ABSTRACT: Aggressive fibromatosis is best defined as a group of non-encapsulated, non-metastasizing fibrous tumors that have tendency for local recurrence. This benign tumor is histologically characterized by fibroblastic proliferation and clinically by the potential to infiltrate and to recur after surgical excision, but does not metastasize. Its occurrence in the head and neck region is not common and very sporadically it may occur in the oral cavity or jaw bones. Its occurrence in the maxilla is even more exceptional. The clinical, radiographic and histological findings of a rare case of aggressive fibromatosis of the maxilla in a six-year-old female patient are presented here. The patients underwent surgical resection with wide surgical margins; excised material was analyzed microscopically and a diagnosis of fibromatosis was rendered.

KEYWORDS: Fibromatosis. Aggressive, Juvenile.

KEYMESSAGES: Aggressive Fibromatosis a rare tumor of Head & Neck region which posses with a diagnostic dilemma at times due to its close histological similarity with fibro sarcoma. High index of suspicion is necessary for early diagnosis of such case.

INTRODUCTION: Aggressive fibromatosis is a non-metastasizing tumor-like fibroblastic growth of unknown pathogenesis involving voluntary muscle as well as aponeurotic and facial structures. The lesion has a strong tendency for local recurrence and aggressive infiltrating growth. It is most common in the shoulder girdle, the thigh and gluteal region of growing adults.¹

Occurrence of fibromatosis in the head and neck region is not common (5-10%) and only sporadically does it occur in the oral cavity or maxillary bones. Head-and-neck aggressive fibromatosis usually occurs in children under 20 years of age.² It is more prevalent in adult females. Clinically, in the oral cavity it usually presents as a painless mass or swelling in the region involved. It may attain a large size and cause compression, infiltration, and destruction of adjacent structures. Such growth behavior presents severe management problems, especially in the head and neck region, making complete excision of the tumor difficult.

The treatment of aggressive fibromatosis is traditionally surgical resection with an area of tumor free tissue. But when the complete surgical excision is not possible, radiation and chemotherapy also can be used.

Macroscopically, fibromatosis traditionally appears as an ill-defined and firm greyish-white mass. Histologically, it is composed of well-differentiated fibroblasts, fibrocytes and myofibroblasts within a collagenous to myxoid stroma. No atypical mitosis or anaplastic elements are seen.

Here, we report such a rare case of fibromatosis of the maxilla. The patient was treated with wide surgical resection with adequate surgical margins; excised material was analyzed microscopically and a diagnosis of aggressive fibromatosis was confirmed.
**CASE REPORT**

**Case History:** A 6 years old female patient of a remote tribal hamlet of Tripura reported to Department of Otorhinolaryngology with huge swelling of right cheek. The swelling was painless and progressive in nature. With in six months it assumed the size of big Pomelo [Fig-1]. Besides huge disfigurement of right face child also complained of complete bilateral nasal obstruction, lacrimation from same side with double vision and difficulty in eating foods. There was no past history of trauma. On examination swelling was about 20 cm in longest diameter and bony hard in consistency. Skin overlying the swelling was free but overstressed. Expansion of hard palate was noticed with irregular dentition of upper jaw.

Hard palate was yielding in nature and bulging in to the oral cavity. Due to extensive expansion of the tumor into maxillary sinus and ipsilateral nasal cavity the child lost her nasal patency completely. Expansion into lateral wall of maxilla and zygomatic bone resulted with disfigurement of right eye. However, no lymph node insolvent was observed.

**Radiological Finding:** Occipitomental view of X-ray PNS showed homogenous opacity of almost whole of right side of face. C T scan revealed huge expansile lesion measuring approximately 20 cm in diameter with foci of mineralization involving the right maxilla with destruction of alveolar arch of right maxilla and anterolateral wall with compression of Nasal cavity, nasopharynx, adjacent Para nasal sinuses and right orbital cavity [Fig-2].

Results of aspiration cytology on two occasions were inconclusive. Therefore, excision biopsy was planned.

**Treatment – Excision:** Tumour was excised under general anesthesia with adequate safety margins with prior elective tracheotomy [Fig-3]. Large surgical defect was repaired with remodelling of residual bony parts and overlying skin. Post-operative period was uneventful except some flap necrosis at nasolabial area which was corrected with second stage forehead rotational flap. All tissue obtained during primary surgery were submitted for histopathological study Microscopic examination revealed a feature of connective tissue proliferation, predominantly of fibroblastic cells in a background of moderate amount of collagen tissue. The cells were large, oval and fibroblastic in nature but pleomorphism was abundant. The blood vessels seemed to be constricted due to the high proliferative nature of the cells around [Fig-4]. Thus, final diagnosis of aggressive fibromatosis was made. The patient was put on regular follow up; no sign of recurrence noted so far [Fig-5].

**DISCUSSION:** Aggressive fibromatosis is a histologically benign yet clinically invasive lesion that involves the jaws. The hallmark of this neoplasm is its high incidence of recurrence (up to 63%). Patients with aggressive fibromatosis often present with a deep, firm mass with or without pain. Mandible is more frequently involved than the maxilla. Females are more commonly affected than males.

The histopathologic differentiation between aggressive fibromatosis and other closely related spindle cell lesions like fibrosarcoma, neurofibroma, nodular fascitis, fibrous histiocytoma and infantile myofibromatosis is a challenge to the pathologist as it requires expertise to differentiate the finer details. Fibromatosis has a more uniform growth pattern, more mature cells and a paucity of mitosis compared with fibrosarcoma. Findings of pre-operative aspiration cytology of the tumour on two occasions were different, hence non conclusive.
The final diagnosis of aggressive fibromatosis was based on a number of factors which included spindle shaped monotonous population of fibroblasts arranged in a whorl like and fasciculated pattern and the presence of collagen.\(^8\)

The treatment of aggressive fibromatosis is traditionally surgical resection with an area of tumor free tissue.\(^6\) Radiation therapy has been used alone when resection might lead to serious morbidity and loss of function and when tumor is inoperable or there is gross residual disease after operative debulking.\(^5\) Chemotherapy alone does not appear to be curative, but it may be effective in controlling unresectable tumors, or in reducing tumor size before surgery. Chemotherapy in combination with enblock resection has also been effective in managing recurrent disease.\(^7\)

The treatment of aggressive fibromatosis is traditionally surgical resection with an area of tumor free tissue. But when the complete surgical excision is not possible, radiation and chemotherapy also can be used.\(^9\)

The prognosis depends entirely upon the initial treatment; if this is inadequate, the tumor will recur one or more times and progress.\(^10\) In this particular case tumour was adequately excised and no sign of recurrence is noted at one year follow-up.

**CONCLUSION:** Aggressive Fibromatosis a rare tumour of Head & Neck region which posses with a diagnostic dilemma at times due to its close histological similarity with fibro sarcoma. Accurate diagnosis is imperative for consideration of appropriate management. Such a rare case is reported here with an unusual presentation.
