(Dated: July 23, 2009)

The feasibility of path integral Monte Carlo ground state calculations with very few beads using a high-order short-time Green’s function expansion is discussed. An explicit expression of the evolution operator which provides dramatic enhancements in the quality of ground-state wave-functions is examined. The efficiency of the method makes possible to remove the trial wave function and thus obtain completely model-independent results still with a very small number of beads. If a single iteration of the method is used to improve a given model wave function, the result is invariably a shadow-type wave function, whose precise content is provided by the high-order algorithm employed.

PACS numbers: 31.15.Kb,02.70.Ss

Quantum Monte Carlo path integral calculations provide a powerful approach to many-body physics, both at zero [1, 2, 3] and finite temperature [4]. They rely on using the classical action of the system in imaginary time to define a path distribution probability, following Feynman’s approach. For systems with Bose statistics, the probability is positive and the only approximation involved in the calculations comes from the discretization of time, which prevents an exact evaluation of the action. In path integral calculations, chains with large numbers of time slices or beads are just a realization of these ideas [5]. If an accurate evaluation of the action for paths with large time steps were possible, the complexity of path integral calculations, and in particular ergodicity issues, would be greatly reduced.

For ground-state calculations, the path integral approach (PIGS) [1, 2, 3] provides a method to systematically improve a trial wave function, by repeated application of the evolution operator in imaginary time, which eventually drives the system into the ground state [3]. Here again, if an accurate implementation of the evolution operator for large time steps were available, it could be used to build variational wave functions of very high quality.

In this letter, we focus on high-order short-time expansions of the Green’s function, which have been the subject of a series of works in recent years [1, 2, 4]. This progress has led to a deep understanding of their properties and provided various extremely accurate decompositions of the evolution operator \( \hat{U} = \exp(\varepsilon \hat{H}) \), with \( \hat{H} = \hat{T} + \hat{V} \), expressed as products of unitary operators of the basic components \( \hat{U} = \exp(\varepsilon \hat{T}) \) and \( \hat{U} = \exp(\varepsilon \hat{V}) \). An important result is that the use of a finite time step \( \varepsilon \) can be renormalized in the potential. This means that for a range of time steps \( \varepsilon \), one is in practice virtually free from finite time step errors.

We make use of the decomposition schemes proposed by Chin [9, 10] in order to evaluate the feasibility of PIGS calculations with high-order propagators using very few beads \( (N_b) \). To this end, we revisit the ground state of bulk superfluid \(^4\)He. We also explore the possibility of performing ground-state calculations of boson systems without any model wave function, i.e., to take as a starting point \( \Psi = 1 \) and rely in the propagator’s quality to build the actual wave function exclusively from the Hamiltonian. It is also interesting to note that if one does make use of a trial wave function, the application of Chin’s evolution operator \( \hat{T} + \hat{V} \) produces a much enhanced model that actually incarnates a shadow wave function [4]. In this way, Chin’s analysis provides a deep understanding of the success of shadow-like wave functions [11, 12] and sheds light onto the actual mechanisms leading to this kind of wave-functions.

Decompositions of the evolution operator preserving unitarity in the form

\[
\exp(\varepsilon (\hat{T} + \hat{V})) = \prod_{i=1}^{N} \exp(t_i \varepsilon \hat{T}) \exp(v_i \varepsilon \hat{V}) + \mathcal{O}(\varepsilon^{n+1})
\]

are the starting point which have culminated in the algorithms due to Chin that we test here. By means of a proper selection of the factorization coefficients \( \{t_i\} \) and \( \{v_i\} \), any given order can be achieved (the resulting expression is \( n \)th order since the effective Hamiltonian is then \( \hat{T} + \hat{V} + \mathcal{O}(\varepsilon^n) \)). However, if some of the \( t_i \) factorization coefficients are negative, involving diffusion processes backwards in time, the algorithm cannot be used in the context of quantum Monte Carlo calculations. Fourth order algorithms, for which Chin has worked out a complete characterization [9], happen to be somehow unique, as for only forward decompositions, the highest order that can be achieved is four. These developments result from a careful use of the expansion

\[
\prod_{i=1}^{N} \exp(t_i \varepsilon \hat{T}) \exp(v_i \varepsilon \hat{V}) = \exp(\varepsilon t \hat{T} + \varepsilon v \hat{V} + \varepsilon^2 t^2 v \hat{T} \hat{V}) \times [\hat{T}, \hat{V}] + \varepsilon^3 t t^2 v [\hat{T}, [\hat{T}, \hat{V}]] + \varepsilon^3 v t v^2 [\hat{V}, [\hat{T}, \hat{V}]] + \ldots
\]

which allows to keep only the simplest term \([\hat{V}, [\hat{T}, \hat{V}]]\),
which produces a sort of renormalized potential
\[
[\hat{V}, [\hat{T}, \hat{V}]] = \hbar^2 \sum_{i=1}^{N} |F_i|^2
\]  
(3)

with \( F_i = \sum_{j \neq i} \nabla_i V(r_{ij}) \). A remarkable characteristic of the resulting expansions is that they lead to a continuous family of 4th order algorithms characterized by one free parameter. It is interesting to note that with a proper choice of that parameter \( t_1 \) in Eq. (3) one is able to fine tune the leading error term of the propagator to any desired value, including changing sign in a controlled way. Thus, one is enabled to minimize the value of the 4th order error coefficient, and in doing so, even try to cancel, to the largest possible extent, the contributions of the next orders. In practice, this means that a particular value of the free parameter entering in the algorithm produces exceedingly accurate and stable results. A different strategy to improve the order of the propagator is the use of a multiproduct expansion with a controlled violation of positivity [12].

Amongst the various decompositions proposed in Ref. [9], the particular scheme chosen in this work is
\[
e^{-\tau \hat{H}} = e^{-v_0 \tau \hat{V}} e^{-t_1 \tau \hat{T}} e^{-v_1 \tau \hat{W}} e^{-t_2 \tau \hat{T}} e^{-v_1 \tau \hat{W}} e^{-t_1 \tau \hat{T}} e^{-v_0 \tau \hat{V}}
\]  
(4)

with \( \hat{W} = \hat{V} + (u_0/v_1) t_2 \)\[\hat{V}, [\hat{T}, \hat{V}]\]. The various factorization coefficients are all dependent on the single free parameter \( t_1 \). The range of possible values for \( t_1 \) is \( 0 \leq t_1 \leq 0.5 \) and experience shows that the optimal value is nearly independent of \( \tau = \varepsilon/N_b \). A similar decomposition has been recently used in path integral Monte Carlo (PIMC) simulations at finite temperature showing high accuracy [14].

The operator splitting (4) allows for an estimation of the Green’s operator \( G(R, S, \tau) = \langle R | e^{-\tau \hat{H}} | S \rangle \), which in turn provides the mechanism for building accurate wave functions starting from a trial wave function, \( \Psi(R) = \int G(R, S, \tau) \Psi_m(S) dS \). More explicitly,
\[
\Psi(R) = \int e^{-v_0 \tau V(R)} e^{-\frac{(R-S_1)^2}{2m\sigma^2}} e^{-v_1 \tau W(S_1)} e^{-\frac{(S_1-S_2)^2}{2m\sigma^2}} e^{-v_1 \tau W(S_2)} e^{-v_0 \tau V(S_3)} \Psi_m(S_3) dS_1 dS_2 dS_3.
\]  
(5)

Equation (5) can also be written in terms of relative rather than absolute auxiliary coordinates,
\[
\Psi(R) = \int e^{-v_0 \tau V(R)} e^{-\frac{(R+S_1-S_2)^2}{2m\sigma^2}} e^{-v_1 \tau W(R+S_1)} e^{-\frac{(R+S_1+S_2-S_3)^2}{2m\sigma^2}} e^{-v_0 \tau V(S_3)} \Psi_m(R + S_1 + S_2 + S_3) dS_1 dS_2 dS_3.
\]  
(6)

Whilst Eqs. (5) and (6) are equivalent, they lead to different estimators for the kinetic energy. The action of the kinetic operator on \( \Psi(R) \) in Eq. (6) involves derivatives of \( \Psi_m \), in contrast to what happens when the prescription given in Eq. (5) is used.

It is possible to use the propagator \( G(R, S, \tau) \) in order to improve the quality of any given trial wave function, with reduced variance in direct proportion to its quality. In fact, Eq. (6) satisfies the principle of zero variance: as \( \tau \) approaches the exact ones. After a quick search we found the optimal value \( t_1 = 0.35 \) which was kept fixed for the rest of the calculations. The dependence of the variational energy on the remaining variational parameter \( \tau \) is shown in Fig. 1, where the variational character of the calculation is clear. The horizontal axis corresponds to the \( \tau \) parameter in K\(^{-1}\) units and the vertical axis represents the total energy per particle in K. The data displayed as empty circles is the variational energy for the wave function based on the high-order action (5). The position of the minimum is a compromise between a large \( \tau \) value suitable for a large suppression of the excited components present in \( \Psi_m(R) \), and a small one suitable for a proper behavior of the variational wave function (5), which relies itself on a short-time expansion. The minimum is located at \( \tau = 0.025 \) and the variational energy obtained is \( E = -7.10 \) K, only \( \sim 0.2 \) K higher than the exact value.

Equally impressive is the data displayed as empty diamonds, which is a variational calculation using the same propagator (5) acting on \( \Psi_m(R) = 1 \), i.e. it is a variational calculation in which only the Hamiltonian and the statistics are used. We see in this case that the compromise between a large suppression of the non-ground-state
components and a small parameter has been shifted towards a higher value \( \tau = 0.04 \), as could be expected. A third model for \( \Psi_m(R) \) consists in a semi-classical approximation, \( \Psi_{m-sc}(R) = \prod_{i<j} \exp[-\varepsilon V_{sr}(r_{ij})] \), with \( V_{sr}(r) = 1/r^{12} \) corresponding to the \( r \)-dependence of the Lennard-Jones potential around the core. This third model does not contain any free variational parameter since \( \varepsilon \) is the total imaginary time of the propagator. The results obtained with \( \Psi_{m-sc}(r) \) (open squares) only improve slightly the variational energy obtained with \( \Psi_m(R) = 1 \).

It is also possible to apply several times the propagator to \( \Psi_m(R) \) in order to obtain better variational results and finally projecting out any excitation present in the model wave functions. This is shown in Fig. 1 with a filled circle point, which corresponds to the propagator applied \( N_b = 4 \) times onto the Jastrow-McMillan wave function \( \Psi_m(R) \) for a total time propagation \( \varepsilon = 0.04 \) \( K^{-1} \). The same figure shows with a filled diamond the result of acting with \( N_b = 10 \) propagators on \( \Psi_m(R) = 1 \) for a total time propagation \( \varepsilon = 0.12 \) \( K^{-1} \). Between these two points, the semiclassical model achieves convergence very fast with \( N_b = 4 \) and time \( \varepsilon = 0.06 \) \( K^{-1} \).

The high-order Green's function can also be used to obtain the total energy following the standard procedure of evaluating the local energy of the trial wave function \( \Psi_m(R) \) at one end of the chain, and its high accuracy translates again in the need for a very small number of beads until convergence is achieved. The results obtained for the total and potential energies per particle are reported in Table I as a function of the total imaginary time \( \varepsilon \). The potential energies are calculated in the center of the chain to remove any possible bias coming from \( \Psi_m(R) \); the total energies are estimated in the extreme, except for the case \( \Psi_m(R) = 1 \) where they are sampled in the center. The number of beads for a given time \( \varepsilon \) is determined simply by the requirement that doubling its number (and simultaneously halving the propagation time per bead \( \tau \)) does not have any effect, which turns to be equivalent to keep the propagation time per bead below \( \tau = 0.15 \) \( K^{-1} \). One would expect that this regime corresponds to keeping the finite time step error just below the detectable level. This is in accordance with Fig. 1, where we see that a propagation time per bead near 0.15 \( K^{-1} \) is close to the maximum value before the time step error starts to become apparent by bending upwards the variational energy curve. When both requirements: \( \tau = \varepsilon/N_b \) to be small enough (\( \tau \leq 0.15 \) \( K^{-1} \)) and \( N_b \) large enough are met, the energy becomes independent of both \( \varepsilon \) and \( N_b \) and a good estimation of the ground-state energy is achieved.

The results of Table I show that the convergence is quickly achieved with only a few number of beads: \( N_b = 4 \) for the McMillan and semiclassical Jastrow factors, and \( N_b = 8 \) for \( \Psi_m(R) = 1 \). Concerning the convergence for the potential energy, one can see in Table I that the exact (asymptotic in \( \varepsilon \)) value is independent of the trial wave function and its value is reached with only \( N_b = 4 \). It should be taken into account however that, as in any PIGS method, the total length of the chain corre-

| \( \varepsilon \) (K\(^{-1}\)) | \( N_b \) | \( E/N \) (K) | \( V/N \) (K) | \( E/N \) (K) | \( V/N \) (K) | \( E/N \) (K) | \( V/N \) (K) |
|---|---|---|---|---|---|---|---|

**TABLE I**: Total and potential energies per particle as a function of the imaginary time \( \varepsilon \) and number of beads \( N_b \) using different models for the initial wave function \( \Psi_m(R) \).
FIG. 3: One-body density matrix $\rho_m(r)$. The solid and dotted lines correspond to present results using for $\Psi_m(R)$ a Jastrow-McMillan factor or $\Psi_m(R) = 1$, respectively. The dashed line is the experimental data from Ref. [17].

FIG. 2: Two-body radial distribution function $g(r)$. The solid and dotted lines correspond to present results using for $\Psi_m(R)$ a Jastrow-McMillan factor or $\Psi_m(R) = 1$, respectively. The dashed line is the experimental data from Ref. [17].

Unbiased (pure) estimations of operators $\hat{O}$ other than the Hamiltonian can only be calculated in the center of the chain, $\langle \hat{O} \rangle = N^{-1}\langle \psi_m | G(\varepsilon)/2 \hat{O} G(\varepsilon)/2 | \psi_m \rangle$. This holds, for instance, for the potential energy reported in Table I and the two-body radial distribution function $g(r)$ shown in Fig. 2. The present PIGS results for $g(r)$ show an excellent agreement with experimental data [17] for the trial wave functions used in this work. Even when $\Psi_m(R) = 1$ the result is the same, the calculation requiring only a few more beads.

Another relevant function that can be computed in an unbiased way is the one-body density matrix $\rho(r)$, whose asymptotic limit is the condensate fraction. The calculation of $\rho(r)$ has been carried out by incorporating worm movements in the sampling [18], a technique that has been developed for path integral Monte Carlo (finite temperature) and that we have extended to PIGS. One of the main advantages of this method is that $\rho(r)$ comes properly normalized, and thus eliminates any uncertainty introduced by the a posteriori normalization factor. In Fig. 3 results for $\rho(r)$ obtained using different trial wave functions $\Psi_m$ are shown. As one can see, the results are statistically indistinguishable and predict a condensate fraction $n_0 = 0.080(2)$, in nice agreement with a recent PIMC estimation at $T = 1$ K ($n_0 = 0.081(2)$) [18].

Summarizing, the high-order short time expansion of the Green’s function presented in this work enables the possibility of performing variational calculations of very high-quality on systems for which no model of wave function is known. This is illustrated in the case of liquid $^4$He at equilibrium density, where the propagator provides for $N_b = 1$ and $\Psi_m(R) = 1$ a variational energy $E/N = -6.20$ K, and converges to the exact value already with $N_b = 8$. When used to improve a Jastrow-McMillan wave function, it produces a shadow-like variational wave function for $N_b = 1$ with a variational ground-state energy $E/N = -7.10$ K, only $\sim 0.2$ K higher than the exact value. Repeated application of the propagator leads to variational results which are asymptotically exact for values as low as $N_b = 4$. The prospects for future work are promising, since this opens the road to being able to obtain results for systems whose ground-state wave function is poorly known or even unknown.

We wish to thank stimulating discussions with Siu Chin. Partial financial support from DGI (Spain) Grant No. FIS2008-04403 and Generalitat de Catalunya Grant No. 2005SGR-00779 is also acknowledged.
