Abstract: Estimation of a single Bernoulli parameter using pooled sampling is among the oldest problems in the group testing literature. To carry out such estimation, an array of efficient estimators have been introduced covering a wide range of situations routinely encountered in applications. More recently, there has been growing interest in using group testing to simultaneously estimate the joint probabilities of two correlated traits using a multinomial model. Unfortunately, basic estimation results, such as the maximum likelihood estimator (MLE), have not been adequately addressed in the literature for such cases. In this paper, we show that finding the MLE for this problem is equivalent to maximizing a multinomial likelihood with a restricted parameter space. A solution using the EM algorithm is presented which is guaranteed to converge to the global maximizer, even on the boundary of the parameter space. Two additional closed form estimators are presented with the goal of minimizing the bias and/or mean square error. The methods are illustrated by considering an application to the joint estimation of transmission prevalence for two strains of the Potato virus Y by the aphid Myzus persicae.

Keywords and phrases: EM algorithm, group testing, multinomial sampling, restricted parameter space.

Received July 2018.

1. Introduction

Estimation of some trait in a population when the (unknown) prevalence is rare and/or only a limited number of tests can be performed is a difficult statistical problem. One approach in such cases is group testing, in which individuals are screened in pools as opposed to individually. Depending on the underlying prevalence and group size, such methods have been shown to yield large gains in efficiency (as measured by mean square error (MSE)) and, often, a reduction in the total number of tests required [see, for example, 30, 27]. Applications can be found in a wide range of areas, although uses in plant and animal sciences are especially common.
The standard group testing problem, in which the goal is estimation of a single trait, has been well studied, yielding an array of efficient estimators [see, as a few examples, 2, 28, 11, 26, 10]. More recently, however, there has been interest in the use of pooled sampling for the simultaneous estimation of two or more traits [see, for example, 12, 25, 3, 29, 32, 16, 14]. This interest has been spurred by the growing availability of multiplex assays in many areas of science designed for screening multiple diseases simultaneously. The benefits of such assays are clear, allowing for reductions in the number of tests needed for gathering data on two or more traits, as well as providing information on the joint distribution of the characteristics under study. This has led to the need to develop new statistical methods to handle data generated from such tools and to efficiently extract information on the underlying multivariate distribution. Furthermore, new methods for designing pooling studies utilizing multiplex assays which take the correlations among diseases into account have been needed as well. While research in these areas has been ongoing, unfortunately, even in the case of two-diseases, results for small sample estimation do not exist, and basic tools such as maximum likelihood estimation have not been adequately addressed.

Conceptually, finding the maximum likelihood estimator (MLE) for the two-trait group testing problem can be expressed as a special case of maximizing a multinomial likelihood with a constrained parameter space (details are provided in the following section). Due to the restrictions on the parameter space, closed form techniques, such as those based on the invariance property of the MLE, do not work in this case [a recent work, 16, did report a closed form MLE based on this principle, but it can easily be checked that it yields estimates outside the parameter space]. While numerical methods are possible, the restriction means that many estimates will fall on the boundary of the parameter space, and it is difficult to ensure convergence to a global maximum in such cases.

Maximization under constrained parameter spaces is a well studied problem for a variety of statistical models [see, for example, 24, 15]. Numerical methods specifically for the multinomial model under a range of convex constraints have been developed as well [see 7, and the references therein].

While these previous methods can be adapted to the group testing problem, our goal here is to provide a much simpler solution for this special case which is guaranteed to yield a global maximizer. We show that, when optimizing over the boundary, the problem is equivalent to a convex optimization problem in one fewer dimension. The maximization can then be carried out using a variety of methods, and we develop here an EM algorithm-based approach. The resulting estimator is shown to converge to the unique global maximizer.

Two additional closed form estimators are presented as well. One, based on the method of moments, is shown to approximate the MLE very closely. The second, a shrinkage estimator based on the one-trait group testing estimator presented in Burrows [2], is developed with the intention of reducing the MSE and/or bias of the MLE.

Numerical comparisons in terms of relative bias and MSE are presented which cover a wide range of applicable situations. The methods are further illustrated by considering two experiments where the transmission rates for prevalences of
different strains of Potato virus Y are to be estimated simultaneously.

2. Statistical model

Let \( \varphi_1 \) and \( \varphi_2 \) be marginally Bernoulli random variables with parameters \( 0 < p_1 < 1 \) and \( 0 < p_2 < 1 \), respectively, each indicating the presence of a given trait. Then, \((\varphi_1, \varphi_2)\) has a one-to-one correspondence to the vector \( \varphi = (\varphi_{10}, \varphi_{01}, \varphi_{11}) \) with joint multinomial distribution \( \varphi \sim MN_3(1,p) \) and parameter space \( \Psi_p = \{ p : 1p < 1, 0 < p < 1 \} \), where \( 1 = (1,1,1)' \), \( p = (p_{10}, p_{01}, p_{11})' \) and \( p_00 = 1 - 1p = 1 - p_{10} - p_{01} - p_{11} \) and \( \prec \) denotes element-wise inequality. Note that the marginal parameters can be expressed as \( p_1 = p_{10} + p_{11} \) and \( p_2 = p_{01} + p_{11} \).

Throughout this work, our primary interest is estimation of the parameter \( p \).

The \( i^{th} \) pooled sample comprised of \( k \) individual units can then be represented by the random variable \( x_i = (\varphi_1^i, \varphi_2^i) = (\max\{\varphi_{11}, \cdots, \varphi_{1k}\}, \max\{\varphi_{21}, \cdots, \varphi_{2k}\}) \) which corresponds to

\[
\theta^i = (\varphi_{10}^i, \varphi_{01}^i, \varphi_{11}^i)' \sim MN_3(1, \theta),
\]

where

\[
\theta' = (\theta_{10}, \theta_{01}, \theta_{11}) = ((p_{00} + p_{10})^k - p_{00}^k, (p_{00} + p_{01})^k - p_{00}^k, 1 - (p_{00} + p_{10})^k - (p_{00} + p_{01})^k + p_{00}^k) \tag{1}
\]

and

\[
\theta_{00} = 1 - 1\theta = p_{00}^k. \tag{2}
\]

If we sample \( n \) such groups, we have the random variable \( \mathbf{x} = (x_{10}, x_{01}, x_{11})' = \sum_{i=1}^n \theta^i \sim MN_3(n, \theta) \) with parameter space \( \Psi_p = \{ \theta(p) : 1p < 1, 0 < p < 1 \} \). For later use, we define \( x_{00} = n - (x_{10} + x_{01} + x_{11}) \).

It should be noted that \( \Psi_p \) is a proper subset of the full parameter space \( \Psi_{p_0} = \{ \theta : 1\theta < 1, 0 < \theta < 1 \} \). For example, with \( k = 2 \), \( \theta = (0.45, 0.45, 0.05)' \) \( \in \Psi_{p_0} \) is achieved if and only if \( p = (0.484, 0.484, -0.192)' \notin \Psi_p \). As such, maximizing the likelihood with respect to \( p \in \Psi_p \) is equivalent to the problem of maximizing a standard multinomial likelihood with respect to \( \theta \) such that the estimate lies in the restricted parameter space \( \Psi_p \).

For use in later results, we define the closure \( \overline{\Psi}_p = \Psi_p \cup \partial \Psi_p \) where \( \partial \Psi_p \) is the boundary of the parameter space. Likewise, let \( \mathcal{X} = \{ x : 0 \preceq x \preceq n \} \), where \( \preceq \) denotes element-wise non-strict inequality, be the sample space of \( \mathbf{x} \) with interior \( \mathcal{X}_0 = \{ x : 0 < x < n \} \).

3. Maximum likelihood estimation

We seek to maximize the log-likelihood

\[
\ell(\theta|\mathbf{x}) \propto x_{00} \log(\theta_{00}) + x_{10} \log(\theta_{10}) + x_{01} \log(\theta_{01}) + x_{11} \log(\theta_{11}), \tag{3}
\]
such that $\theta \in \Psi_p$.

The following lemma, the proof of which is given, together with all subsequent proofs, in Appendix B, establishes the concavity of the log-likelihood function.

**Lemma 1.**

(a) For $x \in X_0$, the log-likelihood given in (3) is strictly concave for all $p \in \Psi_\theta$.

(b) For all $x \in X$, the log-likelihood given in (3) is concave (not necessarily strict) for all $p \in \Psi_\theta$.

Using standard multinomial theory, we know that, when maximizing over $\Psi_\theta$, the unique MLE is given by $\hat{p}_{MLE} = \bar{x} = \frac{x}{n}$ for $x \in X_0$, and this point is the unique maximizer of the likelihood for all $x \in X$ over the closure of $\Psi_\theta$. To find the MLE under the restricted parameter space, $\Psi_p$, we first note that there exists a one-to-one mapping $\theta \mapsto p$ as given in the following lemma. The proof of this lemma is found by inverting (1) and (2).

**Lemma 2.** The unique function $h : \theta \mapsto p$ is given by

- $p_{00} = h_{00}(\theta) = (1 - \theta_{10} - \theta_{01} - \theta_{11})^{1/k}$,
- $p_{10} = h_{10}(\theta) = (1 - \theta_{01} - \theta_{11})^{1/k} - h_{00}(\theta)$,
- $p_{01} = h_{01}(\theta) = (1 - \theta_{10} - \theta_{11})^{1/k} - h_{00}(\theta)$,
- $p_{11} = h_{11}(\theta) = 1 - p_{00} - p_{10} - p_{01}$.

If we define the set

$$R_n = \left\{ x : \left(\frac{x_{00} + x_{10}}{n}\right)^{1/k} + \left(\frac{x_{00} + x_{01}}{n}\right)^{1/k} - \left(\frac{x_{00}}{n}\right)^{1/k} < 1 \right\}$$

then, for any $x \in X_0 \cap R_n$, $h(x) \in \Psi_p$, where $h$ is as in Lemma 2, so that such values provide the unique MLE for $p$ by the invariance property of the MLE. Since the log-likelihood is a concave function on $\Psi_\theta$, it is clear that the maximizer for all $x \not\in R_n$ must lie in $\partial \Psi_p$. This leads to the following result.

**Theorem 1 (Existence and uniqueness of MLE).**

(a) A necessary and sufficient condition for the maximum likelihood estimator of $p \in \Psi_p$ to exist and be unique is that $x \in X_0 \cap R_n$. In this case, the MLE is given by

$$\hat{p}^{MLE} = (\hat{p}_{00}^{MLE}, \hat{p}_{01}^{MLE}, \hat{p}_{11}^{MLE}),$$

where

$$\hat{p}_{00}^{MLE} = \left(\frac{x_{00}}{n}\right)^{1/k},$$
$$\hat{p}_{10}^{MLE} = \left(\frac{x_{00} + x_{10}}{n}\right)^{1/k} - \left(\frac{x_{00}}{n}\right)^{1/k},$$
$$\hat{p}_{01}^{MLE} = \left(\frac{x_{00} + x_{01}}{n}\right)^{1/k} - \left(\frac{x_{00}}{n}\right)^{1/k},$$
$$\hat{p}_{11}^{MLE} = 1 - \hat{p}_{00}^{MLE} - \hat{p}_{10}^{MLE} - \hat{p}_{01}^{MLE}.$$
\[ \hat{p}_{01}^{\text{MLE}} = \left( \frac{x_{00} + x_{01}}{n} \right)^{1/k} - \left( \frac{x_{00}}{n} \right)^{1/k}, \]

and

\[ \hat{p}_{11}^{\text{MLE}} = 1 - \hat{p}_{00}^{\text{MLE}} - \hat{p}_{10}^{\text{MLE}} - \hat{p}_{01}^{\text{MLE}}. \]

(b) As \( n \to \infty \), \( P(x \in \mathcal{X}_0 \cap R_n) = 1 \) so that the MLE as given in (4) exists and is unique with probability one.

### 3.1. Maximization over the boundary

While the above result is complete for large samples, in many cases \( n \) will necessarily be small and we will be interested in maximizing over the closure \( \overline{\Psi}_p \). From here on, \( \hat{p}^{\text{MLE}} \) will refer to the maximizer over this extended space. Defining

\[ \overline{R}_n = \left\{ x : \left( \frac{x_{00} + x_{10}}{n} \right) \left( \frac{x_{00} + x_{01}}{n} \right) \left( \frac{x_{00}}{n} \right)^{1/k} \leq 1 \right\}, \]

the invariance property of the MLE and Lemma 2 are sufficient to establish \( \hat{p}^{\text{MLE}} = h(\overline{x}) \) for all \( x \in \overline{R}_n \).

To get an idea of how common boundary estimates can be, Table 1 provides values of \( P(x \notin \overline{R}_n) \) for a wide range of \( n \) with several realistic values of \( p \) and \( k \). Note that, when \( n = 1 \), this probability is theoretically 0 for all values of \( k \) and \( p \).

From the table, we see that, when \( p_{00} \) is large this probability can be quite substantial, even for large values of \( n \) and small \( k \). While this effect seems to lessen as the probability of at least one positive trait increases, group testing is most commonly used in the context of rare traits. It is apparent, then, that the problem of boundary estimates will be present in many applications.

Unfortunately, despite the concavity of the log-likelihood, the maximum on the boundary will not occur at a stationary point. Furthermore, the problem as previously expressed is not guaranteed to have a unique maximizer over the boundary. As such, maximizing the likelihood over \( \partial \Psi_p \) is a non-trivial optimization problem.

To proceed, the following theorem allows us to reduce the dimension of the parameter space by one, facilitating the use of convex theory results to find the maximizer.

**Theorem 2.** For all \( x \notin \overline{R}_n \) the log-likelihood given in (3) over \( \Psi_p \) is maximized at a point such that \( \hat{p}_{11} = 0 \). If \( x \in \mathcal{X}_0 \) or \( x_{11} = 0 \) is the only zero, then the log-likelihood is uniquely maximized at a point with \( \hat{p}_{11} = 0 \).

As a result of Theorem 2, for values \( x \notin \overline{R}_n \) the objective function given in (3) can be expressed in terms of the simpler two-parameter model in which we

seek to maximize

$$
\ell^*(p^*|x) \propto x_{00} \log((1 - p_{10} - p_{01})^k) + x_{10} \log((1 - p_{01})^k - (1 - p_{10} - p_{01})^k) \\
+ x_{01} \log((1 - p_{10})^k - (1 - p_{10} - p_{01})^k) \\
+ x_{11} \log(1 - (1 - p_{01})^k - (1 - p_{10})^k + (1 - p_{10} - p_{01})^k) 
$$

over the set $\Psi_{p^*} = \{p^*: 1p^* < 1, 0 < p^* < 1\}$ where $p^* = (p_{10}, p_{01})'$.

The following lemma addresses the concavity of this likelihood function.

**Lemma 3.**

(a) For $x \in \mathcal{X}_0 \cap \overline{\mathcal{P}}_n$, the log-likelihood given in (5) is strictly concave for all $(p^*, 0) \in \Psi_{\theta}$.

(b) For all $x \in \mathcal{X} \cap \overline{\mathcal{P}}_n$, the log-likelihood given in (5) is concave (not necessarily strict) for all $(p^*, 0) \in \Psi_{\theta}$. 
As a result of Lemma 3 we establish that, for any $x / \in \mathcal{R}_n$, maximization of (5) over $\Psi_{\hat{p}}$ can be carried out in a number of ways with the resulting estimate, combined with $\hat{p}_{11} = 0$, yielding a global maximum of (3) which is the desired MLE. In the following section, we develop an EM algorithm-based approach to solving this simplified optimization problem.

3.2. EM algorithm

In this section we derive an EM algorithm-based estimator assuming values $x / \in \mathcal{R}_n$, for which we know the maximizing value takes $p_{11} = 0$. For the complete data, we use the true underlying status of each individual in the study.

**Result 1.** Beginning with an initial value $p^{(0)}$, the estimate from the $t^{th}$ iteration, $t = 1, 2, 3, \ldots$, of the EM algorithm is given by

$$p^{(t)}_{10} = \frac{(p^{(t-1)}_{00} + p^{(t-1)}_{11})k_{10} - p^{(t-1)}_{10}}{n} + \frac{[1 - (p^{(t-1)}_{00} + p^{(t-1)}_{11})k_{10} - p^{(t-1)}_{10}]}{n}$$  

$$p^{(t)}_{01} = \frac{(p^{(t-1)}_{00} + p^{(t-1)}_{11})k_{01} - p^{(t-1)}_{01}}{n} + \frac{[1 - (p^{(t-1)}_{00} + p^{(t-1)}_{11})k_{01} - p^{(t-1)}_{01}]}{n}$$  

$$p^{(t)}_{00} = 1 - p^{(t)}_{10} - p^{(t)}_{01}$$  

3.3. Global maximum over the closure

The previous results can be combined to yield an estimator which gives a global maximizer of the likelihood over the closure, $\Psi_{\hat{p}}$. The steps for finding this estimator are given in Algorithm 1.

**Algorithm 1 Global Maximizer**

1: if $x \in \mathcal{R}_n$ then
2: take $\hat{p}^{MLE} = h(\bar{x})$, where $h(\cdot)$ is as in Lemma 2.
3: else
4: beginning with an initial value $p^{*(0)}$, iterate $p^{*(t)}$, $t = 1, 2, 3, \ldots$ as in (6) - (8) until convergence of $\ell$ (call the value at convergence $p^{*(\infty)}$);
5: take $\hat{p}^{MLE} = (p^{*(\infty)}, 0)$.

*In this article, we use a likelihood based convergence criteria (e.g., stop when $|\ell(p^{*(t+1)}|x) - \ell(p^{*(t)}|x)| < \epsilon$ for some $\epsilon > 0$), but other criteria may be used as well.*

For $x \in \mathcal{R}_n$, this estimator yields the unique global maximizer of the likelihood based on the invariance property of the MLE and standard multinomial theory.

For other values in the sample space, using the results in Wu [33], the EM sequence of estimates will be guaranteed to converge to the global maximizer,
Table 2
Comparison of estimates and log-likelihood values for the EM algorithm-based estimator with Nelder Mead optimization for ten randomly generated starting values.

provided the sequence of estimates lies in the interior of the parameter space. In our numerical work, there was not a single case where the final estimate lay on the boundary of the space. To see why this is true, inspection of $\mathcal{R}_n^c$ shows that $x$ is in this set only if $x_{10}$ and $x_{01}$ are both non-zero. This is sufficient to guarantee the likelihood is maximized at a point with $p_{10}$ and $p_{01}$ both positive (otherwise the value of $\ell$ will be $-\infty$). If $x_{00} > 0$, the same theoretical guarantee can be made for $p_{00}$, so that the maximum must lie in the interior and the EM algorithm will always converge to this point. If $x_{00} = 0$, it is more difficult to show theoretically that $p_{00} > 0$ at the maximum, but our numerical work shows that, even in this case, the maximum will tend to occur at very large values of $p_{00}$ (for example, with $n = 250$, $k = 10$, and $x = (100, 100, 50)'$, we have $\hat{p}_{00}^{MLE} = 0.82$).

To demonstrate the global convergence property of this estimator, Table 2 gives estimates and log-likelihood values for the EM algorithm approach compared with numerical optimization on the full likelihood using the Nelder Mead algorithm [23]. This was done for the fixed values $k = 10$, $n = 35$, $x = (25, 5, 2)' \notin \mathcal{R}_n$, and ten starting values randomly generated on the probability simplex. We see that, for many of the starting values, both algorithms yield identical values, but that the EM algorithm-based estimator is extremely consistent across all initial points. For the Nelder Mead algorithm, however, there is variation, with some final estimates far from the true maximizer. While in some cases it may be possible to make a more informed decision about the starting value, the ability to bypass this step all together, while still guaranteeing convergence to the global maximum, is a strong advantage of the EM algorithm-based estimator presented here.

4. Alternative estimators

In this section we propose two closed form estimators which are alternatives to the MLE given in the previous section which requires numerical optimization.
4.1. Restricted method of moments estimator

The first estimator, which is a method of moments type estimator, is motivated by the result in Theorem 2, and simply truncates the value of $p_{11}$ to 0 for values $\mathbf{x} \notin \overline{\mathcal{R}_n}$. This estimator has several advantages, most notably that it has a simple closed form and, as we will show empirically, slightly outperforms the MLE in terms of both bias and MSE in most cases.

**Definition 1** (Restricted method of moments estimator). Let $\hat{\mathbf{p}}^{RMM} = (\hat{p}_{10}^{RMM}, \hat{p}_{01}^{RMM}, \hat{p}_{11}^{RMM})$, where

$$
\begin{align*}
\hat{p}_{11}^{RMM} & = \max \left\{0, 1 - \left(\frac{x_{00} + x_{10}}{n}\right)^{1/k} \right. - \left. \left(\frac{x_{00} + x_{01}}{n}\right)^{1/k} + \left(\frac{x_{00}}{n}\right)^{1/k} \right\}, \\
\hat{p}_{10}^{RMM} & = 1 - \left(\frac{x_{00} + x_{01}}{n}\right)^{1/k} - \hat{p}_{11}^{RMM}, \\
\hat{p}_{01}^{RMM} & = 1 - \left(\frac{x_{00} + x_{10}}{n}\right)^{1/k} - \hat{p}_{11}^{RMM}, \\
\hat{p}_{00}^{RMM} & = 1 - \hat{p}_{10}^{RMM} - \hat{p}_{01}^{RMM} - \hat{p}_{11}^{RMM}.
\end{align*}
$$

It is not hard to see that $\hat{\mathbf{p}}^{RMM} \in \overline{\Psi}_p$ for all $\mathbf{x}$ and that $\hat{\mathbf{p}}^{RMM} = \hat{\mathbf{p}}^{MLE} \in \overline{\Psi}_p$ for all $\mathbf{x} \in \overline{\mathcal{R}_n}$. Further properties showing the relation between the RMM estimator and the MLE are given in Section 4.3.

4.2. Burrows type estimator

One of the main advantages of a closed form estimator as above is the ability to provide simple bias corrections. The problem of bias for the MLE can be generalized from the single-trait group testing case, where this issue is a major focus of the literature. A proof that no unbiased estimator exists for the single-trait group testing problem under a fixed sampling model is given in [10], and this can be extended directly to the two-trait model considered in this paper. The issue of bias for the two-trait case is discussed further in [9], where it is shown that any unbiased estimator found under an alternative sampling plan necessarily yields values outside the parameter space.

In the one-trait case, Burrows’ estimator [2] has been shown repeatedly to improve on the MLE in terms of both bias and MSE [see, for example, 11, 4]. The motivation is to find a shrinkage estimator of the form $(1 - \alpha \bar{z})^{1/k}$ where $\alpha$ is optimal in the sense of removing bias of $O(1/n)$ from the estimator. Burrows [2] showed that this is accomplished by taking $\alpha = \frac{n}{n + \eta}$ where $\eta = \frac{k-1}{2k}$.

In the two disease case, it can be shown that, when the MLE exists in $\overline{\Psi}_p$, applying the identical shrinkage coefficient to each term in the estimator yields the same overall bias reduction. This is true since, for $\mathbf{x} \in \overline{\mathcal{R}_n}$, each term of the MLE as given in Theorem 1 is marginally binomially distributed, so that
the problem is identical to that in Burrows’ original work. In cases where the MLE does not exist in \( \Psi_p \), we can apply the same correction to the terms of the estimator \( \hat{p}_{RMM} \) to get a similar approximate result on the non-truncated terms.

**Definition 2** (Burrows type estimator). Let \( \hat{p}_B = (\hat{p}^B_{10}, \hat{p}^B_{01}, \hat{p}^B_{11}) \), where

\[
\hat{p}^B_{11} = \begin{cases} 
1 - \left( \frac{x_{00} + x_{10} + \eta}{n + \eta} \right)^{1/k} - \left( \frac{x_{00} + x_{01} + \eta}{n + \eta} \right)^{1/k} + \left( \frac{x_{00} + \eta}{n + \eta} \right)^{1/k}, & x \in \mathcal{R}_n \\
0, & \text{otherwise,}
\end{cases}
\]

\[
\hat{p}^B_{10} = 1 - \left( \frac{x_{00} + x_{01} + \eta}{n + \eta} \right)^{1/k} - \hat{p}^B_{11},
\]

\[
\hat{p}^B_{01} = 1 - \left( \frac{x_{00} + x_{10} + \eta}{n + \eta} \right)^{1/k} - \hat{p}^B_{11},
\]

\[
\hat{p}^B_{00} = 1 - \hat{p}^B_{10} - \hat{p}^B_{01} - \hat{p}^B_{11},
\]

with \( \eta = \frac{k - 1}{2k} \).

### 4.3. Theoretical comparisons of estimators

In this section we provide some of the theoretical properties of the three estimators introduced above in terms of their large sample properties.

**Theorem 3.**

(a) \( \hat{p}_{RMM} \sim \hat{p}_{MLE} \);  

(b) \( \sqrt{n}(\hat{p}^j - p) \overset{d}{\rightarrow} N(0, \frac{1}{k} \Sigma) \) for \( j \in \{MLE, RMM, B\} \) where the elements of \( \Sigma \) are given in Appendix A.

Importantly, this theorem shows that each of the three estimators shares the same asymptotic distribution. The following result gives the first order expectations for each of the three estimators.

**Theorem 4.**

(a) 
\[
E(\hat{p}_{10}^{MLE}) = E(\hat{p}_{10}^{RMM}) = p_{10} + \frac{k - 1}{2k^2n} \left( p_{10} + \frac{1}{p_{00}} - \frac{1}{(p_{00} + p_{10})^{k-1}} \right) + O(n^{-2})
\]

\[
E(\hat{p}_{01}^{MLE}) = E(\hat{p}_{01}^{RMM}) = p_{01} + \frac{k - 1}{2k^2n} \left( p_{01} + \frac{1}{p_{00}} - \frac{1}{(p_{00} + p_{01})^{k-1}} \right) + O(n^{-2})
\]

\[
E(\hat{p}_{11}^{MLE}) = E(\hat{p}_{11}^{RMM}) = p_{11} + \frac{k - 1}{2k^2n} \left( p_{11} + \frac{1}{(p_{00} + p_{10})^{k-1}} - \frac{1}{p_{00}^{k-1}} + 1 \right) + O(n^{-2})
\]
\[ (b) \]

\[
\begin{align*}
E(p_{10}^B) &= p_{10} + O(n^{-2}) \\
E(p_{01}^B) &= p_{01} + O(n^{-2}) \\
E(p_{11}^B) &= p_{11} + O(n^{-2})
\end{align*}
\]

5. Numerical comparisons

In this section we provide numerical comparisons for each of the three estimators introduced here in terms of relative bias and MSE. For the \( i \)th component of \( p \) and an estimator \( \hat{p} \), the relative bias is defined to be \( 100 \times \frac{E(\hat{p}_i - p_i)}{p_i} \). Results are provided for four values of \( p \), covering a range of realistic scenarios from very small \( (p = (0.001, 0.001, 0.0001)' \) to moderately small \( (p = (0.25, 0.05, 0.15)' \). Larger values of the prevalence parameters are not considered here as it would be uncommon for group testing to be considered in such cases.

Figures 1 and 2 give the bias and MSE calculations for \( k = 2 \) and \( k = 10 \), respectively, for a fixed number of tests, \( n = 25 \). More complete numerical comparisons are provided as tables in Appendix C for \( n = 10, 25, 50, \) and \( 100 \), as well as two additional prevalence points.

For all values of \( p \), there is a marked increase in bias as \( k \) moves from 2 to 10. It should be noted that if \( k = 1 \), all estimators would yield an identical unbiased estimator. This increase in bias is accompanied by large decreases in MSE for small \( p \), which shows the general advantage of group testing in such cases. Of course, for larger \( p \), \( k = 10 \) yields unacceptably large MSE values. This indicates the importance of choosing an appropriate value of \( k \), a problem which is known to be very difficult, even in the case of estimating a single trait [for discussion of this issue, see 13, 8].

Comparing estimators, we see that the the MLE and RMM estimators yield very similar, and often identical, values for both bias and MSE. While there is some trade off for the bias, the RMM method generally outperforms the MLE method slightly in terms of MSE. This, combined with the estimator’s simple closed form expression, makes a strong argument for preferring the RMM method to the MLE method in practice, even for small sample sizes.

For the Burrows type estimator, comparisons in terms of bias are much more difficult. This is especially true for \( k = 10 \), where the larger overall values occur with wide fluctuation across individual components of the parameter vector. For example, with \( k = 10, n = 10, \) and \( p = (0.15, 0.1, 0.2)' \), the relative bias for the MLE and Burrows estimators, respectively, are \((-15.39, -31.54, 265.91)' \) and \((-84.34, -88.70, 17.27)' \). In both cases, the levels of bias are very high, and would likely be unacceptable in most applications. On the other hand, when \( p \) is very small, or as \( n \) increases, the Burrows estimator does generally offer an, at least modest, bias reduction.

The real advantage of the Burrows type estimator is seen when looking at the MSE. For \( k = 2 \), the MSE values for \( \hat{p}^B \) are moderately smaller than those
Fig 1. Comparisons of 1000 × mean square error (MSE) and relative bias, defined for the ith element to be \(100 \times \frac{E(\hat{p}_i - p_i)}{p_i}\), for \(n = 25\) and \(k = 2\). The varying scales in each individual plot should be noted.

of the other two estimators for all scenarios considered. When \(k\) is increased to 10, we see that this trend of slight improvement continues (with some modest exceptions) for the smaller values of \(p\), which are precisely the cases for which a larger \(k\) is appropriate. As the prevalence increases, however, and the MSE values for the MLE and RMM become highly inflated, the Burrows type estimator is able to maintain much more reasonable levels. This robustness property of \(\hat{p}_B\) is very important, as it lowers the impact of choosing a poor value for the group size \(k\).

We close this section with two interesting observations regarding the numerical comparisons. First, for the bias calculations, we see that each estimator often yields a large positive bias for the \(p_{11}\) component. This is true despite the fact that these estimators truncate the corresponding value to zero for a set of sample values with non-trivial probability (as seen in Table 1). This surprising fact indicates that any attempts at reducing the bias in such cases will likely be very difficult.

Second, from Table 8 in the Appendix we see that, for the larger two values
of \( \mathbf{p} \), some of the MSE values for \( \mathbf{p}^B \) actually increase with \( n \), approaching rapidly the values for the other two estimators. For \( \mathbf{p} = (0.25, 0.05, 0.25)' \), we see from Table 1 that the increasing MSE values correspond with rising values of \( P(\mathbf{x} \notin \mathcal{F}_n) \). While the higher prevalence of boundary estimates largely explains the increasing MSE values, it is interesting that this phenomenon is seen only for the Burrows type estimator and not the MLE or RMM methods.

6. Application to estimation of Potato virus Y transmission rates

Potato virus Y (PVY) is a member of the genus Potyvirus, one of the largest groups of plant viruses in the world [20]. PVY is known to infect over 15 plant species and to be transmitted by over 50 species of aphids [6]. The disease can have a large economic impact due to decreased yield from a variety of symptoms such as leaf necrosis, mosaic or vein banding, and leaf drop. Further losses occur when seeds are excluded from being sold as part of certified seed programs requiring virus incidence rates as low as 1% [6].
In recent years, the ordinary strain, PVY<sup>O</sup>, has declined in prevalence relative to several new and recombinant strains [22]. Notable among such strains in the United States are PVY<sup>N;O</sup> and PVY<sup>NTN</sup>. These developments are important since various strains can present with a variety of different symptoms, and they may not be detected in the current widely available screening tests for PVY. The development of multiplex assays for this purpose has been an active area of research in the plant science literature [see, as a few examples, 1, 19, 20].

Understanding why this shift in strains is occurring remains largely unknown. One possibility that has been frequently tested is that these differences can be accounted for by varying rates in transmission by aphids across strains [22]. Since examining this hypothesis requires an efficient means of carrying out prevalence estimation, we use this example to illustrate the methods presented in this paper.

As a specific example, we consider two experiments estimating the prevalence rates of two sets of PVY strains, PVY<sup>O</sup> and PVY<sup>N;O</sup>, as well as PVY<sup>O</sup> and PVY<sup>NTN</sup>. This was the motivation for two studies found in [22], which looked at transmission rates for these strains by the aphid *Myzus persicae*. Those studies yielded estimates

\[(p_{O}, p_{N;O}, p_{O+N;O}) = (0.067, 0.028, 0.019),\]

where \(p_i\) represents the prevalence of PVY<sup>i</sup>, \(i \in \{O, N : O, O + N : O\}\) and the + indicates infection with both strains, and

\[(p_{O}, p_{NTN}, p_{O+NTN}) = (0.144, 0.158, 0.178),\]

where \(p_i\) represents the prevalence of PVY<sup>i</sup>, \(i \in \{O, NTN, O + NTN\}\). While these estimates give very different values for \(p_O\), it should be noted that each experiment used different source plant species, and that other factors such as aphid populations within species and virus isolates within strains are known to affect transmission rates [6].

Using the above parameter estimates as fact, we calculate the relative bias and MSE for each estimator presented here for various values of \(n\) and \(k\). Included is the case of \(k = 1\) (no group testing), for which all estimators are identical. We note that, while the studies in Mondal et al. [22] did not use pooled sampling, there exist many group testing applications in the PVY literature [see, as just two examples, 21, 5].

Figures 3 and 4 give plots of the relative bias for the first and second experiments, respectively, for \(k\) increasing from 1 to 25 and various values of \(n\). Figures 5 and 6 give similar plots for the \(\log(MSE)\). We use \(\log(MSE)\) here to account for the rapid increases in scale as \(k\) grows.

From Figure 3, we see that, with the exception of \(n = 25\), the relative bias is reasonably close to zero for all values of \(k\). For the largest number of tests, \(n = 250\), the bias has all but disappeared. Even for \(n = 25\) with small \(k\), less than or equal to 10, the level of bias is sufficiently small for all estimators. We note that, in this and all subsequent plots, the MLE and RMM values are indistinguishable, which is unsurprising given the results in the previous section.
Fig 3. Relative bias, defined for the $i$th element to be $100 \times \frac{E(\hat{p}_i - p_i)}{p_i}$, for varying group sizes, $k$, and number of pools tested, $n$, with true $(p_O, p_N, p_{O+N}) = (0.067, 0.028, 0.019)$. Note that the values for the MLE and RMM estimators are indistinguishable in this figure.

In Figure 4, where the underlying prevalence is larger, we see much more variation in the relative bias among estimators and across $k$. Now, only for small values of $k = 1$ or $k = 2$ is the bias near zero. In this case, due to the large value of $p_{O+N}$, as $k$ increases the probability of each test being positive for both strains of PVY goes to one. As such, we see, for all estimators, the relative bias for PVYO and PVYNTN go to $-100$ (since the estimates for each converge to zero). For PVYO + NNTN, the MLE and RMM estimates approach $100 \times \left(1 - \frac{1}{p_{O+N}}\right) = 461.8$. This is another illustration of the importance of choosing an appropriate pool size, so as to avoid the problem of getting all positive groups [for an excellent discussion of the problem of drawing all positive groups in the one-trait estimation case, see 11]. While the Burrows type esti-
Multinomial group testing estimation

Fig 4. Relative bias, defined for the $i^{th}$ element to be $100 \times \frac{E(\hat{p}_i - p_i)}{p_i}$, for varying group sizes, $k$, and number of pools tested, $n$, with true $(p_{OCPNTN}, p_{O+NTN}) = (0.144, 0.158, 0.178)$. Note that the values for the MLE and RMM estimators are indistinguishable in this figure.

For the MSE, from Figure 5, we see the log($MSE$) has a similar parabolic shape for each component of the parameter vector and all $n$. In this particular case, it appears that the same group size, $k = 10$, minimizes the MSE simultaneously for each parameter and number of tests. By carefully noting the change in scale on the $y$-axis, it is clear that the MSE is decreasing appreciably with $n$. The values across estimators are similar for most scenarios, with the Burrows type estimator appearing to offer a slight improvement in MSE. For the PVY$^{O}$ component, which is the largest among the three, we see that Burrows’ estimator is much more robust to the choice of group size (as seen by the more...
Fig 5. log(MSE) for varying group sizes, \( k \), and number of pools tested, \( n \), with true \((p_O, p_N, p_{O+N,N}) = (0.067, 0.028, 0.019)\). Note that the values for the MLE and RMM estimators are indistinguishable in this figure. The varying scales for the subplots should be noted as well.

horizontal nature of its line in the figures), although this advantage decreases with \( n \).

For the MSE in the second experiment, Figure 6 indicates that, for the MLE and RMM estimators, the minimum value is attained at \( k = 2 \) for all values of \( n \) and each parameter. For the Burrows type estimator, this is true for the first two parameters, but not for \( p_{O+N,N} \), for which the MSE appears to continue decreasing as a function of \( k \) (with the exception of \( n = 25 \), where the minimum occurs at \( k = 20 \)). Of course, when considering all three parameters together, the choice of \( k = 2 \) appears ideal, even for the Burrows type estimator. As in Figure 6, the Burrows type estimator outperforms the others, slightly for small \( k \) and to a significant degree for \( k \) between 10 and 20.
Fig 6. log(MSE) for varying group sizes, $k$, and number of pools tested, $n$, with true $(P_0,P_{NTN},P_0+NTN) = (0.144, 0.158, 0.178)$. Note that the values for the MLE and RMM estimators are indistinguishable in this figure. The varying scales for the subplots should be noted as well.

While it is important to look at performance for each component of the parameter vector, the lack of a single index value makes direct quantitative comparison difficult. To address this, we consider looking at the average absolute relative bias and average MSE, where the mean is taken across the three elements of the parameter vector. These values are provided in Tables 3 and 4 for each of the scenarios considered above for the first and second experiments, respectively.

Table 3 shows that, for all estimators, the smallest average MSE value occurs when $k = 10$. This adds support to what was observed in Figure 5. With this group size, the average MSE is 4.4 times smaller when $n = 25$ than the value when group testing is not used. For $n = 250$, this decreases to 4.1, which is still a very large gain in efficiency. This is achieved with only a small increase in the
G. Haber and Y. Malinovsky

Table 3
Average absolute relative bias and average MSE comparisons for PVY example with \((p_O,p_N,O,p_O+N,O) = (0.067, 0.028, 0.019)\).

| Average Absolute Relative Bias | \(k = 1\) | \(k = 2\) | \(k = 5\) | \(k = 10\) | \(k = 15\) | \(k = 20\) | \(k = 25\) |
|-------------------------------|-----------|-----------|-----------|-----------|-----------|-----------|-----------|
| \(n = 25\)                   |           |           |           |           |           |           |           |
| \(\hat{p}^{MLE}\)            | 0.000     | 1.938     | 1.942     | 2.691     | 3.804     | 9.472     | 34.247    |
| \(\hat{p}^{RMM}\)            | 0.000     | 1.941     | 1.914     | 2.654     | 3.740     | 9.370     | 34.213    |
| \(\hat{p}^{B}\)              | 0.000     | 2.265     | 1.833     | 2.636     | 4.751     | 8.244     | 12.063    |
| \(n = 50\)                   |           |           |           |           |           |           |           |
| \(\hat{p}^{MLE}\)            | 0.000     | 0.702     | 0.940     | 1.286     | 2.227     | 3.369     | 5.692     |
| \(\hat{p}^{RMM}\)            | 0.000     | 0.701     | 0.936     | 1.278     | 2.210     | 3.337     | 5.634     |

| \(\hat{p}^{B}\) | 0.725     | 0.398     | 0.218     | 0.182     | 0.202     | 0.284     | 1.418     |
| \(n = 50\)      | 0.725     | 0.398     | 0.217     | 0.182     | 0.202     | 0.283     | 1.416     |
| \(\hat{p}^{RMM}\) | 0.725     | 0.393     | 0.212     | 0.173     | 0.184     | 0.218     | 0.274     |
| \(\hat{p}^{B}\) | 0.363     | 0.200     | 0.109     | 0.091     | 0.103     | 0.130     | 0.175     |
| \(n = 100\)     | 0.363     | 0.200     | 0.109     | 0.091     | 0.103     | 0.129     | 0.175     |
| \(\hat{p}^{RMM}\) | 0.363     | 0.199     | 0.107     | 0.088     | 0.097     | 0.119     | 0.151     |
| \(\hat{p}^{B}\) | 0.145     | 0.080     | 0.043     | 0.036     | 0.040     | 0.052     | 0.072     |
| \(n = 250\)     | 0.145     | 0.080     | 0.043     | 0.036     | 0.040     | 0.052     | 0.072     |
| \(\hat{p}^{B}\) | 0.145     | 0.080     | 0.043     | 0.035     | 0.039     | 0.049     | 0.066     |

bias with, for example, the Burrows type estimator yielding relative bias values of 2.636 for \(n = 25\) and 0.001 when \(n = 250\). This shows a clear advantage to using group testing in similar applications. Even if the ideal group size of 10 was not chosen, we still see a large benefit for all estimators when \(k = 2\) or \(k = 5\). For the Burrows type estimator, even if too large of a group size, such as \(k = 25\), were chosen, the result is still much better than when group testing is not used. For example, with \(n = 50\) and \(k = 25\), the Burrows type estimator yields an average MSE 2.6 times smaller than that achieved without group testing, and an average absolute relative bias of only 5.3. Of course, in the same scenario if the MLE were used instead, the average MSE would be nearly double that of the non-group testing case, showing again the benefit of the Burrows type estimator.
In Table 4 we again see, similar to what was indicated in Figure 6, that the best choice of group size for the second experiment is $k = 2$. In this case, however, the gains relative to the non-grouping case are much more modest with, for example, the average MSE for the Burrows type estimator only 1.2 times smaller when $n = 25$.

### 7. Discussion

In this paper, we have addressed the problem of prevalence estimation for two-trait simultaneously using group-testing methods. While a solution for large samples is straightforward (as shown in Theorem 1), the high probability of the MLE lying on the boundary for small sample cases requires more careful consideration. We have shown that (see Table 1), depending on the underlying...
prevalence, this problem can be substantial, even for sample sizes that are much larger than would be feasible in many applications.

The problem of finding an MLE has been shown as a special case of maximizing a multinomial likelihood with a restricted parameter space. While this is, in general, a difficult problem, we showed that, whenever a closed form maximizer does not exist, the optimization problem can be expressed as a simpler problem in one fewer dimension. This was used to develop an estimation approach based on the EM algorithm which is simple both conceptually and computationally. More importantly, the resulting estimator is guaranteed to converge to the global maximizer for all values in the sample space.

In addition, we have provided a second estimator, based on the method of moments, which very closely approximates the MLE, but has the advantage of a closed form expression. This, in turn, was used to develop a third estimator based on the shrinkage estimator for one-trait group testing estimation presented in Burrows [2].

Among the three estimators, numerical comparisons showed that none uniformly outperforms the others in terms of relative bias and MSE. Still, the Burrows type estimator does generally offer some advantage in terms of MSE, and has the added benefit of being robust to poor specification of the group size. As such, this estimator can be recommended as the best choice in most cases, including those similar to the PVY strain prevalence estimation application considered here.

For many realistic cases, such as with small \( p \) and moderate \( n \), our numerical results indicate that the bias is well contained even though the number of tests is too small to rely on large sample results. It is in these cases that the importance of the results presented here is highlighted, since the use of the large sample MLE or direct numerical optimization can yield poor results. For other cases, such as with very small \( n \) or larger parameter values, the bias is much larger and the estimators presented here are not ideal. Unfortunately, there exist no alternatives in the literature to date for addressing these issues, so that future research in this area is essential.

One important extension that we have not considered here is estimation when tests are subject to misclassification. Among many other examples, group testing studies incorporating testing errors can be found in Tu et al. [31], Liu et al. [18], and Zhang et al. [34]. While very common in medical studies, this issue appears to be less commonly considered in plant science areas such as the PVY application presented here. For example, none of the previously cited papers in the PVY literature [6, 21, 22] included misclassification parameters in their statistical models, although exceptions do exist [see, as one example, 17]. Reasons for this include assumptions that the testing errors are negligible in a given application, as well as sample sizes that are too small for simultaneously estimating the usually unknown misclassification parameters. When testing errors are incorporated into the model, the results presented in this paper which greatly simplify estimation (e.g., Theorem 2) do not hold, so that different approaches must be taken. It is still possible to numerically optimize the likelihood
in such cases, although care must be taken with the starting values when this is done.

A second area which has not been considered here, is how to best choose the group size $k$. In the one-trait estimation case, this has proven to be a very difficult problem with solutions requiring either reasonably precise prior knowledge of the true parameter value [e.g., 27] or adaptive approaches [e.g., 13]. For two traits, an adaptive approach based on optimal design theory has been given [12], but relies heavily on large sample assumptions. Numerical studies or theoretical results for constructing locally optimum designs based on prior information have, to our knowledge, not been done. Further research is necessary to provide reasonable small sample solutions to this problem in order to realize the full benefits of group-testing for a wide range of applications.

Appendix A: Large sample covariance matrix for all estimators

Letting $\lambda_{10} = p_{00} + p_{10}$ and $\lambda_{01} = p_{00} + p_{01}$, the elements of $\Sigma$ as defined in Theorem 3 (b) are given by:

$$
\Sigma_{11} = p_{10}^2 \left( \frac{1}{\lambda_{10}} - 1 \right) + p_{00}^2 \left( \frac{1}{p_{00} - 1} \right)
$$

$$
\Sigma_{22} = p_{01}^2 \left( \frac{1}{\lambda_{01}} - 1 \right) + p_{00}^2 \left( \frac{1}{p_{00} - 1} \right)
$$

$$
\Sigma_{21} = p_{10}p_{01} \left( \frac{p_{00}}{\lambda_{10}^k} - 1 \right) + p_{00}p_{10} \left( \frac{p_{00}}{\lambda_{10}^{k-1}} - 1 \right)
$$

$$
\Sigma_{31} = p_{10}^2 \left( 1 - \frac{1}{\lambda_{10}} \right) + (p_{10}p_{01} + p_{00}p_{10}) \left( 1 - \frac{p_{00}^k}{\lambda_{10}^{k-1}} \right)
$$

$$
\Sigma_{32} = p_{01}^2 \left( 1 - \frac{1}{\lambda_{01}} \right) + (p_{10}p_{01} + p_{00}p_{01}) \left( 1 - \frac{p_{00}^k}{\lambda_{10}^{k-1}} \right)
$$

$$
\Sigma_{33} = p_{10}^2 \left( \frac{1}{\lambda_{10}} - 1 \right) + p_{01}^2 \left( \frac{1}{\lambda_{01}} - 1 \right)
$$

$$
+ 2(p_{10}p_{01} + p_{00}p_{10} + p_{00}p_{01}) \left( \frac{p_{00}^k}{\lambda_{10}^{k-1}} - 1 \right)
$$

\[ + p_{00}^2 \left( \frac{2p_{00}^k}{\lambda_{10}^k \lambda_{01}^k} + \frac{1}{p_{00}^k} - \frac{1}{\lambda_{10}^k} \right) \]

Appendix B: Proofs

B.1. Proof of Lemma 1

(a) We proceed by showing the negative Hessian, \(-H(p)\), to be positive definite. For convenience, we consider the parameter vectors \(\tilde{\theta}' = (\theta_{00}, \theta_{10}, \theta_{01}) = (p_{00}^k, (p_{00} + p_{10})^k - p_{00}^k, (p_{00} + p_{01})^k - p_{00}^k)\) and \(\tilde{p}' = (p_{00}, p_{10}, p_{01})\). For the standard multinomial vector, we have \(-H(\tilde{\theta}) = D + x_{11}'\lambda_{11}'\) where \(D = \text{diag}(\lambda_{00}, \lambda_{10}, \lambda_{01})\) which is positive definite since, for any \(z' = (z1, z2, z3) \in \mathbb{R}^3\) such that \(z \neq 0\),

\[ -z' H(\tilde{\theta}) z = x_{00} z_1^2 + x_{10} z_2^2 + x_{01} z_3^2 > 0. \]  

Now, \(H(\tilde{p}) = \frac{\partial \theta'}{\partial p} H(\tilde{\theta}) \frac{\partial \theta}{\partial p}\), where

\[
\frac{\partial \theta}{\partial p} = k \begin{pmatrix}
  p_{00}^{-1} & 0 & 0 \\
 (p_{00} + p_{10})^{-1} - p_{00}^{-1} & (p_{00} + p_{10})^{-1} & 0 \\
 (p_{00} + p_{01})^{-1} - p_{00}^{-1} & 0 & (p_{00} + p_{01})^{-1}
\end{pmatrix},
\]

and so

\[ -z' H(\tilde{p}) z = -z' H(\tilde{\theta}) z^* > 0 \] by (4) provided

\[ z^* = \frac{\partial \theta}{\partial p} z \neq 0. \] (10)

Since \(\frac{\partial \theta}{\partial p}\) is full rank, (10) holds whenever \(z \neq 0\) and the result follows.

(b) If \(x \in \mathcal{X} \cap \lambda_{00}^k\), so that at least one element is zero, then the inequality in (4) is replaced by

\[ -z' H(\tilde{p}) z \geq 0. \]

The remainder of the proof is identical to that of (a) with the result that \(-H(p)\) is positive semi-definite, hence the log-likelihood is concave (though not necessarily strict).

B.2. Proof of Theorem 1

(a) This follows directly from the previous discussion using the invariance property based on the multinomial MLE.

(b) Let \(g(x) = (\frac{x_{00} + x_{10}}{n})^{1/k} + (\frac{x_{00} + x_{01}}{n})^{1/k} - (\frac{x_{00}}{n})^{1/k}\). Then, by the strong law of large numbers

\[ g(x) \xrightarrow{n \to \infty} (\theta_{00} + \theta_{10})^{1/k} + (\theta_{00} + \theta_{01})^{1/k} - (\theta_{00})^{1/k} = p_{00} + p_{10} + p_{01} < 1, \]
so that for large enough \( n \), \( P(x \in R_n) = 1 \). Likewise, \( x/n \xrightarrow{a.s.} \theta \) implies that \( x \) lies in the interior of its support with probability one. That is, for large enough \( n \), \( P(x \in \mathcal{X}_0) = 1 \). It follows then that \( P(x \in \mathcal{X}_0 \cap R_n) = 1 \).

### B.3. Proof of Theorem 2

For all \( x \), the invariance property of the MLE gives the unique maximizer over \( \Psi_\theta \) to be \( \hat{p} = h(\bar{x}) \), where \( h \) is as in Lemma 2. If \( x \in \mathcal{X}_0 \cap \bar{R}_n \) then we have \( \hat{p}_{11} < 0 \), by the definition of \( \bar{R}_n \). Furthermore, by Lemma 1 (a), the log-likelihood, \( \ell \), is strictly concave over this set and, by (1) and (2), each of \( \hat{p}_{00}, \hat{p}_{10}, \) and \( \hat{p}_{01} \) are non-negative (since otherwise, the corresponding \( \theta \) values would be negative, hence not in \( \Psi_\theta \)). Suppose now that \( p' \in \Psi_\theta \) is the true maximizer over the boundary and satisfies \( p'_{11} > 0 \). Then, since \( \hat{p} \) is a global maximum and \( \ell \) is strictly concave, the line segment \( \ell(t\hat{p} + (1-t)p') \), \( 0 \leq t \leq 1 \) is strictly decreasing as \( t \to 0 \). However, there exists a point in \( \partial \Psi_\theta \) on the line with \( t > 0 \), say \( p'' \), satisfying \( p''_{11} = 0 \) and \( \ell(p'') > \ell(p') \).

If \( x \notin \bar{R}_n \) and at least one of the elements of \( x \) is equal to zero, the log-likelihood is concave (not strictly, Lemma 1 (b)). As such, the previous analysis can be repeated with the conclusion that \( \ell(p'') \geq \ell(p') \), so that \( \ell \) is maximized at a point with \( p_{11} = 0 \), although perhaps not uniquely.

For \( x_{11} = 0 \), the log-likelihood is proportional to \( x_{00}\log(p_{00}^k) + x_{10}\log((p_{00} + p_{10})^k - p_{00}^k) + x_{01}\log((p_{00} + p_{01})^k - p_{00}^k) \). Let \( p \) be any point such that \( p_{11} > 0 \). It is clear that taking the point \( p' = (p_{00}, p_{10} + p_{11}, p_{01}, 0) \) the value of this function can be increased, provided \( x_{10} > 0 \). If instead \( x_{10} = 0 \) but \( x_{01} > 0 \), the same can achieved by taking \( p' = (p_{00}, p_{10}, p_{01} + p_{11}, 0) \). Likewise, if both \( x_{10} = 0 \) and \( x_{01} = 0 \), so that \( x_{00} = n \), the log-likelihood can be increased by taking \( p' = (p_{00} + p_{11}, p_{10}, p_{01}, 0) \). Since one of these three cases must occur, it follows that any point maximizing the log-likelihood will necessarily have \( p_{11} = 0 \).

### B.4. Proof of Lemma 3

The proof of both (a) and (b) is nearly identical to that of Lemma 1, the primary difference being that we now have

\[
\frac{\partial \theta}{\partial p} = k \left( \begin{array}{cc}
-(1 - p_{10} - p_{01})^{k-1} & -(1 - p_{10} - p_{01})^{k-1} \\
(1 - p_{10} - p_{01})^{k-1} & (1 - p_{10} - p_{01})^{k-1} - (1 - p_{01})^{k-1} \\
(1 - p_{10} - p_{01})^{k-1} - (1 - p_{10})^{k-1} & (1 - p_{10} - p_{01})^{k-1}
\end{array} \right).
\]

Since this matrix has full column rank, it follows that (10) holds if and only if \( z \neq 0 \) and the rest of the proof is identical.
B.5. Proof of Result 1

Let $Z_{ij} = (z_{i0j}, z_{i1j})$ represent the (latent) disease status of the $j^{th}$ unit from the $i^{th}$ pool, so that $Z_{ij} \sim MN(1, p^*)$ and set $z_{i0j} = n - z_{i1j} - z_{i0j}$.

Using $Z$ as the complete data in the EM framework, the complete data log-likelihood is given by

$$\ell_C(p^*, z) \propto \sum \sum z_{i0j} \log(1 - p_{10} - p_{01}) + \sum \sum z_{i1j} \log(p_{10}) + \sum \sum z_{i0j} \log(p_{01}).$$

We now proceed to calculate the E and M steps, respectively.

E-step:
Let $\zeta_r(s) = E(Z_{i1j} | \theta_{i0j} = 1, p^*)$, where $r \in \{(00), (10), (01)\}$ is the true status (under the reduced model), and $s \in S = \{(00), (10), (01), (11)\}$ is the observed status, and $p^*$ is the parameter estimate at the $t^{th}$ iteration. Then, we have the expectation of the complete log-likelihood

$$Q(p^*; p^*) \propto k \sum_{s \in S} \zeta^s_{00}(p^*) X_s \log(1 - p_{10} - p_{01}) + k \sum_{s \in S} \zeta^s_{10}(p^*) X_s \log(p_{10}) + k \sum_{s \in S} \zeta^s_{01}(p^*) X_s \log(p_{01}).$$

To calculate the values of $\zeta^s_r(p^*)$, we have

$$\zeta^0^0(r) = E(Z_{i1j}^1 | \theta_{i0j} = 1, p^*) = P(Z_{i1j}^1 = 1 | \theta_{i0j} = 1)$$

$$= \frac{P(\theta_{i0j} = 1 | Z_{i1j}^1 = 1)P(Z_{i1j}^1 = 1)}{P(\theta_{i0j} = 1)} = \frac{\theta_{i0j}^{(t)} k - 1 \theta_{i0j}^{(t)}}{\theta_{i0j}^{(t)}},$$

where the fourth equality holds since, conditioning on the first observation being negative, the pool will be negative if and only if the remaining $k - 1$ units are negative as well.

Likewise,

$$\zeta^0^1(r) = \frac{[\theta_{i0j}^{(t)} + \theta_{i0j}^{(t)}] k - 1 \theta_{i0j}^{(t)} - 1 \theta_{i0j}^{(t)}}{\theta_{i0j}^{(t)}},$$

$$\zeta^{10}(r) = \frac{[\theta_{i0j}^{(t)} + \theta_{i0j}^{(t)}] k - 1 \theta_{i0j}^{(t)} - 1 \theta_{i0j}^{(t)}}{\theta_{i0j}^{(t)}}.$$
\[ \zeta_{11}(p^{*}(t)) = \frac{[1 - (p_{00}^{(t)} + p_{01}^{(t)})^{k-1} - (p_{00}^{(t)} + p_{01}^{(t)})^{k-1} + (p_{00}^{(t)} + p_{01}^{(t)})^{k-1}]}{\theta_{11}^{(t)}} \]

\[ \zeta_{10}(p^{*}(t)) = 0 \]

\[ \zeta_{10}(p^{*}(t)) = \frac{(p_{00}^{(t)} + p_{01}^{(t)})^{k-1}p_{10}^{(t)}}{\theta_{10}^{(t)}} \]

\[ \zeta_{10}(p^{*}(t)) = 0 \]

\[ \zeta_{11}(p^{*}(t)) = \frac{[1 - (p_{00}^{(t)} + p_{01}^{(t)})^{k-1}]}{\theta_{11}^{(t)}} \]

\[ \zeta_{01}(p^{*}(t)) = 0 \]

\[ \zeta_{01}(p^{*}(t)) = \frac{(p_{00}^{(t)} + p_{01}^{(t)})^{k-1}p_{01}^{(t)}}{\theta_{01}^{(t)}} \]

\[ \zeta_{01}(p^{*}(t)) = 0 \]

\[ \zeta_{01}(p^{*}(t)) = \frac{(p_{00}^{(t)} + p_{01}^{(t)})^{k-1}p_{01}^{(t)}}{\theta_{01}^{(t)}} \]

\[ \zeta_{01}(p^{*}(t)) = 0 \]

**M-step:**

Since (11) is a standard multinomial log-likelihood of size \( kn \), the unique global maximizer is given by

\[
\begin{align*}
    p_{00}^{(t+1)} &= \frac{\sum_{s \in S} \zeta_{00}(p^{*}(t))X_s}{n} \\
    p_{10}^{(t+1)} &= \frac{\sum_{s \in S} \zeta_{10}(p^{*}(t))X_s}{n} \\
    p_{01}^{(t+1)} &= \frac{\sum_{s \in S} \zeta_{01}(p^{*}(t))X_s}{n}.
\end{align*}
\]

**B.6. Lemmas for Theorems 3 and 4**

Before proving Theorems 3 and 4, we provide the following three lemmas.

**Lemma 4.** \( P(x \in \mathcal{R}_n^c) = O(n^{-2}) \)

*Proof.* We have \( x \in \mathcal{R}_n^c \) only if \( \left(\frac{x_{00} + x_{10}}{n}\right)^{1/k} + \left(\frac{x_{00} + x_{01}}{n}\right)^{1/k} - \left(\frac{x_{00}}{n}\right)^{1/k} > 1 \). Choose \( \epsilon \) such that \( (\theta_{00} + \theta_{10} + \epsilon)^{1/k} + (\theta_{00} + \theta_{01} + \epsilon)^{1/k} - (\theta_{00} - \epsilon)^{1/k} \leq 1 \) so that \( x \in \mathcal{R}_n^c \) implies the event \( \{n\theta_{00} - x_{00} > n\epsilon\} \cup \{x_{00} + x_{10} - n\theta_{00} - n\theta_{10} - n\theta_{01} > n\epsilon\} \cup \{x_{01} + x_{10} - n\theta_{00} - n\theta_{01} + n\epsilon\} \) occurs. Then, using the Markov inequality,
Lemma 5. Let $f = (f_1, f_2, f_3) = \left( \left( \frac{x_{00} + x_{10}}{n} \right)^{1/k}, \left( \frac{x_{00} + x_{01}}{n} \right)^{1/k}, \left( \frac{x_{00} + x_{10}}{n} \right)^{1/k} \right)$, then the elements of $f$ can be expressed as follows:

(a) $f_1(x_{00} + x_{10}) = p_{00} + p_{10} + \frac{1}{nk(p_{00} + p_{10})} (x_{00} + x_{10} - n(p_{00} + p_{10})^k) + \frac{1}{2n^2k^2(p_{00} + p_{10})^k-1} (x_{00} + x_{10} - n(p_{00} + p_{10})^k)^2 + O_p(n^{-2});$

(b) $f_2(x_{00} + x_{01}) = p_{00} + p_{01} + \frac{1}{nk(p_{00} + p_{01})} (x_{00} + x_{01} - n(p_{00} + p_{01})^k) + \frac{1}{2n^2k^2(p_{00} + p_{01})^k-1} (x_{00} + x_{01} - n(p_{00} + p_{01})^k)^2 + O_p(n^{-2});$

(c) $f_3(x_{00}) = p_{00} + \frac{1}{nk p_{00}} (x_{00} - np_{00}^k) + \frac{1}{2n^2k^2 p_{00}} (x_{00} - np_{00}^k)^2 + O_p(n^{-2}).$

Proof. For each element of $f$, the component random variables can be expressed as a single marginal binomial random variable (e.g., $x_{00} + x_{10} \sim \text{Bin}(n, (p_{00} + p_{10})^k)$). The result then follows by taking the second order Taylor expansion of each element about the mean of the constituent random variable.

We illustrate this for $f_1$. Let $\tilde{x} = x_{00} + x_{10}$ and set $\tilde{x}_0 = E(\tilde{x}) = n(p_{00} + p_{10})^k$. Then, since $\frac{df_1}{dx} = \frac{\xi}{n} \left( \frac{\tilde{x}_0}{n} \right)^{\xi-1}$ and $\frac{d^2 f_1}{dx^2} = \xi (\xi - 1) \left( \frac{\tilde{x}_0}{n} \right)^{\xi-2}$, the Taylor expansion of $f_1$ about $\tilde{x}_0$ yields, letting $\xi = 1/k$,

$$f_1 = \left( \frac{\tilde{x}_0}{n} \right)^\xi + \frac{\xi}{n} \left( \frac{\tilde{x}_0}{n} \right)^{\xi-1} (\tilde{x} - \tilde{x}_0) + \frac{\xi (\xi - 1)}{2n^2} \left( \frac{\tilde{x}_0}{n} \right)^{\xi-2} (\tilde{x} - \tilde{x}_0)^2 + O_p(n^{-2}).$$

Lemma 6. Let

$$g = (g_1, g_2, g_3) = \left( \left( \frac{x_{00} + x_{10} + \eta}{n + \eta} \right)^{1/k}, \left( \frac{x_{00} + x_{01} + \eta}{n + \eta} \right)^{1/k}, \left( \frac{x_{00} + \eta}{n + \eta} \right)^{1/k} \right),$$

then the elements of $g$ can be expressed as follows:
of (a) \( g_1(x_0 + x_{10}) = p_{00} + p_{10} + \frac{1 - (p_{00} + p_{10})^k}{nk(p_{00} + p_{10})^{k-1}} \eta + \frac{1}{nk(p_{00} + p_{10})^{k-1}}(x_0 + x_{10} - n(p_{00} + p_{10})^k) + \frac{1 - (p_{00} + p_{10})^k}{2nk^2(p_{00} + p_{10})^{2k-1}}(x_0 + x_{10} - n(p_{00} + p_{10})^k)^2 + O_p(n^{-2});
\]
(b) \( g_2(x_0 + x_{01}) = p_{00} + p_{01} + \frac{1 - (p_{00} + p_{01})^k}{nk(p_{00} + p_{01})^{k-1}} \eta + \frac{1}{nk(p_{00} + p_{01})^{k-1}}(x_0 + x_{01} - n(p_{00} + p_{01})^k) + \frac{1 - (p_{00} + p_{01})^k}{2nk^2(p_{00} + p_{01})^{2k-1}}(x_0 + x_{01} - n(p_{00} + p_{01})^k)^2 + O_p(n^{-2});
\]
(c) \( g_3(x_0) = p_{00} + \frac{1}{np_{00}} \eta + \frac{1}{np_{00}}(x_0 - np_{00}) + \frac{1}{2np_{00}}(x_0 - np_{00})^2 + O_p(n^{-2}).\)

Proof. The proof proceeds identically as for the previous lemma by first finding the second order Taylor expansion of the elements of \( g \) about the mean of the respective component random variables. The result then follows by finding the Taylor expansion of each resultant term about \( \eta = 0. \)

We illustrate this for \( g_1, \) for which, letting \( \hat{x}, \hat{x}_0, \) and \( \xi \) be as defined in the proof of the previous lemma, has the Taylor expansion about \( \hat{x}_0 \)

\[
g_1 = \left( \frac{\hat{x}_0 + \eta}{n + \eta} \right)^\xi + \frac{\xi(\hat{x}_0 + \eta)^{\xi-1}}{(n + \eta)^\xi} (\hat{x} - \hat{x}_0) + \frac{\xi(\xi - 1)(\hat{x}_0 + \eta)^{\xi-2}}{2(n + \eta)^\xi} (\hat{x} - \hat{x}_0)^2 + O_p(n^{-2}). \tag{12}
\]

For an integer \( r, \) we have

\[
\frac{d}{d\eta} \left( \frac{(\hat{x}_0 + \eta)^{\xi - r}}{(n + \eta)^{\xi}} \right) = \frac{\xi - r}{(n + \eta)^{r+1}} \left( \frac{\hat{x}_0 + \eta}{n + \eta} \right)^{\xi - r - 1} - \frac{\xi}{(n + \eta)^{r+1}} \left( \frac{\hat{x}_0 + \eta}{n + \eta} \right)^{\xi - r},
\]

so that for \( r > 1 \) this derivative is \( O(n^{-3}). \) Likewise, for all \( r \geq 1 \) the second derivative of the same term will be \( O(n^{-3}). \) As such, taking the Taylor expansion of (12) about \( \eta = 0 \) yields

\[
g_1 = \left( \frac{\hat{x}_0}{n} \right)^\xi + \frac{\xi(\hat{x}_0)^{\xi-1}}{n} \eta - \frac{\xi}{n} \left( \frac{\hat{x}_0}{n} \right)^{\xi-1} \eta + \frac{\xi}{x} \left( \frac{\hat{x}_0}{n} \right)^{\xi-1} (\hat{x} - \hat{x}_0) + \frac{\xi(\xi - 1)}{2n^2} \left( \frac{\hat{x}_0}{n} \right)^{\xi-2} (\hat{x} - \hat{x}_0)^2 + O_p(n^{-2})
\]

\[
= p_{00} + p_{10} + \frac{1 - (p_{00} + p_{10})^k}{nk(p_{00} + p_{10})^{k-1}} \eta + \frac{1}{nk(p_{00} + p_{10})^{k-1}}(x_0 + x_{10} - n(p_{00} + p_{10})^k)
\]

\[
+ \frac{1 - k}{2nk^2(p_{00} + p_{10})^{2k-1}}(x_0 + x_{10} - n(p_{00} + p_{10})^k)^2 + O_p(n^{-2}). \quad \Box
\]
B.7. Proof of Theorem 3

(a) By the definition of the \( RMM \) estimator, we have \( p_{RMM} - p_{MLE} = h(x)I(x \in \mathcal{R}_p) \), where \( h \) is some bounded function and \( I \) is the indicator function. Then, from (b) in Theorem 1 the right hand side of this expression converges to zero almost surely, and the result follows.

(b) Each estimator can be expressed as \( \hat{p} = h_1(x) + h_2(x)I(x \in \mathcal{R}_p) \) for some bounded functions \( h_1, h_2 \). By standard multinomial theory, \( x \) is asymptotically normal with rate \( O(n^{-1}) \) so that the first term, \( h_1 \), is as well by the Delta method. By Lemma 4 and the boundedness of \( h_2 \), the second term is of order \( O(n^{-2}) \) so that the overall convergence (up to \( O(n^{-1}) \)) is determined only by the first term. The exact values of the asymptotic covariance matrix can then be calculated directly using the Taylor expansions given in Lemmas 5 and 6. Some algebra shows that each estimator yields an identical covariance matrix, so that the large sample distributions, up to \( O(n^{-1}) \), are identical.

We illustrate the calculations for the covariance matrix (as given in Appendix A) by finding \( \Sigma_{11} \), where \( \frac{1}{n} \Sigma_{11} \) is the asymptotic variance of \( p_{10} \) for the MLE. Note that, for \( p_{11}^{MLE} \), the function \( h_1 \) defined above is given by \( f_1 - f_3 \), where \( f_1, f_3 \) are as in Lemma 5. As such, ignoring terms of \( O(n^{-2}) \), the asymptotic variance of \( p_{10}^{MLE} \) is given by, defining \( \lambda_{10} = \lambda_0 + \lambda_{10} \),

\[
\Sigma_{11} = nk^2 E\left( (x_{10} - x_{10} - n \lambda_{10}^k) \right)^2
\]

\[
= \frac{1}{n} E \left( \frac{(x_{00} + x_{10} - n \lambda_{10}^k)}{\lambda_{10}^{k-1} p_{10}^{k-1}} \right)^2
\]

\[
= \frac{1}{n} \left( \frac{V(x_{00} + x_{10})}{\lambda_{10}^{2k-2}} + \frac{V(x_{00})}{\lambda_{10}^{2k-2}} - 2 \frac{Cov(x_{00} + x_{10}, x_{00})}{\lambda_{10}^{k-1} p_{10}^{k-1}} \right)
\]

\[
= \frac{1}{n} \left( \frac{n \lambda_{10}^k (1 - \lambda_{10}^k)}{\lambda_{10}^{2k-2}} + \frac{n \lambda_{10}^k (1 - \lambda_{10}^k)}{\lambda_{10}^{2k-2} p_{10}^{k-2}} + \frac{2 n \lambda_{10}^k (1 - \lambda_{10}^k - n p_{00}^k (\lambda_{10}^k - \lambda_{10}^k))}{\lambda_{10}^{k-1} p_{10}^{k-1}} \right)
\]

\[
= \frac{1}{\lambda_{10}^k} \left[ \lambda_{10}^2 - 2 \lambda_{10} p_{00} + p_{00}^2 \right] + \frac{2 p_{00}^2}{p_{10}^2} \left( 1 - \lambda_{10}^k \right) \]

Similar calculations yield the other values of \( \Sigma \), noting that the \( h_1 \) functions for \( p_{01}^{MLE} \) and \( p_{11}^{MLE} \) are given by \( f_2 - f_3 \) and \( 1 - f_1 - f_2 + f_3 \), respectively.

To see that the Burrows estimator yields the same asymptotic covariance matrix, note that the function \( h_1 \) defined above for \( p_{10}^B \) is \( g_1 - g_3 \), where \( g_i \)
and $g_3$ are as defined in Lemma 6. Now, for any value of $\eta$, we have, ignoring terms of $O(n^{-2})$, $g_1 - g_3 = f_1 - f_3 + C$, where $C$ is constant with respect to x and of order $O(n^{-1})$. As such, the asymptotic variance of $\hat{p}_{10}$ is given by $\text{E}(f_1 - f_3 + C - \hat{p}_{10})^2 = \frac{1}{m^2} \Sigma_{11} + 2CE(f_1 - f_3 - \hat{p}_{10}) + C^2 = \frac{1}{m^2} \Sigma_{11} + O(n^{-2})$. Similar reasoning holds for the other elements of the asymptotic covariance matrix for the Burrows estimator.

**B.8. Proof of Theorem 4**

This proof is nearly identical to (b) in the previous theorem. The first order expectations can be found using the Taylor expansions in Lemmas 5 and 6, and combined as in the proof the the previous theorem.
