(STAR Collaboration)
Values of the ratios in the mid-rapidity yields of $\bar{\Lambda}/\Lambda = 0.71 \pm 0.01({\text{stat.}}) \pm 0.04({\text{sys.}})$, $\Xi^+/\Xi^- = 0.83 \pm 0.04({\text{stat.}}) \pm 0.05({\text{sys.}})$, $\bar{\pi}^+ / \pi^- = 0.95 \pm 0.15({\text{stat.}}) \pm 0.05({\text{sys.}})$ and $K^+/K^- = 1.092 \pm 0.023({\text{combined}})$ were obtained in central $\sqrt{s_{\text{NN}}} = 130$ GeV Au+Au collisions using the STAR detector. The ratios indicate that a fraction of the net-baryon number from the initial system is present in the excess of hyperons over anti-hyperons at mid-rapidity. The trend in the progression of the baryon ratios, with increasing strange quark content, is similar to that observed in heavy-ion collisions at lower energies. The value of these ratios may be related to the charged kaon ratio in the framework of simple quark-counting and thermal models.

additional requirement of a high CTB threshold, corresponding approximately to the 14% most central events. On these events a further centrality selection was made off-line, by cutting on the observed track multiplicity in the TPC after event reconstruction. This analysis used approximately 180,000 central $\sqrt{s_{NN}} = 130$ GeV Au+Au events after the multiplicity cut, corresponding to the most central 11% of the total hadronic cross-section.$^{24}$

Two techniques were used to extract the raw yields of strange particles. First, charged kaons were identified via their specific ionization, or energy loss ($dE/dx$), in the TPC. Second, these and other strange particles were reconstructed from their decay topology.

Up to 45 ionization samples were measured for each track. The $dE/dx$ resolution was measured to be 11% following the procedure of.$^{21}$ For the charged kaon $dE/dx$ analysis only tracks below a momentum of 0.6 GeV/c were used, where the $dE/dx$ of kaons is distinct from those of other particle species. In addition, tracks were required to originate from the primary interaction vertex within 3 cm. Similar to.$^{22}$ the distribution of $Z = \log((dE/dx)_{\text{true}}/(dE/dx)_{BB})$, where $(dE/dx)_{BB}$ is the $dE/dx$ from a Bethe-Bloch parameterization, is fitted with a convolution of Gaussian functions. The kaon raw yields were extracted from the fit results for each $p_T$ bin within rapidity $|y| < 0.4$.

The most versatile technique for the reconstruction of strange particles is via their decay topologies.$^{23}$ The decay $\Lambda \rightarrow n\pi^−$ (64% branching ratio) and the charge conjugate decay for $\overline{\Lambda}$ result in two charged particles in the final state. The $\Lambda$ particles from the electromagnetic decay of the $\Sigma^0$ are included in the $\Lambda$ sample since they were not experimentally distinguishable from the primary $\Lambda$ population. The momenta of these charged daughter particles are calculated from their trajectories in the TPC. Both tracks can be extrapolated back toward the primary interaction vertex to locate their common point of origin, where the kinematic properties of the parent can be calculated. In this process, all pairs of positively and negatively charged tracks in an event are considered. To reduce the large combinatorial background which results from random crossings of tracks interior to the TPC fiducial volume, additional cuts must be made. The most important criteria for improving the signal to noise ratio are that the decay vertex is well separated from the primary interaction and that the parent originates from the primary interaction vertex while the daughters do not. An additional requirement that the $dE/dx$ of the daughters is compatible with the expected decay mode is also applied. For example the positively charged daughter of a $\Lambda$ should have a $dE/dx$ compatible with it being a proton. This helps to suppress the background from fake decays with two pion daughter particles with $p \lesssim 1$ GeV/c. This technique is extended to enable the reconstruction of the $\Xi^− \rightarrow \Lambda\pi^−$ and $\Omega^− \rightarrow \Lambda K^−$ decays (100% and 68% branching ratios respectively) and their charge conjugate $\Xi^+$ and $\Omega^+$ decays. Here, only $\Lambda$ (or $\overline{\Lambda}$) candidates within $\pm 7$ MeV/c$^2$ of the expected mass.$^{24}$ are used and the requirement that the $\Lambda$ (or $\overline{\Lambda}$) originates from the primary interaction vertex is relaxed. The resulting invariant mass distributions for $\Lambda$, $\Xi^-$ and $\Omega^-$, with their anti-particle distributions superimposed, are shown in Figure 1. The remaining background under the peak in each invariant mass distribution was subtracted by using a linear interpolation between the background regions a few MeV/c$^2$ on either side of the peak region.

Charged kaons can also be reconstructed using a variation on this topological technique via their one-prong decay channels. The most prominent of these are $K \rightarrow \mu\nu$ and $K \rightarrow \pi\pi^0$, with 64% and 21% branching ratios, respectively. In this “kink” method the tracks from the charged kaon and charged daughter particle are used to reconstruct the kinematics of the decay. In order that both parent and daughter are reconstructed in the TPC with good momentum resolution, the fiducial volume for the location of the decay vertex is restricted to radii of 130 – 180 cm. The background comes from charged pion decays, multiple scattering and hadronic interactions in the TPC gas and combinatorics. The pion decay contribution can be largely eliminated by a cut on the opening angle between the parent and daughter tracks. This angle, for a given momentum, is much smaller for a pion.

FIG. 1: Invariant mass distributions for $p\pi^−$ and $\overline{p}\pi^+$ (top panel), $\Lambda\pi^−$ and $\overline{\Lambda}\pi^+$ (middle panel) and $\Lambda K^−$ and $\overline{\Lambda}K^+$ (lower panel).
decay than a kaon decay. The remaining background level was estimated to be approximately 15% \cite{21}. The method allows charged kaons to be identified over a wide range in \(p_T\).

The central assumption in forming the anti-particle to particle ratios is that the detector response is symmetric with respect to charge and therefore no corrections to the yields for the reconstruction efficiency or detector acceptance are required. However, losses due to the absorption of anti-protons in the detector material have the potential to modify the \(\bar{\Lambda}/\Lambda, \Xi^+/-/\Xi^-\) and \(\Omega^-/\Omega^-\) ratios and feed-down from the decay of heavier strange baryons can modify both the \(\bar{\Lambda}/\Lambda\) and \(\Xi^+/-/\Xi^-\) ratios. Absorption causes the final state anti-proton from \(\Lambda\) decay to fail to be reconstructed more often than the proton from \(\Lambda\) decay. The size of this effect has been estimated and corrected for using a GEANT simulation of the detector. Absorption reduces the apparent \(\bar{\Lambda}/\Lambda\) and \(\Xi^+/-/\Xi^-\) ratios by 1% and 0.2% respectively. The decaying anti-particles also have a larger absorption cross-section than their corresponding particles, but since they decay within a few centimeters, before most of the absorbing materials have been traversed, this correction is even smaller and is implicitly included in the numbers given above. The observed \(\bar{\Lambda}/\Lambda\) includes feed-down contributions. The total \(\Lambda\) yield contains \(\Lambda\) originating from \(\Xi^-\), \(\Xi^0\) and \(\Omega^-\) decays, estimated to be \(27 \pm 6\%\) \cite{20}. Their anti-particle decays similarly contribute to \(\bar{\Lambda}\). Assuming that these feed-down contributions to \(\Lambda\) and \(\bar{\Lambda}\) are in the ratio of the \(\Xi^+/-/\Xi^-\) measurement, we obtain an actual \(\bar{\Lambda}/\Lambda\) ratio, which we quote, \(0.05 - 0.015\) lower than the observed value. The only feed-down contribution to the \(\Xi^+/-/\Xi^-\) comes from the \(\Omega^- \rightarrow \Xi^- \pi^0\) channel with a 9% branching ratio and was therefore neglected. Two processes modify the \(K^+/K^-\) ratio. Feed-down of kaons from the decay \(\phi \rightarrow K^+K^-\) was estimated, using the measured \(\phi/K\) ratio \cite{27, 28}, to reduce the apparent \(K^+/K^-\) ratio by 0.8% at \(p_T = 0.4\ GeV/c\) and less than 0.3% above \(p_T = 1\ GeV/c\). Secondary interactions were studied using GEANT simulations of HIJING \cite{25} events and were found to increase the measured ratio by 0.7%. These corrections were applied in producing the final ratio.

After the absorption correction the value of the \(\bar{\Lambda}/\Lambda\) ratio is \(0.74 \pm 0.01\)\((stat.)\) in the measured acceptance interval of \(p_T > 0.4\ GeV/c\) and within one unit of rapidity centered at mid-rapidity. This is the same as the value for the corrected data reported previously \cite{26}. The feed-down correction reduces this to a final value of \(0.71 \pm 0.01\)\((stat.)\). The \(\Xi^+/-/\Xi^-\) ratio after correction is \(0.83 \pm 0.04\)\((stat.)\), measured over the same rapidity interval and \(p_T > 0.5\ GeV/c\). In order to admit a larger sample of \(\Omega^-\) and \(\Omega^+\), the \(\Omega^+/-/\Omega^-\) ratio was calculated using a larger interval, of ±1 units of rapidity, and a value of \(0.95 \pm 0.15\)\((stat.)\) was obtained. The \(\bar{\Lambda}/\Lambda\) and \(\Xi^+/-/\Xi^-\) ratios as a function of \(p_T\) out to 2.5 \(GeV/c\) and 3.5 \(GeV/c\) are shown in Figure 2 and are consistent with a constant value. Within statistics the \(\bar{\Lambda}/\Lambda\) ratio appears to be independent of the charged particle yield at mid-rapidity. Systematic uncertainties on the \(\bar{\Lambda}/\Lambda\) and \(\Xi^+/-/\Xi^-\) of 0.04 and 0.05 respectively have been estimated by varying the cuts used to identify decay candidates. There were insufficient data to estimate the systematic uncertainty on the \(\Omega^+/-/\Omega^-\) this way so the \(\Xi^+/-/\Xi^-\) systematic uncertainty was used since the reconstruction methods are identical. The \(K^+/K^-\) ratio is \(1.075 \pm 0.008\)\((stat.)\), measured via the \(dE/dx\) method, in the range \(0.15 < p_T < 0.6\ GeV/c\) and ±0.4 units of rapidity around mid-rapidity. The same ratio measured by the kink method is \(1.13 \pm 0.015\)\((stat.)\) and extends out to 2 \(GeV/c\) in \(p_T\). The systematic error of the kink measurement due to detector effects is estimated to be 0.05 and that for the \(dE/dx\) is estimated at 0.03. The small discrepancy in the \(K^+/K^-\) from the two methods is within the estimated systematic errors and a combined value of \(1.092 \pm 0.023\) was calculated, following the method of the PDG \cite{24} when combining results from different experiments. As Figure 2 shows, with both methods, the ratio shows no significant deviation from a constant as a function of \(p_T\). As all the \(p_T\) intervals cover a large fraction of the total yield (over 70% \cite{26, 28, 31}) we assume that the ratios we measure are a good indication of the ratios in the integrated yields.

The strange anti-baryon to baryon ratios are plotted in Figure 3 together with their values found in central Pb+Pb collisions at \(\sqrt{s_{NN}} = 17\ GeV\) \cite{31} at the CERN Super Proton Synchrotron. Also shown are the \(\bar{p}/p\) ratios from STAR \cite{32} and two measurements at the lower energy from NA44 \cite{33} and NA49 \cite{34}. Figure 3 shows that the ratios increase with increasing strangeness content of the baryon at both \(\sqrt{s_{NN}} = 17\ GeV\) and \(\sqrt{s_{NN}} = 130\ GeV\). The increasing trend in the ratios may be explained in a simple quark coalescence model \cite{14, 17}, which predicts that the anti-baryon to baryon ratios should be related to one another by a common multiplicative factor. The

\begin{figure}
\centering
\includegraphics[width=\textwidth]{figure2.png}
\caption{The ratios \(\bar{\Xi}/\Xi, K^+/K^-\) and \(\Xi^+/-/\Xi^-\) as a function of \(p_T\). The error bars indicate the statistical errors and the brackets the systematic uncertainties.}
\end{figure}
multiplicative factor is given by the value of the \( K^+/K^- \) ratio. This is in approximate agreement with the data presented here, as shown in Table I.

Within the coalescence model hadrons are formed from a system of independent quarks and anti-quarks. An alternative description of particle production which nevertheless gives equivalent predictions for the ratios discussed here is the statistical model approach [42], which does not distinguish between quark or hadron degrees of freedom. In this case the multiplicative factor is given by \( \exp(2\mu_B/3T - 2\mu_s/T) \), where \( \mu_B \) is the baryon chemical potential, \( \mu_s \) is the strange quark chemical potential and \( T \) is the chemical freeze-out temperature. The \( K^+/K^- \) ratio can therefore be interpreted as an indirect measure of the baryon chemical potential. If the central region in Au+Au collisions at \( \sqrt{s_{NN}} = 130 \text{ GeV} \) were net baryon free (\( \mu_B = 0 \)), then the \( K^+/K^- \) ratio would be equal to one, and in both models the anti-baryon to baryon ratios would also be equal to one, under the assumption that strangeness is locally conserved. However, while the anti-baryon to baryon ratios at this higher energy are closer to unity, reflecting a lower net-baryon density, this density is nevertheless still positive. This is thought to be a consequence of baryon number transport (or stopping) during the collision process. There is an excess of \( u \) and \( d \) quarks over their anti-quarks favoring the production of baryons over anti-baryons and \( K^+ \) over \( K^- \). We find, from a fit to all the ratios, that \( \mu_B/T = 0.18 \pm 0.03 \) and \( \mu_s/T = 0.001 \pm 0.011 \) with \( \chi^2/\text{dof} = 2.5 \) when including all the systematic errors. A statistical model analysis using preliminary data [43] is also consistent giving \( \mu_B/T = 0.26 \pm 0.03 \) where \( \mu_B = 45 \text{ MeV} \) and \( T = 170 \text{ MeV} \). This compares to \( \mu_B/T = 1.58 \pm 0.04 \) at \( \sqrt{s_{NN}} = 17 \text{ GeV} \) where \( \mu_B = 266 \text{ MeV} \) and \( T = 168 \text{ MeV} \) [12]. We also note that the flatness of the \( \overline{\Lambda}/\Lambda \) and \( K^+/K^- \) ratios in Figure 2 suggests that the transverse momentum distributions of the particles and their anti-particles are very similar. The matching \( p_T \) distributions are especially interesting for the \( \Lambda \) and \( \overline{\Lambda} \), since there may be different production mechanisms. The \( \Lambda \) are believed to have component due to associated production (e.g. \( pp \to pAK \)) by the incoming baryons.

In summary, we have reported strange anti-particle to particle ratios measured by the STAR experiment at mid-rapidity in the 11% most central Au+Au collisions at \( \sqrt{s_{NN}} = 130 \text{ GeV} \). The ratios indicate that a fraction of the net-baryon number from the initial system is present in the excess of hyperons over anti-hyperons at mid-rapidity. The ratios are consistent with simple quark counting models and with a statistical description of particle production which is governed by a common baryon chemical potential and chemical freeze-out temperature.
