r \) value in the XUV disk.

We note that the H I maps used here for the analysis were produced with masking imposed at 3\( \sigma \) and a beam size of 6\( \arcsec 7 \times 5\arcsec 4 \). Stellar associations were extracted from the GALEX maps, which have a resolution of 4\( \arcsec 2 \). As a result, some regions that are smaller than the H I beam have poorly resolved \( \sigma_{\text{los}} \) measurements. These regions are shown in a different transparency in Figure 14. Excluding them from the analysis, we find that the Pearson \( r \) values change to \( 0.11 \) and \( 0.26 \) in the optical and XUV disk, respectively. Overall, this does not impact our result. In the Appendix, we also discuss the effect of the signal-to-noise ratio and resolution on the observed correlations.

In Figure 14(b), we plot \( \Sigma_{\text{SFR}} \) as a function of \( \Sigma_{\text{KE}} \) in the optical and XUV disk of NGC 3344. Energy inputs of different supernova (SN) efficiency values, \( \epsilon_{\text{SN}} = 0.05, 0.1, 0.2, 0.5, 1.0 \) and magnetorotational instabilities (MRI) energy input at maximum efficiency, \( \epsilon_{\text{MRI}} = 1.0 \) from Tamburro et al. (2009) are plotted as purple and orange dashed lines, respectively. Since \( \Sigma_{\text{KE}} \) is a product of \( \Sigma_{H1} \) and \( \sigma_{\text{los}}^2 \), the observed distribution of \( \Sigma_{\text{KE}} \) in NGC 3344 is mainly a result of variations in \( \Sigma_{H1} \) as \( \sigma_{\text{los}} \) shows little variation with \( \Sigma_{\text{SFR}} \).

We find almost no correlation (Pearson \( r = 0.10 \)) between \( \Sigma_{\text{SFR}} \) and \( \Sigma_{\text{KE}} \) of the stellar complexes in the disk of NGC 3344, Hunter et al. (2021) also found poor correlation between \( \Sigma_{\text{KE}} \) and \( \Sigma_{\text{SFR}} \) in the LITTLE THINGS sample of dwarf irregular galaxies. They found that both the \( \Sigma_{\text{KE}} \) and FUV maps of the dwarf irregular galaxies show clumps, but the positions of the FUV clumps do not line up with those in the \( \Sigma_{\text{KE}} \) map. We also observe a similar disposition of the clumps.
Correlation between \( \Sigma_{\text{SFR}} \) and (a) velocity dispersion and (b) \( \text{H}\text{I} \) kinetic energy surface density \( \Sigma_{\text{KE}} \). The red triangles and blue circles are regions in the optical and the XUV disks, respectively. Regions with areas smaller than the \( \text{H}\text{I} \) beam are shown in different transparency. Models of supernova energy input with different efficiency values (\( \epsilon_{\text{SN}} = 1, 0.5, 0.2, 0.1, 0.05 \)) and magnetorotational instabilities at maximum efficiency (\( \epsilon_{\text{MRI}} = 1 \)) from Tamburo et al. (2009) are shown in purple and orange lines, respectively. We find no correlations between \( \Sigma_{\text{SFR}} \) and the gas kinematic in NGC 3344. Supernovae explosions can maintain turbulence at high \( \Sigma_{\text{SFR}} \) but MRI, feedback mechanisms, and spiral density waves may be important in the low \( \Sigma_{\text{SFR}} \)–high \( \Sigma_{\text{KE}} \) regions.

5.4. Connection Between Circumgalactic Gas Flows and Star Formation in the Disk

We discuss the two possibilities for the CGM gas flow detected in the stronger metal-line component of the QSO absorption system at an impact parameter of 29.5 kpc from the center of the galaxy and 19.26 kpc from the edge of the \( \text{H}\text{I} \) disk. The blueshifted absorption feature at 113.5 km s\(^{-1}\) with respect to the disk gas closest to the sightline is consistent with gas flowing into the disk from behind or out of the disk in the front. We will consider the implications of both scenarios in an attempt to identify which is most likely.

First, we estimate how likely it is for us to detect outflowing material at the observed impact parameter and velocity offset. Assuming that the opening angle of the outflow cone is as large as some of those seen in starburst galaxies in the redshift universe of \( \theta \approx 60^\circ \) (Heckman et al. 1990), the “true” three-dimensional velocity of the cloud would be \( \approx 131 \text{ km s}^{-1} \) with a transverse velocity of 66 km s\(^{-1}\). At this rate, it would take the cloud about 500–600 Myr to reach 29.5 kpc depending on its point of origin in the star-forming disk at a constant velocity. This would indicate the current star formation seen in the XUV disk is not responsible for generating the observed cloud as outflow. In addition, the cloud would encounter the gravitational pull of the galaxy as well as interaction with the hot gas (drag force) that would likely limit its survival times.

Another line of argument would be to look at the velocity of ejection. It is expected that the velocity at the time of ejection was greater than the velocity inferred above as drag and ballistic nature of the motion would act to reduce the velocity as a function of the distance from the point of ejection. A detailed analysis of the motion of starburst-driven clouds in the
CGM of starburst galaxies by Afruni et al. (2021) indicates that an initial kick velocity of \( \approx 370 \text{ km s}^{-1} \) would get as far as 40 kpc before returning back toward the galaxy. However, the kick velocity would imply that a much higher \( \Sigma_{SFR} \) of the order of \( 1 \text{ M}_\odot \text{ yr}^{-1} \text{kpc}^{-2} \) (Heckman & Borthakur 2016) is needed, i.e., essentially requiring a starburst in the galaxy. Therefore, it is unlikely that the blueshifted cloud seen as a QSO absorption feature is star formation–driven outflowing material.

It is worth noting that the velocity kinematics of the blueshifted cloud are consistent with HVCs seen in the Milky Way halo. They are predominantly tracing inflowing material (Fox et al. 2019) that has a significant fraction of metals. These include returning material, such as the Smith cloud and complex C in the Milky Way halo (Lockman et al. 2008; Fox et al. 2016; Fraternali et al. 2015). Therefore, it is likely that the blueshifted cloud could be infalling material that might have originated in the disk long back and is now returning gas from the CGM or the intergalactic medium that has undergone metal mixing. Similarly, kinematically anomalous clouds have been observed in nearby galaxies (Fraternali et al. 2001; Thilker et al. 2004; Westmeier et al. 2005; Heald 2015; Gim et al. 2021).

Additionally, the cloud might be tracing a faint but gradual inflow event. The atomic gas in NGC 3344 indicates no major merger signature in the gas dynamics; however, the entire outer disk covering an area of about 340 kpc\(^2\) from a radius of 6–12 kpc is undergoing a star formation event that is no more than 100 Myr old. This suggests that there must have been a global event that triggered star formation throughout the outer disk. We can eliminate major mergers as we do not see a companion nor do we see the atomic gas disk showing any strong dynamical perturbations. Interestingly, the cold gas mass of this galaxy is dominated by atomic gas (87\% of total gas mass), and the depletion time for HI is almost an order of magnitude larger than that of molecular gas. This may suggest that perhaps this is an accretion event that is smooth and gradual that does not disrupt the disk but builds the immense gas reservoir. In this picture, the fact that most of the metals in the QSO sightline probe the CGM at 30 kpc shows that a gas flow velocity of about 113 km s\(^{-1}\) would support gradual gas accretion.

### 6. Summary

In this paper, we study the star formation and its effect on the ISM and the inner CGM of the XUV disk galaxy NGC 3344. We investigate radial variations in stars, dust, and gas using surface photometry of FUV, \( \text{H}\alpha \), \( r \)-, \( g \)-band, 24 \( \mu \)m, and HI-21 cm emission. We identify 320 young stellar complexes in the disk of NGC 3344 with typical physical sizes between 150 pc and 1 kpc. Further, we study the relationship between star formation and the ISM properties for these stellar complexes using aperture photometry and investigate how these properties differ in the inner and outer disk. Our key results are summarized below:

1. We find that FUV emission shows scale length 1.4 times larger than those from \( g \), \( B \), \( r \), \( \text{H}\alpha \), and 24 \( \mu \)m. This indicates that young stars have extended distribution, while old stellar populations and dust are concentrated more toward the center. We identify a break at 6 kpc using the FUV and \( r \)-band surface brightness profiles, marking a transition from the inner optical disk to the outer XUV disk.

2. Comparing the non-dust-corrected (FUV, \( \text{H}\alpha \)) and dust-corrected (FUV+24 \( \mu \)m, \( \text{H}\alpha +24 \mu \)m) star formation tracers shows that both FUV and FUV+24 \( \mu \)m tracers are more sensitive indicators of star formation in the XUV disk, while dust-corrected tracers are more effective in the optical disk and on the global scale.

3. We also find that the SFRs traced by \( \text{H}\alpha \) are consistently lower than FUV SFRs, especially in the XUV disk. Investigation of the \( \text{H}\alpha +24 \mu \)m and FUV+24 \( \mu \)m SFRs for the identified stellar complexes shows that lower \( \text{H}\alpha \)-to-FUV ratios in the XUV disk are likely due to stochastic sampling of the IMF along with the effect of a steeper upper IMF and/or truncation.

4. We observe that sSFR increases from \( 1 \times 10^{-10} \text{ yr}^{-1} \) in the optical disk to \( 10^{-8} \text{ yr}^{-1} \) in the XUV disk, suggesting that the XUV disk is a “starburst”, actively forming stars with a slowly growing optical disk. This provides evidence for inside-out growth of the disk.

5. \( \Sigma_{SFR} \) of the stellar complexes show no correlation with \( \Sigma_{H\text{I}} \) in the disk. In the XUV disk, however, we find moderate correlation (Pearson \( r = 0.51 \)). This is a consequence of an ISM that is \( \text{H}_2 \)-dominated in the optical disk and \( \text{H}\text{I} \)-dominated in the XUV disk. The XUV disk points also show high \( \Sigma_{H\text{I}} \) and low \( \Sigma_{SFR} \) and mark the onset of a deviation from the traditional Kennicutt–Schmidt law.

6. The \( \text{H}\text{I} \) star formation efficiency decreases as a function of the galactocentric distance, and we find longer \( \text{H}_1 \) depletion times. This suggests that the \( \text{H}\text{I} \) reservoir, which has only recently started forming stars, will continue to do so for \( \sim 10 \) Gyr in the XUV disk and also feed the optical disk.

7. Correlation between \( \Sigma_{SFR} \) and \( \Sigma_{KE} \) shows that stellar feedback via supernovae explosions can maintain the observed \( \text{H}\text{I} \) velocity dispersion in the optical and XUV disks. MRI and additional mechanisms, such as spiral density waves, may be playing a subdominant role in the high \( \Sigma_{KE} \)-low \( \Sigma_{SFR} \) regime in the XUV disk to maintain the ISM turbulence.

8. We detect two absorbing systems in the QSO sightline probing the inner CGM at 30 kpc from the center. The CGM is metal-rich and has a low-ionization potential, as indicated by the presence of strong Si\text{II}, Si\text{III}, and C\text{II} and a relatively weak Si\text{IV} associated with the strong component. The weak component was seen in Ly\text{a} and Si\text{III} only.

9. The CGM shows a component (the weaker component) that is consistent with rotation. The stronger metal-line component shows a velocity offset of 113 km s\(^{-1}\), thus making it similar to high-velocity clouds in the Milky Way halo. While the velocity offset confirms gas flow, the cloud could either be inflowing or outflowing material. Based on the kinematics and the energies necessary to propel a gas cloud with the observed velocity out to 40 kpc, we conclude that it is unlikely that the cloud is tracing outflow. Instead, the observations are consistent with inflowing gas, which might perhaps be related to the triggers of star formation in the XUV disk.

XUV disks are unique laboratories to test our theories of star formation and feedback. Future deep optical and UV imaging of XUV disks will further our understanding of the formation of XUV disks and galaxy growth.
M.P., S.B., R.J., and D.T. are supported by NASA ADAP grant 80NSSC21K0643. S.B. and H.G. are also supported by NSF Award Number 2009409, and S.B., H.G., and T.H. are supported by HST grant HST-GO-14071 administrated by STScI, which is operated by AURA under contract NAS 5-26555 from NASA.

We thank the staff at the Space Telescope Science Institute, the National Radio Astronomy Observatory (NRAO) Array Operations center at Socorro, the Steward Observatory, and the Vatican Advanced Technology Telescope for their help and support on this project. We thank the referee for their constructive feedback. We thank the members of the ASU STARs lab (Jacqueline Monkiewicz, Lee Chiffelle, Chris Dupuis, Tyler McCabe, and Ed Buie II) for their extensive help and feedback during the course of this work. M.P., S.B., H.G., and R.J. acknowledge the land and the native people that Arizona State University’s campuses are located in the Salt River Valley. The ancestral territories of Indigenous peoples, including the Akimel O’odham (Pima) and Pee Posh (Maricopa) Indian Communities, whose care and keeping of these lands allows us to be here today.

GALEX is a NASA Small Explorer, launched in 2003 April. We gratefully acknowledge NASA’s support for the construction, operation, and science analysis of the GALEX mission, developed in cooperation with the Centre National d’Études Spatiales (CNES) of France and the Korean Ministry of Science and Technology.

This work is also partly based on observations with the VATT: the Alice P. Lennon Telescope and the Thomas J. Bannan Astrophysics Facility.

The National Radio Astronomy Observatory is a facility of the National Science Foundation operated under cooperative agreement by Associated Universities, Inc.

Based on observations made with the NASA/ESA Hubble Space Telescope, obtained from the data archive at the Space Telescope Science Institute. STScI is operated by the Association of Universities for Research in Astronomy, Inc. under NASA contract NAS 5-26555.

Funding for the SDSS and SDSS-II has been provided by the Alfred P. Sloan Foundation, the Participating Institutions, the National Science Foundation, the U.S. Department of Energy, the National Aeronautics and Space Administration, the Japanese Monbukagakusho, the Max Planck Society, and the Higher Education Funding Council for England. The SDSS website is http://www.sdss.org/.

This work is based [in part] on observations made with the Spitzer Space Telescope, which was operated by the Jet Propulsion Laboratory, California Institute of Technology under a contract with NASA.

The SDSS is managed by the Astrophysical Research Consortium for the Participating Institutions. The Participating Institutions are the American Museum of Natural History, Astrophysical Institute Potsdam, University of Basel, University of Cambridge, Case Western Reserve University, University of Chicago, Drexel University, Fermilab, the Institute for Advanced Study, the Japan Participation Group, Johns Hopkins University, the Joint Institute for Nuclear Astrophysics, the Kavli Institute for Particle Astrophysics and Cosmology, the Korean Scientist Group, the Chinese Academy of Sciences (LAMOST), Los Alamos National Laboratory, the Max-Planck-Institute for Astronomy (MPIA), the Max-Planck-Institute for Astrophysics (MPA), New Mexico State University, Ohio State University, University of Pittsburgh, University of Portsmouth, Princeton University, the United States Naval Observatory, and the University of Washington.

Facilities: GALEX, HST, Sloan, Spitzer, VATT, VLA.

Appendix

Effect of Spatial Resolution and Signal-to-noise Ratio on Relations of $\Sigma_{\text{H}1}$, $\sigma_{\text{los}}$, $\Sigma_{\text{KE}}$ with $\Sigma_{\text{SFR}}$

We investigated the influence of the resolution and signal-to-noise ratio of the various $\text{H}1$ maps on the relations observed in Section 5.3. We first study the effect of the signal-to-noise ratio on the ISM–$\Sigma_{\text{SFR}}$ relations. For this, we produced the $\Sigma_{\text{H}1}$, $\sigma_{\text{los}}$, and $\Sigma_{\text{KE}}$ maps above 2$\sigma$ and 4$\sigma$ using the method prescribed in Section 3.3. Pixels with extremely small values of velocity dispersion were masked in all maps. For the 4$\sigma$ maps, the number of pixels masked was the highest, which in turn reduced the number of regions with valid pixel values. Figures 15(a) and (c) show the ISM–$\Sigma_{\text{SFR}}$ relations for the 2$\sigma$ and 4$\sigma$ maps plotted along with 3$\sigma$ (Figure 15(b)) for comparison. We do not find much variation in the $\Sigma_{\text{H}1}$–$\Sigma_{\text{SFR}}$ distribution in the three plots except the regions with all pixels masked are missing in the 4$\sigma$ plot. The variations in the $\Sigma_{\text{KE}}$–$\Sigma_{\text{SFR}}$ plots are, hence, caused by the variations in the $\sigma_{\text{los}}$ values at different signal-to-noise ratio levels. At a higher signal-to-noise ratio cut, we get lower $\sigma_{\text{los}}$ values compared to the lower signal-to-noise ratio cuts as we lose out on the high velocity wing of the profile.

We also study the effect of resolution by using only D-configuration VLA data. We produced the $\Sigma_{\text{H}1}$, $\sigma_{\text{los}}$, and $\Sigma_{\text{KE}}$ maps above 3$\sigma$ at a resolution of 59$''$ × 41$''$. The typical size of the star-forming regions are 6$''$–40$''$ (150 pc–1 kpc); hence, these maps represent semi-local average ISM properties around the star-forming regions. Figure 16 shows the $\sigma_{\text{los}}$ versus $\Sigma_{\text{SFR}}$ and $\Sigma_{\text{KE}}$ versus $\Sigma_{\text{SFR}}$ relations for these maps. We find that the gas is kinematically spread out (8–25 km s$^{-1}$). In Figure 14, we find that, in the optical disk, both $\sigma_{\text{los}}$ and $\Sigma_{\text{KE}}$ show moderate correlation with $\Sigma_{\text{SFR}}$ with Pearson $r$ values of 0.59 and 0.65, respectively. The correlations are weak in the XUV disk with Pearson $r$ values of 0.23 and 0.34, respectively. Figure 16(c) also shows that mechanisms other than SN feedback are likely dominant in the XUV disk in contributing to the turbulence of the ISM, with MRI playing no role. These results are likely not representing a real scenario as feedback acts on scales much smaller than 0.5 kpc (Combes et al. 2012). The observations are probably caused by the $\Sigma_{\text{KE}}$ values now representing semi-local averages around the FUV clumps at that resolution.
Figure 15. Correlations of $\Sigma_{\text{SFR}}$ with $\Sigma_{\text{HI}}$ (top panel), $\sigma_{\text{los}}$ (middle panel), and $\Sigma_{\text{KE}}$ (bottom panel) above (a) $2\sigma$, (b) $3\sigma$, and (c) $4\sigma$. The red triangles and blue circles are regions in the optical and the XUV disks, respectively. Regions with areas smaller than the HI beam are shown in different transparency in the $\Sigma_{\text{SFR}}$–$\sigma_{\text{los}}$ and $\Sigma_{\text{SFR}}$–$\Sigma_{\text{KE}}$ plots. The green (dashed) line in the top panel shows the Kennicutt–Schmidt law for an index of 1.4 (Kennicutt 1998b). Models of SN energy input with different efficiency values ($\epsilon_{\text{SN}} = 1, 0.5, 0.2, 0.1, 0.05$) and MRI input at maximum efficiency ($\epsilon_{\text{MRI}} = 1$) from Tamburro et al. (2009) are shown in purple and orange lines, respectively, in the bottom panel.
Figure 16. Correlations between $\Sigma_{\text{SFR}}$ and (a) $\Sigma_{\text{HI}}$, (b) $\sigma_{\text{disp}}$, and (c) $\Sigma_{\text{KE}}$ from the VLA D-configuration data. The red triangles and blue circles are regions in the optical and the XUV disks, respectively, with red (solid) and blue (dotted) lines representing the lines of best fit to the corresponding points. The green (dashed) line in the top panel shows the Kennicutt–Schmidt law for index of 1.4 (Kennicutt 1998b). Models of SN energy input with different efficiency values ($e_{\text{SN}} = 1, 0.5, 0.2, 0.1, 0.05$) and MRI input at maximum efficiency ($e_{\text{MRI}} = 1$) from Tamburo et al. (2009) are shown in purple and orange lines, respectively.
