Abstract

Background: Variants in the complement cascade genes and the LOC387715/HTRA1, have been widely reported to associate with age-related macular degeneration (AMD), the most common cause of visual impairment in industrialized countries.

Methods/Principal Findings: We investigated the association between the LOC387715 A69S and complement component C3 R102G risk alleles in the Finnish case-control material and found a significant association with both variants (OR 2.98, p = 3.75 × 10−9; non-AMD controls and OR 2.79, p = 2.78 × 10−19; blood donor controls and OR 1.83, p = 0.008; non-AMD controls and OR 1.39, p = 0.039; blood donor controls), respectively. Previously, we have shown a strong association between complement factor H (CFH) Y402H and AMD in the Finnish population. A carrier of at least one risk allele in each of the three susceptibility loci (LOC387715, C3, CFH) had an 18-fold risk of AMD when compared to a non-carrier homozygote in all three loci. A tentative gene-gene interaction between the two major AMD-associated loci, LOC387715 and CFH, was found in this study using a multiplicative (logistic regression) model, a synergy index (departure-from-additivity model) and the mutual information method (MI), suggesting that a common causative pathway may exist for these genes. Smoking (ever vs. never) exerted an extra risk for AMD, but somewhat surprisingly, only in connection with other factors such as sex and the C3 genotype. Population attributable risks (PAR) for the CFH, LOC387715 and C3 variants were 58.2%, 51.4% and 5.8%, respectively, the summary PAR for the three variants being 65.4%.

Conclusions/Significance: Evidence for gene-gene interaction between two major AMD associated loci CFH and LOC387715 was obtained using three methods, logistic regression, a synergy index and the mutual information (MI) index.

Introduction

Age-related macular degeneration (AMD [MIM 603075]) is the most common cause of irreversible visual loss in the elderly in the Western world. It is characterized by drusen deposits in its early forms. The late forms are geographic atrophy and exudative AMD, which especially affects central vision [1]. AMD is a complex disease with both genetic susceptibility and environmental risk factors contributing to the disease pathogenesis. Of the environmental risk factors, age and smoking have most consistently been identified as major risks [2,3]. In the past few years, research into the genetics of AMD has been very successful. An association between the Y402H polymorphism of the complement factor H (CFH [MIM 134370]) gene on chromosome 1 and AMD has been confirmed in several Caucasian populations [4–19]. In addition, an association between the LOC387715/high temperature requirement factor A-1 (HTRA1) locus on chromosome 10q and AMD both in Caucasian, and in Japanese and Chinese populations has been found [11,20–31]. Due to the close proximity of LOC387715/HTRA1 and controversial results in functional studies [27,32–34] the true disease-associated variant at this locus has remained so far unknown.
Most recently, a common polymorphism (rs2230199) in the complement component 3 (C3 [MIM 120700]) gene of complement cascade was associated with AMD in two case-control sets [35] and confirmed in a large case-control sample [36]. With regard to the previously observed association to CFH this is an interesting observation because CFH is known to inhibit activation of C3 in the complement system [37]. We have previously shown that the CFHY402H polymorphism is associated with AMD in Finnish patients [16]. Here we investigated whether the LOC387715 A69S (rs10490924), HTRA1 promoter (rs11200638), or C3 R102G (rs2230199) variants are associated with AMD in the Finnish population. In addition, we compared three different statistical methods to estimate the combined risks and gene-gene and gene-environment interaction of CFH Y402H, LOC387715 A69S, C3 R102G, and smoking to the development of AMD.

Materials and Methods

Patient material

The patient material comprised 332 Finnish patients with AMD attending the Departments of Ophthalmology of Helsinki (n = 201), Oulu (n = 10) and Kuopio (n = 39) University Hospitals, or private offices and outpatient clinics (n = 82) [16]. A total of 151 patients were sporadic cases with no known relatives with AMD and 181 were familial cases with at least one first or second degree relative with AMD. Of the 154 sporadic AMD cases in our previous study [16] we excluded two patients because of genotyping failure and one of the sporadic cases was reported to have a novel AMD case in his family and was thus transferred to the familial group. Of the 181 previous familial cases one from Kuopio University Hospital could not be genotyped because of insufficient sample. Otherwise the patient material was the same as in our previous study (Table S1). We had two control groups, as previously reported [16]: 105 age-matched non-AMD controls, to identify possible genotyping problems. No deviations were found (p > 0.5 for all tests). The overall success rate in genotyping was 99.5%. The LOC387715 rs10490924 and HTRA1 rs11200638 were found to be in almost perfect LD with rs11200638 were found to be in almost perfect LD with rs10490924.

In the family members of the index patients, the AMD stage was verified from fundus photographs or angiograms in 45 (60.0%), from the medical records in 28 (37.3%) and from an examination by a retinal specialist belonging to the study group in two of the patients (2.7%). In the rest of the subjects (index cases, sporadic cases and non-AMD controls) the AMD stage was verified from fundus photographs or angiograms in 338 (93.4%), from an examination by a retinal specialist belonging to the study group in four (1.1%) and from medical records in 20 (5.5%) of the subjects. The verification of the AMD status of patients was carried out as described in [16]. Blood samples for genotyping were obtained from all the patients with AMD and control individuals. We chose to use two control groups, 105 ophthalmologically investigated non-AMD controls, and 350 anonymous blood donor controls. Information on smoking was available in only the non-AMD controls. The study was approved by the Ethics Committee of the Helsinki University Eye and Ear Hospital and The Red Cross Blood Transfusion Service, Helsinki, Finland, and performed in accordance with the Declaration of Helsinki. Informed consent was obtained from all of the subjects after explanation of the nature and possible consequences of the study.

Information on smoking

Information about the smoking history of the study participants was obtained by telephone. The following data were recorded: Had a participant ever smoked, the ages at which he/she started and quit (if he/she had quit) smoking, as well as the numbers of cigarettes smoked per day during that period. Then, the numbers of pack-years were calculated (cigarettes smoked per day × years smoked/20 [cigarettes per pack]). A binary variable, never/ever, was based on the information obtained on whether a study participant had smoked < one pack-year (never-smoker), or > one pack-year (ever-smoker) in his/her lifetime.

Genotyping

The genotyping procedure for CFH was described in the previous article [16]. The DNA of the study subjects was amplified by the polymerase chain reaction (PCR) and sequenced using primers for LOC387715 rs10490924 forward 5-GGTTGCTCCGTGTTCCCTTCA-3 and reverse 5-GGGGTTAAGCCCTGATCATCTT-3 [29], for HTRA1 rs11200638 forward 5-ATGCCACCGCAACAACTT-3 and reverse 5-CGCGTCCTCCAAACTTGAATGG-3 [27], and for C3 rs2230199 forward 5-GGAAACAGACCCCCCTGAAATGG-3 and reverse 5-CTTGTGGTTGACGGTGAAAGA-3. Amplification was performed in a DNA 2720 Thermal Cycler (ABI, Foster city, CA, USA). The polymerase chain reaction conditions were as follows: 5 min at 94°C followed by 35 cycles of the denaturation step: 30 s at 94°C; the annealing step: 30 s at 59°C (rs10490924), 52°C (rs 11200638) and 60°C (rs2230199); the elongation step: 45 s at 72°C; and final extension for 7 min at 72°C terminated the reaction after final annealing. Sequencing was performed using cycle sequencing with the Big Dye Terminator kit (version 3.1) supplied by Applied Biosystems (ABI, Foster City, CA, USA), and reactions were run on an ABI 3730 capillary sequencer according to the manufacturer’s instructions.

Statistical analysis

Allele and genotype frequencies were estimated by direct counting. Deviations from Hardy-Weinberg Equilibrium (HWE) were tested with the standard Chi square test separately in cases and controls, to identify possible genotyping problems. No deviations were found (p > 0.5 for all tests). The overall success rate in genotyping was 99.5%. The LOC387715 rs10490924 and HTRA1 rs11200638 were found to be in almost perfect LD with each other (D’ = 0.99).

Individual SNPs

The allelic and genotypic associations of the individual loci (LOC387715 rs10490924, HTRA1 rs11200638, C3 rs2230199) were measured by the standard Pearson’s Chi square test with one degree of freedom (or Fisher’s exact test, where necessary). Marginal odds ratios (OR) and their confidence intervals were estimated for all significantly associated loci to assess the strength of the association. This was carried out with R scripts freely available on the Internet (R Package Epitools [http://sites.google.com/site/medepi/epitools, function odds ratio]). Furthermore, population attributable risks (PAR) were estimated with Levin’s formula; (100% × proportion of exposed × (OR – 1))/[(proportion of exposed × (OR – 1) + 1)], where the proportion of exposed is the frequency the allele or genotype in the blood donor controls).

Descriptive analyses of G × G interactions

Joint ORs for pairs of loci (CFHY402H and LOC387715 A69S; LOC387715 A69S and C3 rs2230199; CFHY402H and C3 rs2230199) were calculated for each 2-locus genotype separately, using the non-risk double homozygote genotype (TTGG, GGCC, TTGC, respectively) as a reference (Table 1). All patients with AMD (n = 332) were compared to blood donor controls (n = 350). The estimation was carried out with the aforementioned R package Epitools.
Multivariable and interaction analyses

Multivariable logistic regression was used for assessing the relationship between the independent variables and the outcome, estimating the effects of the individual SNPs and covariates (age, sex, smoking) and for dissecting potential gene-gene (G × G) and gene-environment (G × E) interactions in our data. This was carried out with the SPSS Binary logistic regression modeling procedure, in which stepwise backward variable selection procedure was used to screen out the informative covariates from the uninformative. We coded the loci genotypes following the notation presented by Cordell (2002) [38,39], to be able to assess the additive and dominance effects separately, and to compare our numerical results to those obtained by e.g. Schmids et al 2006 [21], who used the same notation. The data was restricted to the patients and non-AMD controls, since no smoking data was available from the blood donor controls. A series of models, which included the additive and dominance effects for each locus (CFH Y402, LOC387715 A69S and C3 R102G) and environmental effects (sex, smoking) and various G × G, G × E and E × E interactions were fitted to the data. The non-nested models were compared by the means of Akaikes information criterion (AIC), where there is a difference of 2 or more between the AICs of the models including and excluding the term in question, respectively, is taken as evidence of a significantly better fit to the data (as suggested by North et al. 2005) [39]. The existence of dominance effects of individual loci could be ruled out. Thus, at the next stage, when the possible interactions were examined in more detail, only the additive genetic terms (and no dominance terms) were allowed for. This was also necessary in order to keep the number of parameters in the model to a reasonable number.

In addition to the logistic regression approach, which is known to have only modest powers for distinguishing interactions [40,41], the possible interactions were further sought using two complementary approaches. i) Departure from the additivity model as described by Rothman [42] and implemented by Anderson et al. 2005 [www.epinet.se] [43]. Rothman has shown that independent risk factors adhere to an additive model where interaction is assessed based on departure from additivity of the disease rates. In this model, biological interaction (that is different from the term biological interaction in cell biology) is assessed using three measures: RERI (the relative excess risk due to interaction), AP (the attributable proportion due to interaction) and S (the synergy index) [43]. A synergy index exceeding 1.00 suggests the presence of at least one shared (metabolic) pathway in the pathogenesis of the disease, where both of the risk factors are required. ii) the mutual information-based statistics for testing interaction between two unlinked loci. Mutual information statistics is designed to measure the dependence between two random variables that can be detected by testing their independence [Methods S1] [44]. Logistic regression analyses and synergy index were calculated either with the SPSS (SPSS Inc., Chicago, Illinois; release 15.0, 2006) statistical software or with R language. We considered two loci G1 and G2, with each locus having two alleles.

Results

Individual genetic effects

The AMD-associated LOC387715 A69S risk allele T was over-represented in our patient material with the T allele frequency reaching 48% in AMD cases compared to 19.5% in non-AMD controls (p = 3.75 × 10^{-9}) and 24.7% in blood donor controls (p = 2.78 × 10^{-15}) (Tables S2, S3 and S4). Both familial and sporadic cases also carried the LOC387715 risk genotype TT more often than the GG genotype (compared to the non-AMD controls: p = 2.73 × 10^{-12}; familial and p = 9.95 × 10^{-12}; sporadic cases or compared to the blood donor controls: p = 1.35 × 10^{-15}; familial and p = 8.48 × 10^{-7}; sporadic cases). The difference between the genotype frequencies in the familial and sporadic cases (Table S2) was not statistically significant (p = 0.09).

We also analyzed the HTRA1 rs 11200638 polymorphism (Table S2). LOC387715 rs 10490924 and HTRA1 rs 11200638 are located only 6.1 kb from each other, and correspondingly, we observed only 5 genotypes out of 787 that were different among these two variants. This is inconsistent with perfect LD between the two SNPs. As there is accumulating evidence for LOC387715 A69S to be the actual causal variant in AMD [32,33], we focused on the association analyses of the LOC387715 gene in this study.

The C3 R102G variant corresponding to the electrophoretic protein variant C3F (fast), was associated with AMD in familial cases when compared to non-AMD controls (p = 0.008) or to blood donor controls (p = 0.039) (Tables S2, S3 and S4). The heterozygous risk genotype GG was also detected more often in familial cases than in non-AMD or blood donor controls with p-values of 0.013 and 0.049, respectively. However, the difference in the frequency of the homozygous risk genotype GG between cases and controls did not reach statistical significance since there were too few GG cases in our material. However the trend is clear:

| Genotypic combination of CFH and LOC387715 | OR (95%CI) | p-value | Number of risk alleles |
|-------------------------------------------|------------|---------|-----------------------|
| TTGG                                      | 1.00       |         |                       |
| CTTG                                      | 2.31       | 3.42 × 10^{-2} | 1                     |
| CCGG                                      | 8.83       | 3.52 × 10^{-9} | 2                     |
| TTGT                                      | 2.89       | 2.41 × 10^{-2} | 1                     |
| CTGG                                      | 8.48       | 1.18 × 10^{-10} | 2                    |
| CCCT                                      | 14.41      | 1.08 × 10^{-13} | 3                     |
| CTTT                                      | 21.38      | 2.08 × 10^{-7}  | 2                     |
| CTTG                                      | 17.35      | 2.75 × 10^{-11} | 3                     |
| CCGG                                      | 26.57      | 1.66 × 10^{-12} | 4                     |

Eight genotype combinations are compared to the non-risk genotype combination TTGG. The risk alleles are C (CFH) and T (LOC387715). All the patients with AMD (n = 332) are compared to the blood donor controls (n = 350). Note the strong correlation between number of risk alleles present in each two-locus genotype and the estimated odd's ratios.

doi:10.1371/journal.pone.0003833.t001

Table 1. Two-locus odds ratios (OR), 95% confidence intervals (95%CI), and p-values for different genotypic combinations of the complement factor H Y402H (genotypes CC/CT/TT) and the LOC387715 A69S (genotypes TT/TG/GG) polymorphisms.
C3 an additive effect was seen \( (p = 0.007) \), which was slightly weaker than the individual effects of \( CFH \) and \( LOC387715 \), but still made the overall fit of the three-locus model statistically significantly better than any two-locus models. No dominance effect could be demonstrated for either \( CFH \)’s 402H, \( LOC387715 \) A69S, or \( C3 \) R102G.

Interestingly, an interaction between \( CFH \) and \( LOC387715 \) was suggested \( (p = 0.057) \), with the estimated effect being only a bit smaller than the additive effect of \( C3 \) locus alone. With the departure-from-additivity model the attributable proportion due to interaction of the loci was 70% \((95\%CI 51–89\%\)\) and 8, the synergy index 3.79 \((95\%CI 1.82–7.89\)\) (Fig 1). Also, mutual information-based (MI) statistics \([44]\) resulted in a \( p \)-value of \( 1.69 \times 10^{-6} \) supporting the results obtained with logistic regression analysis and the departure-from-additivity model \( (Table S3) \). No evidence for \( G \times E \) interaction was obtained with another major susceptibility gene \( LOC387715 \) and smoking \( (p = 0.14) \) whereas the \( G \times E \) interaction with sex \( (p = 1.04 \times 10^{-6}) \) was shown using MI statistics. Here the higher number of female patients in our study material might affect the result.

No evidence for an independent effect of smoking could be detected in the logistic regression modelling in our data \( (p = 0.795) \). Instead, \( E \times X \) and \( G \times E \) interactions were suggested: sex \( \times E \) smoking \( (p = 0.043) \) and \( C3 \times E \) smoking \( (p = 0.086) \). When combined into a 3-way interaction \( C3 \times E \times X \) smoking \( (p = 0.016) \) the 2-way interaction \( C3 \times E \) smoking disappeared. The sex \( \times E \) smoking interaction term preserved borderline significance \( (now, p = 0.065) \) \( (Table S3) \). Based on the difference in the AICs of the model including the two 2-way terms vs. one 3-way interaction term proved the latter to be more parsimonious \( (data not shown) \). However, synergy index and mutual information statistics \( (Table S5) \) failed to show evidence for interaction between neither sex, smoking nor \( C3 \). Possible explanations for this complexity in the logistic regression modelling showed up in further stratified analyses, where we found out that \( i \) ever-smoker women had 4.68-fold \((95\%CI 1.95–14.12, p = 3.60 \times 10^{-4}) \) risk of AMD when compared to never-smoker women, whereas in men the odd’s ratio was smaller \((OR = 2.57) \) and of borderline significance \((95\%CI 0.99–6.86, p = 0.054) \). Thus, the effect of smoking was more pronounced in women, which also explains the significance of the sex \( \times E \) smoking interaction. At the same time it explains why no independent main effect for smoking

Table 2. Three-locus risks (odds ratios [OR], 95% confidence intervals [95%CI], and \( p \)-values) for combinations of the risk allele carriers and non-carriers of the complement factor \( H \) \( (CFH) \) Y402H, the \( LOC387715 \) A69S and the complement component 3 \( (C3) \) R102G polymorphisms.

| At least one risk allele present in: | OR (95%CI) | \( p \)-value |
|------------------------------------|------------|-------------|
| None | 1.00 | |
| CFH (C) | 5.45 | \((2.18–16.83)\) \(1.26 \times 10^{-4}\) |
| \( LOC387715 \) (T) | 4.89 | \((1.73–16.43)\) \(3.72 \times 10^{-3}\) |
| CFH (C) and \( LOC387715 \) (T) | 15.55 | \((6.42–47.22)\) \(1.42 \times 10^{-12}\) |
| \( C3 \) (G) | 2.12 | \((0.52–8.70)\) 0.296 |
| CFH (C) and \( C3 \) (G) | 5.57 | \((2.14–17.72)\) \(2.75 \times 10^{-4}\) |
| \( LOC387715 \) (T) and \( C3 \) (G) | 12.59 | \((3.63–50.89)\) \(3.62 \times 10^{-5}\) |
| CFH (C) and \( LOC387715 \) (T) and \( C3 \) (G) | 17.91 | \((7.12–55.88)\) \(1.70 \times 10^{-12}\) |

Seven combinations are compared to individuals who carry no risk allele. Risk alleles are C \((CFH)\), \( T \) \((LOC387715)\), and \( G \) \((C3)\). Patients with AMD \((n = 332)\) are compared to blood donor controls \((n = 350)\).

doi:10.1371/journal.pone.0003833.t002

Table 3. Final model parameters from the logistic regression analyses: the logarithm of odds of being a case rather than a control is explained by genetic effects and their interactions and a set of covariates \( (for details, see text)\), from which an automatic stepwise procedure selects the final set of statistically significant variables and estimates their magnitudes.

| Variable | \( p \)-value | \( \text{Exp(b)} \) | 95% CI for \( \text{Exp(b)} \) |
|----------|-------------|-----------------|----------------------|
| \( CFH \) additive effect | 0.000 | 5.774 | 3.225–10.339 |
| \( LOC387715 \) additive effect | 0.000 | 5.537 | 3.250–9.434 |
| \( C3 \) additive effect | 0.003 | 2.421 | 1.346–4.355 |
| \( CFH \) additive \( \times \) \( LOC387715 \) additive | 0.057 | 1.945 | 0.980–3.863 |
| Sex \( \times E \) smoking | 0.065 | 1.684 | 0.967–2.931 |
| \( C3 \) additive \( \times \) sex \( \times \) smoking | 0.016 | 0.429 | 0.216–0.852 |
| Constant | 0.000 | 6.078 | |

\( \text{Exp(b)} \) is the coefficient corresponding to a one unit change in the explanatory variable. Nagelkerke R Square for the final model was 0.431 \((n = 382)\).

doi:10.1371/journal.pone.0003833.t003

there seems to be a higher OR for homozygotes than for heterozygous cases.

The estimated population attributable risks (PAR) for a carrier of the risk allele of \( CFH \) Y402H, \( LOC387715 \) A69S and \( C3 \) R102G (using blood donor controls as a reference group) were 58.2%, 51.4%, and 5.8%, respectively. The joint population attributable risk for the three loci was 65.4%. Since carrying a risk allele in one locus does not exclude also carrying a risk allele in the other locus the summary PAR is less than the sum of the three single PARs. The PAR for smoking was 47.7%, note, however that it had to be estimated using non-AMD controls as a reference group; thus it cannot be interpreted as a true population-wise figure. Also, it is not directly comparable to the gene-wise PARs given above due to different reference group used.

Smoking

Odds ratio for smoking was 3.22 \((95\%CI 1.81–6.09, p = 4.69 \times 10^{-5}\)\), non-AMD controls), and the joint OR for the three loci and smoking was 74.3 \((95\%CI 10.81–2123.6, p = 1.54 \times 10^{-7}\)\), non-AMD controls).

Joint ORs

We also assessed the joint ORs of \( CFH \) Y402H \( (CFH) \), the \( LOC387715 \) A69S polymorphism, previously shown to be associated with AMD in the Finnish population \([16]\), and \( LOC387715 \) A69S polymorphism. Joint analysis of ORs for the two variants showed that the risk of AMD was 27-fold \( (p = 1.66 \times 10^{-12}\)\), blood donor controls) if an individual had both homozygous risk genotypes, \( CC \) \((CFH)\) and \( TT \) \((LOC387715)\), compared to the non-risk genotype \( TTGG \) respectively, and all the other joint ORs ranging from 2 to 21 \((Table 1)\). Three-locus risk-allele carrier \( CFH \) Y402H, \( LOC387715 \) A69S and \( C3 \) R102G) joint ORs are given in Table 2. The risk of AMD was 18-fold for a carrier of at least one risk allele per susceptibility loci when compared to a non-carrier of risk alleles at any loci in blood donor controls \( (Table 2) \).

Interaction analyses

In the logistic regression modelling, we found highly significant \((p<0.001)\) additive gene effects for the \( LOC387715 \) and \( CFH \) loci, both having approximately the same effect size \( (Table 3) \). Also, for
alone was obtained. ii) C3×smoking: smoking seemed to have a significant risk-conferring effect on the non-risk genotype CC, but the effect is not that strong (and non-significant) in G-carrying genotypes (although the trend is the same). In the never-smokers, the C3 G allele predisposed to AMD as expected, whereas, interestingly, in ever-smokers the effect of G allele was virtually indistinguishable. iii) C3×sex×smoking: here we saw the highest OR for ever-smoker women with the non-risk genotype CC (OR = 8.55, [95%CI 2.45–58.46], p = 0.0002), and non-significant effects in G-carrying genotypes (though the trend is the same, that is, smoking predisposed to AMD in all genotype×sex classes, OR:s around 2). Overall, both smoking and carriership of the G allele confers risk for AMD, but the effect could be mediated via a different pathway.

Discussion

Here we report joint risks of three gene (CFH, LOC387715 and C3) loci, and smoking in AMD. We found tentative evidence for a gene-gene interaction between CFH and LOC387715, the two major susceptibility genes of AMD using three different statistical approaches. The first evidence for interaction was obtained using logistic regression; however, because the power of logistic regression to detect interactions is low [40], it de facto necessitated the use of other, more sensitive methods. Thus we applied the departure-from-additivity model that is based on additive disease rates [42,43]. This method has also been used by Despriet et al [45] who reported increased risks of AMD in CFH risk genotype carriers with high C-reactive protein serum levels, elevated sedimentation rate (ESR), leucocyte count and smoking and more recently by Baird et al., [46] who demonstrated a G×E-interaction between a pathogenic load of C. pneumoniae and the CFH Y402H in the aetiology of AMD. The third method, mutual information statistics, has not been previously utilized in analyzing risk factors for AMD also suggested strong evidence for interaction of CFH and LOC387715.

The strong association of the LOC387715 A69S with AMD in our Finnish patient material is in agreement with previous results from other populations [11,15,21–24,32,47–51] (Table 4). Furthermore, joint risks for CFH Y402H and LOC387715 A69S were also of similar magnitude as observed by Rivera et al., [11]. In addition, the joint additive effect of CFH and LOC387715 has been shown to be strengthened by rare C2 variants [51]. However, discoveries of interactions between these loci (or smoking) have been scarce and they have not been replicated. Thus, we want to point out that most of the analyses of G×G and G×E interaction have been based on logistic regression modelling [11,15,21,22,47], which according to our present state of understanding is statistically not a very powerful approach [40,41]. Thus, reanalysis of existing data with more sensitive methods for detecting interaction might, possibly, change the picture a bit. Indeed, a true biological interaction between CFH and LOC387715 would be plausible based on recent cell biological data by Kanda et al. (2007) and Fritsche et al. (2008) showing that LOC387715 is localized to mitochondria [32,33] and on the earlier evidence that mitochondria activate complement [52]. Interestingly, mitochondrial dysfunction involving altered mitochondrial translation, import of nuclear-encoded proteins, and ATP-synthase activity was suggested in recent proteomics studies on retinal pigment epithelium (RPE) in AMD by age [53]. Further cell and neurobiological studies are warranted to elucidate whether the CFH and the LOC387715 genes indeed belong to a common causative pathway.

A G×E interaction between CFH Y402H and smoking could be detected in our material using MI statistics (p = 8.24×10⁻³; Table S5). In the Rotterdam study increased risks of AMD in CFH risk genotype carriers with smoking, elevated C-reactive protein serum levels, sedimentation rate (ESR) and leucocyte count were
reported using the departure from additivity model (synergy index of 2.30 [95%CI 1.06–5.35]) [45] concordant with our results. An interaction between smoking and CFH would be plausible, since cigarette smoke has been shown to activate the complement system [54]. Smoking also increases serum CRP concentrations [55] and further, impaired binding of C-reactive protein to the CC or CT variants of CFH(Y402H) has been detected [56,57]. However, in studies using logistic regression analyses smoking and CFH Y402H have consistently been found to be statistically independent risk factors for AMD [15,58–60].

We did not find an interaction between LOC387715 and smoking with any of the three statistical methods used that is in agreement with several previous findings [15,23,48,60], although Schmidt et al. have reported a statistical interaction between LOC387715 and smoking [21] and most recently, an interaction between HTRA1 rs11200638 and smoking was reported [34]. Here we also demonstrate that C3 seems to have a milder, though a statistically significant effect on AMD, as noted earlier [35,36] (Table 5). Accordingly, the risk of AMD was 16-fold for a carrier of at least one risk allele at both CFH Y402H and LOC387715 A69S loci, while adding the risk allele of the C3 R102G increased the OR to only 18 using logistic regression analysis (Table 2). C3 plays a crucial role in all the three pathways of the complement system, the classic, the lectin and the alternative pathway [37]. C3 has also been identified in drusen deposits, the hallmarks of AMD [7]. Considering this, the G×G interaction of C3 and CFH Y402H in AMD obtained using MI statistics is reasonable. Furthermore, activation of an alternative pathway of the complement system by cigarette smoke has been shown to be mediated by C3[61,62]. Considering this it would be reasonable to think that a true C3×smoking interaction might have exist.

The population attributable risks (PAR) for the CFH Y402H (58.2%) and LOC387715 A69S (51.4%) are in line with other reports where PARs for CFH Y402H range from 43 to 68 % [5,13,15,20,21] and for LOC387715 A69S from 36 to 57% [15,20,21]. Instead, the PAR for C3 R102G in Yates et al. was higher (22%) [35] than what we obtained (5.8%). It is possible that the C3 G allele effect is diluted in our data by the stronger effect of CC genotype in ever-smoking women (C3×sex×smoking). Schmidt

| Study | AMD cases (n) | Controls (n) | ORhet (95% CI) | ORhom (95%CI) |
|-------|---------------|--------------|----------------|--------------|
| This study | 332 | 105 | 3.37 (2.09–5.52) cases compared to 105 non-AMD controls | 17.69 (6.23–76.92) |
| Rivera et al. 2005 | 1120 | 922 | 2.69 (2.22–3.27) | 8.21 (5.79–11.65) |
| Schmidt et al. 2006 | 610 | 259 | 1.65 (1.12–2.43) | 5.73 (3.07–10.71) |
| Conley et al. 2006 | AREDs sample | 701 | 175 | 3.06 (2.13–4.39) | 17.26 (6.22–47.89) |
| | CHS sample | 126 | 1051 | 1.58 (1.05–2.39) | 4.75 (2.56–8.80) |
| Tanimoto et al. 2007 | 95 | 99 | 2.15 (1.16–4.03)* | 
| Ross et al. 2007 | NEI sample+ AREDs sample | 399 | 329 | 2.61 (1.89–3.61) | 8.59 (4.49–16.46) |
| | BMES sample | 278 | 557 | 1.69 (1.25–2.28) | 2.20 (1.05–4.62) |
| Kanda et al. 2007 | 535 | 288 | 2.64 | 7.05† |

ORhet refers to comparison of GT to GG and ORhom to comparison of TT to GG. T allele is the risk allele.

| Study | AMD cases (n) | Controls (n) | ORhet (95% CI) | ORhom (95%CI) |
|-------|---------------|--------------|----------------|--------------|
| This study | 332 | 105 | 1.64 (1.00–2.75) cases compared to 105 non-AMD controls | 1.92 (0.61–8.82) |
| | 350 | 270 | 1.21 (0.87–1.67) cases compared to 350 blood donor controls | 1.30 (0.62–2.79) |
| Yates et al. 2007 | English group | 603 | 350 | 1.6 (1.2–2.2) | 2.4 (1.3–4.4) |
| | Scottish group | 505 | 351 | 1.8 (1.2–2.6) | 2.9 (1.4–5.9) |
| Maller et al. 2007 | 1238 | 934 | 1.61 | 3.26 |

ORhet refers to comparison of CG to CC and ORhom to comparison of GG to CC. C allele is the risk allele.
et al. [21] also reported a PAR for smoking which was 20% and thus lower than ours (47.7%), but here it should be noted that we could not estimate the true population-based PAR due to a lack of smoking information in our blood donor controls, and hence ours may be an overestimate. However, the ever-smokers’ risk is mediated through the non-risk genotype CC of the C3 gene whereas in the never-smokers the risk effect comes from the reported risk allele warrants further studies.

In conclusion, analysis of gene-gene and gene-environment interaction of risk factors in AMD benefits from combination of several statistical methods and the available biochemical data.
